

FOURTEENTH EDITION

BROCK BIOLOGY OF MICROORGANISMS

MADIGAN • MARTINKO • BENDER • BUCKLEY • STAHL

Brief Contents

UNIT 1

The Foundations of Microbiology

- CHAPTER 1** Microorganisms and Microbiology
- CHAPTER 2** Microbial Cell Structure and Function
- CHAPTER 3** Microbial Metabolism
- CHAPTER 4** Molecular Microbiology
- CHAPTER 5** Microbial Growth and Growth Control

UNIT 2

Genomics,
Genetics, and
Virology

- CHAPTER 6** Microbial Genomics
- CHAPTER 7** Metabolic Regulation
- CHAPTER 8** Viruses and Virology
- CHAPTER 9** Viral Genomes and Diversity
- CHAPTER 10** Genetics of *Bacteria* and *Archaea*
- CHAPTER 11** Genetic Engineering and Biotechnology

UNIT 3

Microbial
Diversity

- CHAPTER 12** Microbial Evolution and Systematics
- CHAPTER 13** Metabolic Diversity of Microorganisms
- CHAPTER 14** Functional Diversity of *Bacteria*
- CHAPTER 15** Diversity of *Bacteria*
- CHAPTER 16** Diversity of *Archaea*
- CHAPTER 17** Diversity of Eukaryotic Microorganisms

UNIT 4

Microbial Ecology
and Environmental
Microbiology

- CHAPTER 18** Methods in Microbial Ecology
- CHAPTER 19** Microbial Ecosystems
- CHAPTER 20** Nutrient Cycles
- CHAPTER 21** Microbiology of the Built Environment
- CHAPTER 22** Microbial Symbioses

UNIT 5

Pathogenicity and
Immunology

- CHAPTER 23** Microbial Interactions with Humans
- CHAPTER 24** Immunity and Host Defense
- CHAPTER 25** Immune Mechanisms
- CHAPTER 26** Molecular Immunology
- CHAPTER 27** Diagnostic Microbiology

UNIT 6

Infectious Diseases
and Their
Transmission

- CHAPTER 28** Epidemiology
- CHAPTER 29** Person-to-Person Bacterial and Viral Diseases
- CHAPTER 30** Vectorborne and Soilborne Bacterial and Viral Diseases
- CHAPTER 31** Water and Food as Vehicles of Bacterial Diseases
- CHAPTER 32** Eukaryotic Pathogens: Fungal and Parasitic Diseases

Appendices, Glossary, Index

Because LEARNING EVOLVES, So Does Your Classroom

MasteringMicrobiology®

***Brock Biology of Microorganisms* is now
available with MasteringMicrobiology!**

MasteringMicrobiology is Pearson's online homework, tutorial, and assessment system designed to improve results by helping students quickly master concepts. Students benefit from self-paced tutorials that feature immediate wrong-answer feedback and hints that emulate the office-hour experience to help keep students on track.

Learning REVOLUTIONIZED

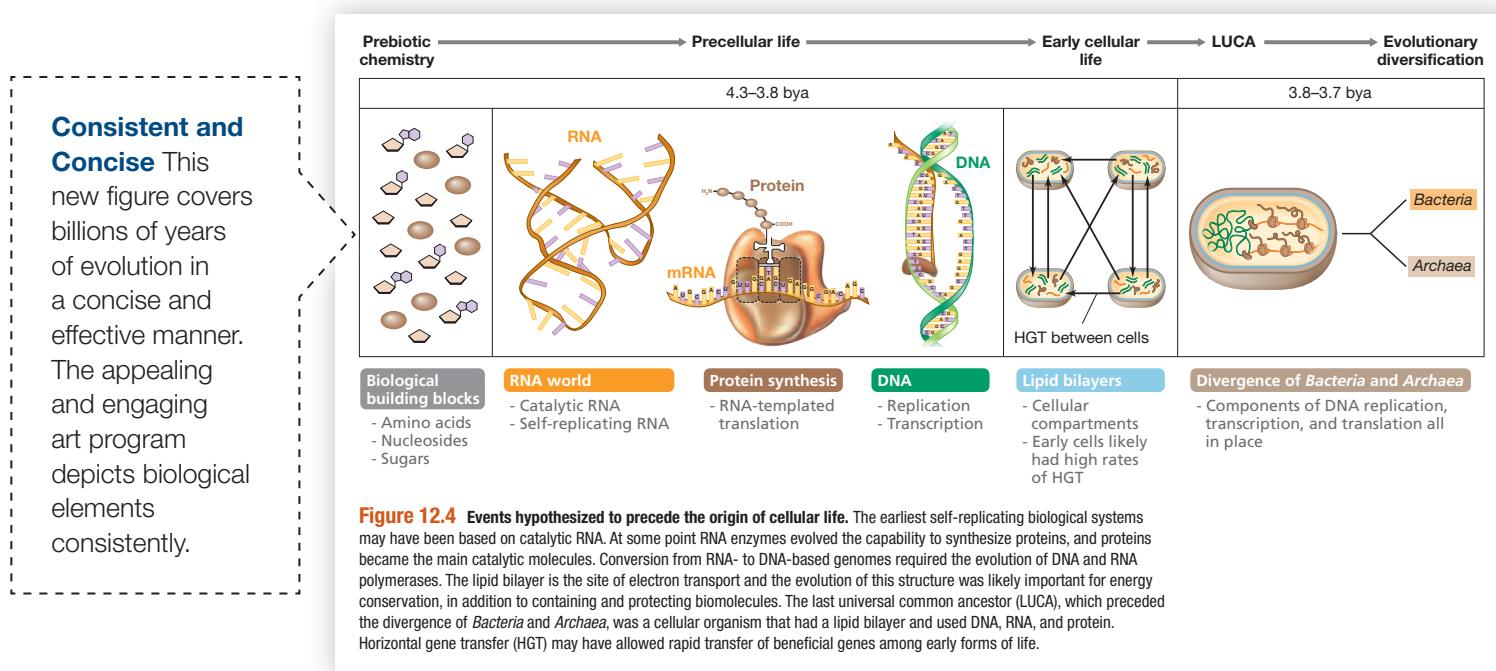

Up-to-Date Presentation

Reorganized and reimagined, the Fourteenth Edition of *Brock Biology of Microorganisms* provides the most up-to-date, accurate, and approachable introduction to the study of microbiology for today's students. Recognizing that mastering the principles of the dynamic field of microbiology today requires understanding the underlying molecular biology, the Fourteenth Edition provides both the foundation for the science and the science itself.

Brock Biology of Microorganisms guides students through the six major themes of microbiology in the 21st century as outlined by the American Society of Microbiology Conference on Undergraduate Education (ASMCUE): Evolution, Cell Structure and Function, Metabolic Pathways, Information Flow and Genetics, Microbial Systems, and The Impact of Microorganisms. Reflecting how the “omics” revolution has transformed all of biology, an undercurrent of genomics supports content in every chapter of the Fourteenth Edition.

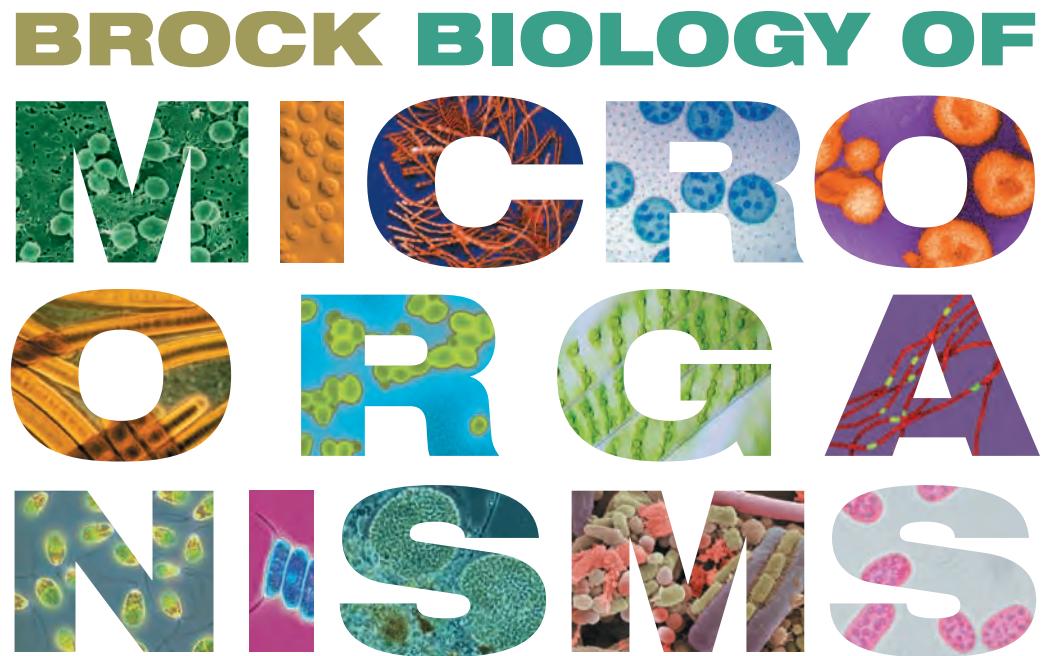

New Dynamic Art

An enhanced and revised art program in the Fourteenth Edition provides the consistency and context students need to visualize microbiology. With new illustrations, significant art style updates, and nearly 200 new color photos, the Fourteenth Edition beautifully presents microbiology as the visual science it is today.

About the Authors

Michael T. Madigan received his B.S. in Biology and Education from Wisconsin State University– Stevens Point (1971) and his M.S. (1974) and Ph.D. (1976) in Bacteriology from the University of Wisconsin– Madison. His graduate research was on the hot spring bacterium *Chloroflexus* in the laboratory of Thomas Brock. Following three years as a postdoctoral scientist at Indiana University, Mike moved to Southern Illinois University Carbondale, where he taught courses in introductory microbiology and bacterial diversity as a professor of microbiology for 33 years. In 1988 Mike was selected as the Outstanding Teacher in the College of Science and in 1993, the Outstanding Researcher. In 2001 he received the SIUC Outstanding Scholar Award. In 2003 he received the Carski Award for Distinguished Undergraduate Teaching from the American Society for Microbiology, and he is an elected Fellow of the American Academy of Microbiology. Mike's research is focused on bacteria that inhabit extreme environments, and for the past 15 years he has studied Antarctic microbiology. In addition to research papers, he has edited a major treatise on photo-trophic bacteria and served for 10 years as chief editor of the journal *Archives of Microbiology*. He currently serves on the editorial board of the journals *Environmental Microbiology* and *Antonie van Leeuwenhoek*. Mike's other interests include forestry, swimming, reading, and caring for his dogs and horses. He lives on a quiet lake with his wife, Nancy, four shelter dogs (Gaino, front in photo, deceased 30 September 2013; Pepto, back in photo; Peanut; and Merry), and three horses (Eddie, Gwen, and Festus).

trophic bacteria and served for 10 years as chief editor of the journal *Archives of Microbiology*. He currently serves on the editorial board of the journals *Environmental Microbiology* and *Antonie van Leeuwenhoek*. Mike's other interests include forestry, swimming, reading, and caring for his dogs and horses. He lives on a quiet lake with his wife, Nancy, four shelter dogs (Gaino, front in photo, deceased 30 September 2013; Pepto, back in photo; Peanut; and Merry), and three horses (Eddie, Gwen, and Festus).

John M. Martinko received his B.S. in Biology from Cleveland State University. He then worked at Case Western Reserve University, conducting research on the serology and epidemiology of *Streptococcus pyogenes*. His doctoral work at the State University of New York at Buffalo investigated antibody specificity and antibody idiotypes. As a postdoctoral fellow, he worked at Albert Einstein College of Medicine in New York on the structure of major histocompatibility complex proteins. Since 1981, he has been in the Department of Microbiology at Southern Illinois University Carbondale where he was Associate Professor and Chair, and Director of the Molecular Biology, Microbiology, and Biochemistry Graduate Program. His research interests centered on the structure–function relationships of immune system proteins, including immunoglobulins, T cell receptors, and major histocompatibility proteins. His teaching interests include an advanced course in immunology as well as immunology and inflammation instruction to medical students.

For his educational efforts, he won the 2007 Southern Illinois University Outstanding Teaching Award. He has been active in a number of educational outreach programs for pre-university students and teachers. He has also been a faculty member at Bard College in its innovative Citizen Science program, an interactive laboratory, computer, and problem-based-learning science curriculum that introduces freshmen students to critical thinking through the discovery and application of scientific principles. He was the Chair of the Institutional Animal Care and Use Committee at SIUC and continues to act as a consultant in the area of animal care. He is also an avid golfer and cyclist. John lives in Carbondale with his wife Judy, a high school science teacher.

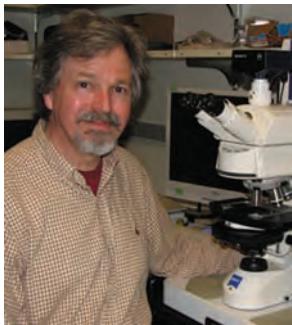

Kelly S. Bender received her B.S. in Biology from Southeast Missouri State University (1999) and her Ph.D. (2003) in Molecular Biology, Microbiology, and Biochemistry from Southern Illinois University Carbondale. Her dissertation work focused on the genetics of perchlorate-reducing bacteria. During her postdoctoral fellowship, Kelly worked on the genetic regulation of sulfate-reducing bacteria in the laboratory of Judy Wall at the University of Missouri–Columbia. She also completed a transatlantic biotechnology fellowship at Uppsala University in Sweden researching regulatory small RNAs in bacteria. In 2006, Kelly returned to her alma mater, Southern Illinois University Carbondale, as an Assistant Professor in the Department of Microbiology and was tenured and promoted to Associate Professor in 2012. Her lab studies a range of topics including the regulation of stress responses by small RNAs, microbial community dynamics of sites impacted by acid mine drainage, and the bioremediation of uranium by metal- and sulfate-reducing bacteria. Kelly teaches courses in microbial genetics and molecular biology, has served on numerous federal grant review panels, and is an active member of the American Society for Microbiology. Her other interests include biking, cooking, and spending time with family, friends, and her miniature schnauzer, Pepper.

Daniel H. Buckley is an Associate Professor at Cornell University in the Department of Crop and Soil Sciences. He earned his B.S. in Microbiology (1994) at the University of Rochester and his Ph.D. in Microbiology (2000) at Michigan State University. His graduate research focused on the ecology of soil microbial communities and was conducted in the laboratory of Thomas M. Schmidt in affiliation with the MSU Center for Microbial Ecology. Dan's postdoctoral research examined linkages between microbial diversity and biogeochemistry in marine microbial mats and stromatolites and was conducted in the laboratory of Pieter T. Visscher at the University of Connecticut. Dan joined the Cornell faculty in 2003. His research program investigates the ecology and evolution of microbial communities in soils with a focus on the causes and consequences of microbial diversity. He has taught both introductory and advanced courses in microbiology, microbial diversity, and microbial genomics. He received a National Science Foundation Faculty Early Career Development (CAREER) award in 2005 for excellence in integrating research and education. He has

served as Director of the Graduate Field of Soil and Crop Sciences at Cornell and Codirector of the Marine Biological Laboratory Microbial Diversity Summer Course in Woods Hole, Massachusetts. He currently serves on the editorial boards of *Applied and Environmental Microbiology* and *Environmental Microbiology*. Dan lives in Ithaca, New York, with his wife Merry and sons Finn and Colin. Dan enjoys running and a variety of outdoor sports but, most of all, catching critters down at the creek with his boys.

David A. Stahl received his B.S. degree in Microbiology from the University of Washington, Seattle, and completed graduate studies in microbial phylogeny and evolution with Carl Woese in the Department of Microbiology at the University of Illinois at Urbana-Champaign. Subsequent work as a postdoctoral fellow and research associate with Norman Pace, then at the National Jewish Hospital in Colorado, involved early applications of 16S rRNA-based sequence analysis to the study of natural microbial communities. In 1984 Dave joined the faculty at the University of Illinois with appointments in Veterinary Medicine, Microbiology, and Civil Engineering. In 1994 he moved to the Department of Civil Engineering at Northwestern University, and in 2000 returned to the University of Washington as professor in the Departments of Civil and Environmental Engineering and Microbiology. Dave is known for his work in microbial evolution, ecology, and systematics, and received the 1999 Bergey Award and the 2006 ASM Procter & Gamble Award in Applied and Environmental Microbiology. He is a fellow in the American Academy of Microbiology and a

member of the National Academy of Engineering. His main research interests surround the biogeochemistry of nitrogen and sulfur and the microbial communities that sustain the associated nutrient cycles. His laboratory was first to culture ammonia-oxidizing *Archaea*, a group believed to be the key mediators of this process in the nitrogen cycle. Dave has taught several courses in environmental microbiology, was one of the founding editors of the journal *Environmental Microbiology*, and has served on many advisory committees. Outside the lab, Dave enjoys hiking, bicycling, spending time with family, reading a good science fiction book, and—with his wife Lin—renovating an old farmhouse on Bainbridge Island.

Dedications

Michael T. Madigan

dedicates this book to the memory of his old friend, Snuffy. I sure miss those long walks, just you and me.

John M. Martinko

dedicates this book to his mother Lottie, who inspired all her children to achieve and excel.

Kelly S. Bender

dedicates this book to the memory of her grandmother, Alberta, whose biggest regret in life was not being able to attend school past the fifth grade.

Daniel H. Buckley

dedicates this book to Merry. Thanks for sharing this adventure and all the others.

David A. Stahl

dedicates this book to his wife, Lin. My love, and one that helps me keep the important things in perspective.

This page intentionally left blank

Preface

Because learning evolves, so do we. Streamlined, completely up to date, and written with deference to the history of microbiology and excitement for the future, the Fourteenth Edition of *Brock Biology of Microorganisms* is the strongest yet. For three generations, students and instructors have relied on the accuracy, authority, consistency, and up-to-date science of *Brock Biology of Microorganisms* to learn the core principles of microbiology and pique their interest in the future of the discipline. With the Fourteenth Edition, students will benefit from the book's emphasis on cutting-edge research, its seamless integration of and introduction to modern molecular microbiology, and a visually stunning art program revision. Additionally, for the first time, *Brock Biology of Microorganisms* is supported by MasteringMicrobiology, Pearson's online homework, tutorial, and assessment system.

Experienced authors Madigan, Martinko, and Stahl welcome two new coauthors on the Fourteenth Edition: Kelly S. Bender and Daniel H. Buckley. Significantly revising the coverage of molecular biology and microbial genetics, Kelly has been highly praised for both her undergraduate teaching and graduate student mentoring at Southern Illinois University. At Cornell, Dan participates in the Cornell Institute for Biology Teachers' summer workshop for high school science teachers and codirects the world-famous Summer Course in Microbial Diversity at Woods Hole. Both new coauthors have greatly strengthened the core mission of *Brock Biology of Microorganisms*: to remain the best learning resource for today's microbiology students and instructors.

What's New in the 14th Edition?

Reorganized and reimagined, the Fourteenth Edition guides students through the six major themes of microbiology in the 21st century as outlined by the American Society of Microbiology Conference on Undergraduate Education (ASMCUE): Evolution, Cell Structure and Function, Metabolic Pathways, Information Flow and Genetics, Microbial Systems, and the Impact of Microorganisms. With enhanced and revised artwork and nearly 200 new color photos, *Brock Biology of Microorganisms* beautifully presents microbiology as the visual science it is. The new chapter-opening features, titled "MicrobiologyNow," engage students in cutting-edge research relevant to each chapter's content and connect to assignable and assessable MasteringMicrobiology coaching activities. "Explore the Microbial World" features focus on specific topics that help students get a feel for the "big picture" in microbiology while simultaneously fueling their scientific curiosity.

Genomics, and all of the various "omics" it has spawned, support content in every chapter of *Brock Biology of Microorganisms*,

reflecting how the omics revolution has transformed all of biology. Gone is the day of microbiology as a descriptive science. Mastering the principles of the dynamic field of microbiology today requires understanding the underlying molecular biology. As authors, we are well aware of this, and have written *Brock Biology of Microorganisms* in a way that provides both the foundation for the science and the science itself. The result is a truly robust and eminently modern treatment of microbiology.

To strengthen the learning experience, additional MasteringMicrobiology content includes chapter-specific reading quizzes, MicroLab Tutorials, MicrobiologyNow coaching activities, Clinical Case and MicroCareer coaching activities, animation quizzes, MCAT Prep questions, and many additional study and assessment tools. Collectively, the content and presentation of *Brock Biology of Microorganisms*, coupled with the powerful learning tools of MasteringMicrobiology, create an unparalleled educational experience in microbiology.

Revision Highlights

Chapter 1

- Chapter 1 has been revised to provide an up-to-date and succinct introduction to and overview of microbiology, including basic elements of cell structure and the phylogenetic tree of life.
- The power of genomics for solving mysteries in microbiology is revealed in a new Explore the Microbial World feature, "The Black Death Decoded" on forensic studies of victims of Europe's "Black Death" outbreak over 650 years ago.

Chapter 2

- Coverage of microbial cell structure and function now combines material on *Bacteria* and *Archaea* with that of microbial eukaryotes, giving students a thorough introduction to comparative cell structure and providing the instructor with all of the tools necessary for effective classroom presentations.

Chapter 3

- The essential features of microbial metabolism necessary for understanding how microorganisms transform energy are laid out in a logical sequence with an appropriate level of detail on metabolic diversity for introductory students. Newly rendered art makes mastering key metabolisms a more visual and engaging experience.

Chapter 4

- The basic principles of molecular microbiology are heavily revised and beautifully presented early in the text to provide a useful background for students as they proceed through the book.
- Beautiful new art stresses consistency and simplicity to make complex molecular concepts easy to learn, retain, and apply.

Chapter 5

- To close Unit 1, this chapter draws on the previous four chapters in describing the end result of molecular biology and physiology: cell division and population growth.
- The chapter now incorporates the essentials of microbial growth control to allow instructors to better tie important practical content to the basic science of the growth process itself.

Chapter 6

- Complete coverage of microbial genomics and the omics revolution that is driving the science of microbiology today appears much earlier in the book than in the previous edition. Coverage of the technology, biology, and evolution of genomes is laid out in a new and exciting fashion.
- Marvel at the power of genomics in a new Explore the Microbial World feature on single-cell genomics: “Genomics, One Cell at a Time.”

Chapter 7

- Chapter 7 contains major updates on the regulation of gene expression—one of the hottest areas in microbiology today—including expanded coverage of cell sensing capacities and signal transduction.
- Explore new aspects of gene regulation, including the importance of small RNAs and the regulation of special events in model bacteria such as sporulation in *Bacillus*, cell differentiation in *Caulobacter*, and heterocyst formation in the nitrogen-fixing cyanobacterium *Anabaena*.

Chapter 8

- The basic principles of virology are presented without extraneous detail and use bacteriophage T4 as a model for depicting key virological concepts.
- New coverage of the virosphere and viral ecology reveals the overwhelming genetic diversity of viruses.

Chapter 9

- Coverage of viral genomes and diversity now directly follows the basic virology chapter to better link the two closely related topics.
- New coverage of the evolution of viral genomes and a new organization that more directly contrasts the biology of DNA and RNA viruses support a more consistent and conceptual understanding of viral diversity.

Chapter 10

- Coverage of the fundamental principles of the genetics of *Bacteria* and *Archaea* is now strategically located in the book to better incorporate supporting concepts from molecular microbiology, growth, regulation, and virology.

Chapter 11

- Complete coverage of the molecular biology of gene cloning and other major genetic manipulations forms a prelude to coverage of the application of these methods in the fast-moving field of biotechnology.
- Enter the world of synthetic biology and learn how this hot new area promises yet another revolution in biology.

Chapter 12

- Microbial evolution and systematics benefits from a major revision that focuses on the mechanisms of microbial evolution, including the importance of genomic evolution and horizontal gene transfer.
- Consider how metabolic interdependencies in microbial communities may have evolved in a fascinating new Explore the Microbial World feature, “The Black Queen Hypothesis.”

Chapter 13

- Microbial metabolic diversity is now presented in a single chapter to better compare and contrast the key metabolisms of *Bacteria* and *Archaea* and to emphasize how “the unity of biochemistry” has pervaded microbial metabolism.
- Metabolic diversity is now strategically positioned to naturally segue into the new chapter on bacterial functional diversity.

Chapters 14 and 15

- Chapter 14, “Functional Diversity of *Bacteria*,” now explores bacterial diversity with respect to the ecological, physiological, and morphological characteristics of well-known bacteria. Chapter 15, “Diversity of *Bacteria*,” presents the diversity of bacterial life in a truly phylogenetic context. New, colorful, and easy-to-follow phylogenetic trees summarize bacterial diversity in both chapters.

Chapter 16

- Archaeal diversity is revised with a stronger phylogenetic thread and new coverage of the more recently discovered archaeal phyla of *Thaumarchaeota*, *Nanoarchaeota*, and *Korarchaeota*.
- Learn how the previously unrecognized *Thaumarchaeota* are probably the most common *Archaea* on Earth and review the physicochemical limits to life, all of which are currently defined by species of *Archaea*.

Chapter 17

- Eukaryotic microbial diversity benefits from new phylogenetic coverage and a chapter prelude on the importance of endosymbioses in the evolution of eukaryotic cells.
- Many new color micrographs portray the beauty and diversity of eukaryotic microbial life.

Chapter 18

- The modern tools of the microbial ecologist are described with examples of how each has sculpted the science. Also, learn how the omics revolution has provided a new window for simplifying complex problems in microbial ecology.
- In the new Explore the Microbial World feature “Culturing the Uncultured,” discover how novel ecological methods have yielded laboratory cultures of the marine bacterium *Pelagibacter*, the most abundant organism on Earth.

Chapter 19

- The properties and microbial diversity of the major microbial ecosystems are compared and contrasted in an exciting new way.
- New environmental census data for freshwater habitats and the microbial ecology of arid landscapes highlight new material in this chapter, along with fresh coverage of the link between marine microorganisms and climate change.

Chapter 20

- Chapter 20 includes new coverage of the remarkable abilities of microorganisms to respire solid metal oxides in the iron and manganese cycles.
- Learn how humans are profoundly affecting the nitrogen and carbon cycles, including inorganic nutrient overloads and other forms of pollution, and how all of this feeds back into climate change.

Chapter 21

- A new chapter on the “built environment” shows how humans create new microbial habitats through construction of buildings, supporting infrastructure, and habitat modification. Witness the substantial positive and negative effects microorganisms have on important human infrastructure including wastewater treatment, microbial mining and acid mine drainage, corrosion of metals, the biodeterioration of stone and concrete, and the problem of pathogens in drinking water.

Chapter 22

- Here you will find expanded coverage of how microorganisms profoundly affect the physiology of plants and animals through symbiotic associations, including the dynamic topic of the human microbiome and its relationship to health and disease.
- Discover how a common mechanism used by bacteria and fungi to form symbiotic associations with the roots of plants provides the plants with key nutrients.

Chapter 23

- Major topics in human microbiology including the normal microflora, pathogenesis, and host factors in infection and disease are presented in a style that unites these concepts and reveals how they tip the balance toward health or disease.

Chapter 24

- Chapter 24 is designed to be the straightforward and concise overview of immunology that many instructors use to teach the fundamental concepts of the science.
- This chapter is loaded with practical information on vaccines, inflammation, and allergic responses in an easily teachable format.

Chapter 25

- Built on the shoulders of the previous chapter, Chapter 25 offers a more complete picture of immune mechanisms, with an emphasis on the molecular and cellular interactions that control innate and adaptive immunity.

Chapter 26

- This is a brief chapter that considers immunology from a completely molecular perspective, including the important receptor–ligand interactions that trigger the immune response and the genetics of the key proteins that drive adaptive immunity.

Chapter 27

- Reorganized and up to date, Chapter 27 describes the role of the clinical microbiologist and introduces the tools used to identify and track infectious diseases in clinical laboratories.
- New coverage of antimicrobial agents and their clinical usage underscores the important role of both drug therapy and drug resistance in medicine today.

Chapter 28

- A revised discussion of epidemiology introduces the concept of the reproduction number (R) and its implications for disease spread and control by herd immunity.
- Find up-to-date coverage of emerging infectious diseases and current pandemics, including those of HIV/AIDS, cholera, and influenza, and the role of the epidemiologist in public health microbiology.

Chapter 29

- Coverage of diseases transmitted from person to person is reorganized and illustrated with dozens of new color photos showing symptoms and treatments. To better consolidate material that fits a common theme, infectious diseases in this and each of the next three chapters are presented by taxonomy.

Chapter 30

- Bacterial and viral diseases transmitted by insect vectors or from soil are consolidated and illustrated by dozens of new color photos.
- This chapter contains new coverage of important viral diseases such as yellow fever and dengue fever and the bacterial diseases anthrax, tetanus, and gas gangrene.

Chapter 31

- Common-source diseases linked to contaminated food and water are now consolidated to better emphasize their similar modes of transmission. Coverage within the chapter is by taxonomy—bacterial versus viral—and illustrated with nearly 30 new color photos.
- Find new coverage of the potentially fatal foodborne infection caused by the intracellular bacterium *Listeria*.

Chapter 32

- All infectious diseases caused by eukaryotic microorganisms—fungi and parasites—are consolidated into one chapter to retain the taxonomic theme of medical microbiology. The visual experience is bolstered by 35 new color photos showing the pathogens and disease symptoms. Coverage of fungal and microbial parasitic diseases is expanded; the chapter also includes first-time coverage of major helminthic infections.

Other Learning Tools

- Two appendices, including a primer on bioenergetic calculations and a list of higher order taxa described in *Bergey's Manual of Systematic Bacteriology*; a glossary; and a thorough index round out the learning package in *Brock Biology of Microorganisms*, 14e.

Acknowledgments

A textbook is a complex entity and emerges from the contributions of a large book team. Besides the authors, the team is composed of folks both inside and outside of Pearson. Acquisitions Editor Kelsey Churchman and Associate Editor Nicole McFadden, both of Pearson, were the workhorses in editorial. Kelsey paved the way for the Fourteenth Edition of *Brock Biology of Microorganisms* (*BBOM* 14e) and skillfully maneuvered the book around the challenges inherent in any major textbook project. Nicole ran the day-to-day operations of the *BBOM* team, expertly processing the manuscript and keeping all facets of the project on track. The authors thank Kelsey and Nicole for their dedication to *BBOM* and professionalism in seeing the Fourteenth Edition through to completion.

The *BBOM* 14e production and design team in San Francisco was composed of Michele Mangelli (Mangelli Productions), Yvo Riezebos (Tandem Creative, Inc.), and Elisheva Marcus (Pearson). Michele managed the production team and kept everyone on mission and on budget. The artistic magic of Yvo is clearly visible in the beautiful text and cover designs of *BBOM* 14e. Elisheva (Ellie) was our art development editor and created the new art look for *BBOM* 14e, one that readers will immediately appreciate for its clarity, consistency, and modern style. Ellie's strong background in both science and art will be obvious throughout the book and her contributions were a major improvement to this edition. Thank you, Michele, Yvo, and Ellie. The authors also thank the art team at Imagineering (Toronto) for helping the authors convey a strong educational message and for their excellent suggestions for art improvements.

Other important people in the production team included Karen Gulliver, Jean Lake, Kristin Piljay, Betsy Dietrich, and Martha Ghent. Karen was our excellent and highly efficient production editor; Karen kept pages moving smoothly and tolerated the authors' many requests. Jean was our art coordinator, tracking and routing art and handling interactions between the art studio, art reviewers, and the authors, to ensure quality control and a timely schedule. Betsy and Martha worked with Jean and Karen to ensure an art program and text free of both bloopers and subtle errors. Kristin was our photo researcher who helped the authors acquire photos that meet the exacting standards of *BBOM*. The authors are extremely grateful to Karen, Jean, Kristin, Betsy, and Martha for transforming literally thousands of pages of text and art manuscript into the superb learning tool you have in front of you.

Special thanks go out to two other members of the production team. Anita Wagner was our absolutely spectacular copyeditor; the authors could not have had a more skillful and effective person in this key position on the book team. Anita improved the accuracy, clarity, and consistency of the text and rendered her editorial services in a style that the authors found both helpful and time saving. Elizabeth McPherson (University of Tennessee)

was our accuracy checker; her eagle eye, extensive knowledge of all areas of microbiology, and prompt service ensured the authority of the final product.

Thanks are also due to Joe Mochnick of the Pearson media team, as well as Ashley Williams for conducting reviews and managing the supplements to this text. And, since no book is worth a hoot if it does not do well in the marketplace, many thanks go to Neena Bali, who leads the marketing efforts for this title.

The authors also wish to acknowledge the excellent contributions of Matt Sattley (Indiana Wesleyan University), who composed the Instructor's Manual that accompanies *BBOM* 14e, and Christopher Gulvik (Georgia Institute of Technology) and Sherry L. Seston (Alverno College), who revised the test bank questions for this edition. We are also grateful to the top-notch educators who constructed the MasteringMicrobiology program that accompanies this text; these include: Ann Paterson, Narveen Jandu, Jennifer Hatchel, Susan Gibson, Ines Rauschenbach, Lee Kurtz, Vicky McKinley, Clifton Franklund, Benjamin Rohe, Ben Rowley, and Helen Walter. And finally, special thanks go out to Nicolás Pinel (Institute for Systems Biology) for producing the beautiful overview figures that summarize the microbial diversity of major microbial habitats.

No textbook in microbiology could be published without reviewing of the manuscript and the gift of new photos from experts in the field. We are therefore extremely grateful for the kind help of the many individuals who provided manuscript reviews and new photos. These include:

- Jill Banfield, *University of California, Berkeley*
Dennis A. Bazylinski, *University of Nevada Las Vegas*
J. Thomas Beatty, *University of British Columbia*
Jayne Belnap, *US Geological Survey*

As hard as a publishing team may try, no textbook can ever be completely error-free. Although we are confident the reader will be hard pressed to find errors in BBOM 14e, any errors that do exist, either of commission or omission, are the responsibility of the authors. In past editions, users have been kind enough to contact us when they spot an error so we can fix it in a subsequent printing. Users should feel free to continue to contact the authors directly about any errors, concerns, questions, or suggestions they have about the book. We are always happy to hear from users; your comments help make the book stronger.

Brief Contents

UNIT 1

The Foundations of Microbiology

- CHAPTER 1** Microorganisms and Microbiology
- CHAPTER 2** Microbial Cell Structure and Function
- CHAPTER 3** Microbial Metabolism
- CHAPTER 4** Molecular Microbiology
- CHAPTER 5** Microbial Growth and Control

UNIT 2

Genomics,
Genetics, and
Virology

- CHAPTER 6** Microbial Genomics
- CHAPTER 7** Metabolic Regulation
- CHAPTER 8** Viruses and Virology
- CHAPTER 9** Viral Genomes and Diversity
- CHAPTER 10** Genetics of *Bacteria* and *Archaea*
- CHAPTER 11** Genetic Engineering and Biotechnology

UNIT 3

Microbial
Diversity

- CHAPTER 12** Microbial Evolution and Systematics
- CHAPTER 13** Metabolic Diversity of Microorganisms
- CHAPTER 14** Functional Diversity of *Bacteria*
- CHAPTER 15** Diversity of *Bacteria*
- CHAPTER 16** Diversity of *Archaea*
- CHAPTER 17** Diversity of Eukaryotic Microorganisms

UNIT 4

Microbial Ecology
and Environmental
Microbiology

- CHAPTER 18** Methods in Microbial Ecology
- CHAPTER 19** Microbial Ecosystems
- CHAPTER 20** Nutrient Cycles
- CHAPTER 21** Microbiology of the Built Environment
- CHAPTER 22** Microbial Symbioses

UNIT 5

Pathogenicity and
Immunology

- CHAPTER 23** Microbial Interactions with Humans
- CHAPTER 24** Immunity and Host Defense
- CHAPTER 25** Immune Mechanisms
- CHAPTER 26** Molecular Immunology
- CHAPTER 27** Diagnostic Microbiology

UNIT 6

Infectious Diseases
and Their
Transmission

- CHAPTER 28** Epidemiology
- CHAPTER 29** Person-to-Person Bacterial and Viral Diseases
- CHAPTER 30** Vectorborne and Soilborne Bacterial and Viral Diseases
- CHAPTER 31** Water and Food as Vehicles of Bacterial Diseases
- CHAPTER 32** Eukaryotic Pathogens: Fungal and Parasitic Diseases

UNIT 1 The Foundations of Microbiology

CHAPTER 1

Microorganisms and Microbiology 1

microbiologynow

Microbial Life Is Everywhere 1

I Introduction and Major Themes of Microbiology 2

- 1.1 What Is Microbiology About and Why Is It Important? 2
- 1.2 Structure and Activities of Microbial Cells 2
- 1.3 Evolution and Diversity of Microbial Cells 5
- 1.4 Microorganisms and Their Environments 6
- 1.5 The Impact of Microorganisms on Humans 8

II Microbiology in Historical Context 13

- 1.6 The Discovery of Microorganisms 13
- 1.7 Pasteur and Spontaneous Generation 13
- 1.8 Koch, Infectious Disease, and Pure Cultures 16

EXPLORE THE MICROBIAL WORLD

The Black Death Decoded 19

- 1.9 The Rise of Microbial Diversity 20

- 1.10 Modern Microbiology and Genomics 22

CHAPTER 2

Microbial Cell Structure and Function 25

microbiologynow

Archaeal Tortoise and Hare 25

I Microscopy 26

- 2.1 Discovering Cell Structure: Light Microscopy 26
- 2.2 Improving Contrast in Light Microscopy 27
- 2.3 Imaging Cells in Three Dimensions 29
- 2.4 Probing Cell Structure: Electron Microscopy 31

II Cells of *Bacteria* and *Archaea* 32

- 2.5 Cell Morphology 32
- 2.6 Cell Size and the Significance of Being Small 33

III The Cytoplasmic Membrane and Transport 35

- 2.7 Membrane Structure 35
- 2.8 Membrane Function 36
- 2.9 Nutrient Transport 39

IV Cell Walls of *Bacteria* and *Archaea* 41

- 2.10 Peptidoglycan 41
- 2.11 LPS: The Outer Membrane 44
- 2.12 Archaeal Cell Walls 46

V Other Cell Surface Structures and Inclusions 48

- 2.13 Cell Surface Structures 48
- 2.14 Cell Inclusions 49
- 2.15 Gas Vesicles 51
- 2.16 Endospores 52

VI Microbial Locomotion 56

- 2.17 Flagella and Swimming Motility 56
- 2.18 Gliding Motility 59
- 2.19 Chemotaxis and Other Taxes 61

VII Eukaryotic Microbial Cells 64

- 2.20 The Nucleus and Cell Division 64
- 2.21 Mitochondria, Hydrogenosomes, and Chloroplasts 66
- 2.22 Other Major Eukaryotic Cell Structures 67

CHAPTER 3

Microbial Metabolism 73

microbiologynow

A Metabolic Surprise 73

I Laboratory Culture of Microorganisms 74

- 3.1 Cell Chemistry and Nutrition 74
- 3.2 Media and Laboratory Culture 76

II Energetics, Enzymes, and Redox 79

- 3.3 Energy Classes of Microorganisms 79
- 3.4 Bioenergetics 80
- 3.5 Catalysis and Enzymes 81
- 3.6 Electron Donors and Acceptors 82
- 3.7 Energy-Rich Compounds 84

III Fermentation and Respiration 86

- 3.8 Glycolysis 86
- 3.9 Fermentative Diversity and the Respiratory Option 88

- 3.10 Respiration: Electron Carriers 89
- 3.11 Respiration: The Proton Motive Force 91
- 3.12 Respiration: Citric Acid and Glyoxylate Cycles 93
- 3.13 Catabolic Diversity 95

IV Biosyntheses 96

- 3.14 Sugars and Polysaccharides 97
- 3.15 Amino Acids and Nucleotides 98
- 3.16 Fatty Acids and Lipids 99
- 3.17 Nitrogen Fixation 100

CHAPTER 4

Molecular Microbiology 107

microbiologynow

The Essence of Life: Molecular Microbiology 107

I The Blueprint of Life: Structure of the Bacterial Genome 108

- 4.1 Macromolecules and Genes 108
- 4.2 The Double Helix 109
- 4.3 Genetic Elements: Chromosomes and Plasmids 111

II Transmission of Genetic Information: DNA Replication 115

- 4.4 Templates and Enzymes 115
- 4.5 The Replication Fork 116
- 4.6 Bidirectional Replication and the Replisome 118

III RNA Synthesis: Transcription 120

- 4.7 Transcription 121
- 4.8 The Unit of Transcription 123
- 4.9 Transcription in Archaea and Eukarya 125

IV Protein Synthesis 127

- 4.10 Polypeptides, Amino Acids, and the Peptide Bond 127
- 4.11 Translation and the Genetic Code 128
- 4.12 Transfer RNA 131
- 4.13 Protein Synthesis 132
- 4.14 Protein Folding and Secretion 135

CHAPTER 5

Microbial Growth and Control 143

microbiologynow

Did the First Cells on Earth Have Cell Walls? 143

I Bacterial Cell Division 144

- 5.1 Binary Fission 144
- 5.2 Fts Proteins and Cell Division 144
- 5.3 MreB and Cell Morphology 147
- 5.4 Peptidoglycan Biosynthesis 148

II Population Growth 149

- 5.5 Quantitative Aspects of Microbial Growth 149
- 5.6 The Growth Cycle 151
- 5.7 Continuous Culture 152

III Measuring Microbial Growth 154

- 5.8 Microscopic Counts 154
- 5.9 Viable Counts 155
- 5.10 Spectrophotometry 157

IV Effect of Temperature on Microbial Growth 158

- 5.11 Temperature Classes of Microorganisms 158

EXPLORE THE MICROBIAL WORLD

Stick or Swim 159

- 5.12 Microbial Life in the Cold 161
- 5.13 Microbial Life at High Temperatures 163

V Other Environmental Effects on Microbial Growth 165

- 5.14 Effects of pH on Microbial Growth 165
- 5.15 Osmolarity and Microbial Growth 167
- 5.16 Oxygen and Microbial Growth 168

VI Control of Microbial Growth 171

- 5.17 General Principles and Growth Control by Heat 171
 - 5.18 Other Physical Control Methods: Radiation and Filtration 173
 - 5.19 Chemical Control of Microbial Growth 176
-

UNIT 2 Genomics, Genetics, and Virology

CHAPTER 6

Microbial Genomics 183

microbiologynow

Genomics and New Archaea 183

I Investigating Genomes 184

- 6.1 Introduction to Genomics 184
- 6.2 Sequencing Genomes 184
- 6.3 Bioinformatics and Annotating Genomes 189

II Microbial Genomes 190

- 6.4 Genome Size and Content 190
- 6.5 Genomes of Organelles 194
- 6.6 Eukaryotic Microbial Genomes 197

III Functional Genomics 198

- 6.7 Microarrays and the Transcriptome 198
- 6.8 Proteomics and the Interactome 201

- 6.9 Metabolomics and Systems Biology 203
 6.10 Metagenomics 204

EXPLORE THE MICROBIAL WORLD
 Genomics, One Cell at a Time 205

IV The Evolution of Genomes 206

- 6.11 Gene Families, Duplications, and Deletions 206
 6.12 Horizontal Gene Transfer and Genome Stability 208
 6.13 Core Genome versus Pan Genome 209

CHAPTER 7

Metabolic Regulation 215

microbiologynow
 Luminescence or Lethality? 215

I Overview of Regulation 216

- 7.1 Major Modes of Regulation 216

II DNA-Binding Proteins and Transcriptional Regulation 217

- 7.2 DNA-Binding Proteins 217
 7.3 Negative Control: Repression and Induction 219
 7.4 Positive Control: Activation 220
 7.5 Global Control and the *lac* Operon 222
 7.6 Transcription Controls in Archaea 224

III Sensing and Signal Transduction 225

- 7.7 Two-Component Regulatory Systems 225
 7.8 Regulation of Chemotaxis 226
 7.9 Quorum Sensing 228
 7.10 Other Global Control Networks 230

IV Regulation of Development in Model Bacteria 232

- 7.11 Sporulation in *Bacillus* 232
 7.12 *Caulobacter* Differentiation 233
 7.13 Nitrogen Fixation, Nitrogenase, and Heterocyst Formation 234

V RNA-Based Regulation 236

- 7.14 Regulatory RNAs: Small RNAs and Antisense RNA 236
 7.15 Riboswitches 237
 7.16 Attenuation 238

VI Regulation of Enzymes and Other Proteins 240

- 7.17 Feedback Inhibition 240
 7.18 Post-Translational Regulation 241

CHAPTER 8

Viruses and Virology 245

microbiologynow

Where Did Viruses Come From? 245

I The Nature of Viruses 246

- 8.1 What Is a Virus? 246
 8.2 Structure of the Virion 247
 8.3 Overview of the Virus Life Cycle 249
 8.4 Culturing, Detecting, and Counting Viruses 250

II Bacteriophage Life Cycles 251

- 8.5 Attachment and Entry of Bacteriophage T4 251
 8.6 The T4 Genome 252
 8.7 Replication of Bacteriophage T4 253
 8.8 Temperate Bacteriophages and Lysogeny 255

III Viral Diversity and Ecology 257

- 8.9 An Overview of Bacterial Viruses 257
 8.10 An Overview of Animal Viruses 258
 8.11 The Virosphere and Viral Ecology 261

CHAPTER 9

Viral Genomes and Diversity 265

microbiologynow

Ever-Expanding Viral Diversity 265

I Viral Genomes and Evolution 266

- 9.1 Size and Structure of Viral Genomes 266
 9.2 Viral Evolution 268

II Viruses with DNA Genomes 270

- 9.3 Single-Stranded DNA Bacteriophages: φX174 and M13 270
 9.4 Double-Stranded DNA Bacteriophages: T7 and Mu 272
 9.5 Viruses of Archaea 273
 9.6 Uniquely Replicating DNA Animal Viruses 274
 9.7 DNA Tumor Viruses 276

III Viruses with RNA Genomes 277

- 9.8 Positive-Strand RNA Viruses 277
 9.9 Negative-Strand RNA Animal Viruses 279
 9.10 Double-Stranded RNA Viruses 281
 9.11 Viruses That Use Reverse Transcriptase 282

IV Subviral Agents 285

- 9.12 Viroids 285
 9.13 Prions 286

CHAPTER 10**Genetics of Bacteria and Archaea 291****microbiologynow**

Defunct Viruses or Secret Agents of Gene Transfer? 291

I Mutation 292

- 10.1** Mutations and Mutants 292
- 10.2** Molecular Basis of Mutation 293
- 10.3** Reversions and Mutation Rates 295
- 10.4** Mutagenesis 297

II Gene Transfer in Bacteria 299

- 10.5** Genetic Recombination 300
- 10.6** Transformation 301
- 10.7** Transduction 303
- 10.8** Conjugation 305
- 10.9** The Formation of Hfr Strains and Chromosome Mobilization 307

III Gene Transfer in Archaea and Other Genetic Events 309

- 10.10** Horizontal Gene Transfer in Archaea 309
- 10.11** Mobile DNA: Transposable Elements 310
- 10.12** Preserving Genome Integrity: CRISPR Interference 311

CHAPTER 11**Genetic Engineering and Biotechnology 315****microbiologynow**

From Pathogen to Tumor Assassin 315

I Methods for Manipulating DNA 316

- 11.1** Restriction Enzymes and Nucleic Acid Separation 316
- 11.2** Nucleic Acid Hybridization 318
- 11.3** Polymerase Chain Reaction (PCR) 319
- 11.4** Essentials of Molecular Cloning 321
- 11.5** Molecular Methods for Mutagenesis 323
- 11.6** Gene Fusions and Reporter Genes 324

II Gene Cloning 326

- 11.7** Plasmids as Cloning Vectors 326
- 11.8** Hosts for Cloning Vectors 328
- 11.9** Shuttle Vectors and Expression Vectors 328
- 11.10** Other Cloning Vectors 331

III Products from Genetically Engineered Microorganisms 333

- 11.11** Expressing Mammalian Genes in Bacteria 333

- 11.12** Somatotropin and Other Mammalian Proteins 335
- 11.13** Transgenic Organisms in Agriculture and Aquaculture 336
- 11.14** Genetically Engineered Vaccines 339
- 11.15** Mining Genomes 340
- 11.16** Engineering Metabolic Pathways 341
- 11.17** Synthetic Biology 342

UNIT 3 Microbial Diversity**CHAPTER 12****Microbial Evolution and Systematics 347****microbiologynow**

Gene Exchange and the Evolution of Marine *Vibrio* 347

I Early Earth and the Origin and Diversification of Life 348

- 12.1** Formation and Early History of Earth 348
- 12.2** Photosynthesis and the Oxidation of Earth 351
- 12.3** Endosymbiotic Origin of Eukaryotes 353

II Living Fossils: DNA Records the History of Life 355

- 12.4** Molecular Phylogeny and the Tree of Life 355
- 12.5** Molecular Phylogeny: Making Sense of Molecular Sequences 359

III Microbial Evolution 363

- 12.6** The Evolutionary Process 363
- 12.7** The Evolution of Microbial Genomes 366

EXPLORE THE MICROBIAL WORLD

The Black Queen Hypothesis 368

IV Microbial Systematics 369

- 12.8** The Species Concept in Microbiology 369
- 12.9** Taxonomic Methods in Systematics 370
- 12.10** Classification and Nomenclature 374

CHAPTER 13**Metabolic Diversity of Microorganisms 379****microbiologynow**

Unraveling Microbial Metabolisms 379

I Phototrophy 380

- 13.1** Photosynthesis and Chlorophylls 380
- 13.2** Carotenoids and Phycobilins 383

13.3	Anoxygenic Photosynthesis	385
13.4	Oxygenic Photosynthesis	388
13.5	Autotrophic Pathways	390
II Chemolithotrophy 393		
13.6	Inorganic Compounds as Electron Donors	393
13.7	Hydrogen (H_2) Oxidation	394
13.8	Oxidation of Reduced Sulfur Compounds	395
13.9	Iron (Fe^{2+}) Oxidation	396
13.10	Nitrification and Anammox	398
III Fermentations 401		
13.11	Energetic and Redox Considerations	401
13.12	Lactic and Mixed-Acid Fermentations	402
13.13	Clostridial and Propionate Fermentations	404
13.14	Fermentations without Substrate-Level Phosphorylation	407
13.15	Syntropy	408
IV Anaerobic Respirations 410		
13.16	Principles of Anaerobic Respiration	410
13.17	Nitrate Reduction and Denitrification	411
13.18	Sulfate and Sulfur Reduction	413
13.19	Acetogenesis	415
13.20	Methanogenesis	417
13.21	Other Electron Acceptors	421
V Hydrocarbon Metabolism 424		
13.22	Aerobic Hydrocarbon Metabolism	424
13.23	Aerobic Methanotrophy	425
13.24	Anoxic Hydrocarbon Metabolism	427

CHAPTER 14

Functional Diversity of Bacteria 433		
microbiologynow		
One Culture Away 433		
I Functional Diversity as a Concept 434		
14.1	Making Sense of Microbial Diversity	434
II Diversity of Phototrophic Bacteria 435		
14.2	Overview of Phototrophic Bacteria	435
14.3	Cyanobacteria	436
14.4	Purple Sulfur Bacteria	440
14.5	Purple Nonsulfur Bacteria and Aerobic Anoxygenic Phototrophs	442
14.6	Green Sulfur Bacteria	443
14.7	Green Nonsulfur Bacteria	444
14.8	Other Phototrophic Bacteria	446
III Bacterial Diversity in the Sulfur Cycle 447		
14.9	Dissimilative Sulfate-Reducing Bacteria	447

14.10	Dissimilative Sulfur-Reducing Bacteria	448
14.11	Dissimilative Sulfur-Oxidizing Bacteria	449
IV Bacterial Diversity in the Nitrogen Cycle 452		
14.12	Diversity of Nitrogen-Fixing Bacteria	453
14.13	Diversity of Nitrifying and Denitrifying Bacteria and Archaea	454
V Diversity of Other Distinctive Chemotrophic Bacteria 456		
14.14	Dissimilative Iron-Reducing Bacteria	456
14.15	Dissimilative Iron-Oxidizing Bacteria	457
14.16	Hydrogen-Metabolizing Bacteria	458
14.17	Methanotrophic and Methylotrophic Bacteria	459
14.18	Acetic Acid Bacteria and Acetogens	461
14.19	Predatory Bacteria	462
VI Morphological Diversity of Bacteria 466		
14.20	Spirochetes and Spirilla	466
14.21	Budding and Prosthecate/Stalked Bacteria	468
14.22	Sheathed Bacteria	472
14.23	Magnetic Bacteria	472
14.24	Bacterial Bioluminescence	474

CHAPTER 15**Diversity of Bacteria 479****microbiologynow**

Discovering Novel Microbial Phyla 479

I Proteobacteria 480		
15.1	Alphaproteobacteria	481
15.2	Betaproteobacteria	484
15.3	Gammaproteobacteria—Enterobacterales	486
15.4	Gammaproteobacteria—Pseudomonadales and Vibrionales	488
15.5	Deltaproteobacteria and Epsilonproteobacteria	489
II Firmicutes, Tenericutes, and Actinobacteria 491		
15.6	Firmicutes—Lactobacillales	491
15.7	Firmicutes—Nonsporulating Bacillales and Clostridiales	493
15.8	Firmicutes—Sporulating Bacillales and Clostridiales	494
15.9	Tenericutes: The Mycoplasmas	497
15.10	Actinobacteria: Coryneform and Propionic Acid Bacteria	499
15.11	Actinobacteria: <i>Mycobacterium</i>	500
15.12	Filamentous Actinobacteria: <i>Streptomyces</i> and Relatives	501
III Bacteroidetes 504		
15.13	Bacteroidales	504
15.14	Cytophagales, Flavobacteriales, and Sphingobacteriales	505

IV Chlamydiae, Planctomycetes, and Verrucomicrobia 506

- 15.15 Chlamydiae 506
- 15.16 Planctomycetes 508
- 15.17 Verrucomicrobia 509

V Hyperthermophilic Bacteria 510

- 15.18 Thermotogae and Thermodesulfobacteria 510
- 15.19 Aquificae 511

VI Other Bacteria 512

- 15.20 Deinococcus–Thermus 512
- 15.21 Other Notable Phyla of Bacteria 513

CHAPTER 16

Diversity of Archaea 517

microbiologynow

Archaea and Global Warming 517

I Euryarchaeota 518

- 16.1 Extremely Halophilic Archaea 519
- 16.2 Methanogenic Archaea 522
- 16.3 Thermoplasmatales 525
- 16.4 Thermococcales and Methanopyrus 526
- 16.5 Archaeoglobales 527

II Thaumarchaeota, Nanoarchaeota, and Korarchaeota 528

- 16.6 Thaumarchaeota and Nitrification in Archaea 528
- 16.7 Nanoarchaeota and the “Hospitable Fireball” 529
- 16.8 Korarchaeota and the “Secret Filament” 530

III Crenarchaeota 531

- 16.9 Habitats and Energy Metabolism of Crenarchaeota 531
- 16.10 Crenarchaeota from Terrestrial Volcanic Habitats 532
- 16.11 Crenarchaeota from Submarine Volcanic Habitats 534

IV Evolution and Life at High Temperatures 537

- 16.12 An Upper Temperature Limit for Microbial Life 537
- 16.13 Molecular Adaptations to Life at High Temperature 538
- 16.14 Hyperthermophilic Archaea, H₂, and Microbial Evolution 540

CHAPTER 17

Diversity of Eukaryotic Microorganisms 543

microbiologynow

Horizontal Gene Transfer in an Extremophilic Eukaryote 543

I Organelles and Phylogeny of Microbial Eukaryotes 544

- 17.1 Endosymbioses and the Eukaryotic Cell 544
- 17.2 Phylogenetic Lineages of Eukarya 545

II Protists 547

- 17.3 Diplomonads and Parabasalids 547
- 17.4 Euglenozoans 548
- 17.5 Alveolates 549
- 17.6 Stramenopiles 551
- 17.7 Cercozoans and Radiolarians 552
- 17.8 Amoebozoa 554

III Fungi 556

- 17.9 Fungal Physiology, Structure, and Symbioses 556
- 17.10 Fungal Reproduction and Phylogeny 557
- 17.11 Chytridiomycetes 558
- 17.12 Zygomycetes and Glomeromycetes 559
- 17.13 Ascomycetes 560
- 17.14 Mushrooms and Other Basidiomycetes 561

IV Red and Green Algae 562

- 17.15 Red Algae 562
- 17.16 Green Algae 563

UNIT 4 Microbial Ecology and Environmental Microbiology

CHAPTER 18

Methods in Microbial Ecology 567

microbiologynow

Stitching Together Genomes 567

I Culture-Dependent Analyses of Microbial Communities 568

- 18.1 Enrichment 568
- 18.2 Isolation 572

EXPLORE THE MICROBIAL WORLD

Culturing the Uncultured 574

II Culture-Independent Microscopic Analyses of Microbial Communities 575

- 18.3 General Staining Methods 575

1 • Microorganisms and Microbiology

microbiologynow

Microbial Life Is Everywhere

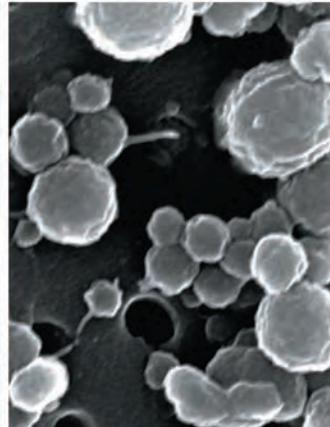

As you embark on your journey to the microbial world, you will be astounded to learn where microorganisms live in nature. In brief, they live everywhere, including locations too harsh for macroorganisms. For example, a research team studying the permanently ice-covered Lake Vida in the McMurdo Dry Valleys of Antarctica (top photo) found living bacteria immersed in a subfreezing salt solution at -13°C ! These hardy microorganisms were discovered by microbiologists wearing protective clothing to prevent contamination during the drilling process (bottom photos).

The Lake Vida bacteria, a metabolic group called psychrophiles (a term that means “cold loving”), were shown to carry out various metabolic reactions at the temperature of their icy home. Specific genes isolated from the various Lake Vida bacteria were used to classify the organisms, and future studies of their genetic blueprints—their genomes—should help to reveal the genetic secrets that allow these organisms to thrive in the constant cold.

Lake Vida is unusual even for Antarctic lakes, since its ice cover extends all the way to the bottom. Sunlight, only available 6 months of the year, cannot penetrate deeply into the lake. So the Lake Vida bacteria are probably metabolizing and growing, albeit extremely slowly, on organic carbon that was trapped in the ice at the time the lake became ice-sealed, millennia ago.

Microbiologists study bacteria from extreme environments to reveal the environmental limits to life and to search for unique products that might benefit humans or our planet. But in addition to contributing to basic and applied science, the Lake Vida bacteria are models for the kinds of life forms that could inhabit other icy worlds, such as Mars, or Jupiter’s moon, Europa.

Murray, A.E., et al. 2012. Microbial life at -13°C in the brine of an ice-sealed Antarctic lake. *Proc. Natl. Acad. Sci. (USA)*. 109: 20626–20631.

- I **Introduction and Major Themes of Microbiology 2**
- II **Microbiology in Historical Context 13**

I • Introduction and Major Themes of Microbiology

1.1 What Is Microbiology About and Why Is It Important?

The science of microbiology is all about **microorganisms** and how they work, especially the bacteria, a very large group of very small cells (**Figure 1.1**) that have enormous basic and practical importance. Microbiology is also about diversity and evolution of microbial cells, about how different kinds of microorganisms arose and why. Microbiology embraces ecology, so it is also about where microorganisms live on Earth, how they associate and cooperate with each other, and what they do in the world at large, in soils and waters and in animals and plants.

The science of microbiology revolves around two interconnected themes: (1) understanding the nature and functioning of the microbial world, and (2) applying our understanding of the microbial world for the benefit of humankind and planet Earth. As a *basic* biological science, microbiology uses microbial cells to probe the fundamental processes of life. In so doing, microbiologists have developed a sophisticated understanding of the chemical and physical basis of life and have learned that all cells share much in common. As an *applied* biological science, microbiology is at the forefront of many important breakthroughs in human and veterinary medicine, agriculture, and industry. From infectious diseases to soil fertility to the fuel you put in your automobile, microorganisms affect the everyday lives of humans in both beneficial and detrimental ways.

Microorganisms existed on Earth for billions of years before plants and animals appeared, and we will see later that the genetic and physiological diversity of microbial life dwarfs that of the plants and animals. Although microorganisms are the smallest forms of life (Figure 1.1), collectively they constitute the bulk of

biomass on Earth and carry out many necessary chemical reactions for higher organisms. In the absence of microorganisms, higher life forms would never have appeared and could not be sustained. Indeed, the very oxygen we breathe is the result of past microbial activity. Moreover, humans, plants, and animals are intimately dependent on microbial activities for the recycling of key nutrients and for degrading organic matter. It is thus safe to say that no other life forms are as important as microorganisms for the support and maintenance of life on Earth.

This chapter begins our journey into the microbial world. Here we will begin to discover what microorganisms are and what they do and explore their evolutionary history and impact on planet Earth. We will also place microbiology in historical context, as a process of scientific discovery. From the landmark contributions of both early microbiologists and scientists practicing today, the microbial world will begin to unfold.

MINIQUIZ

- If microbial life had not evolved, would you be here today? Give one good reason why or why not.
- Why are microbial cells useful tools for basic science? Why are microorganisms important to humans?

1.2 Structure and Activities of Microbial Cells

Microbial cells are living compartments that interact with their environment and with other cells in dynamic ways. In Chapter 2 we will examine the structure of cells in detail and relate specific structures to specific functions. Here we present a snapshot of

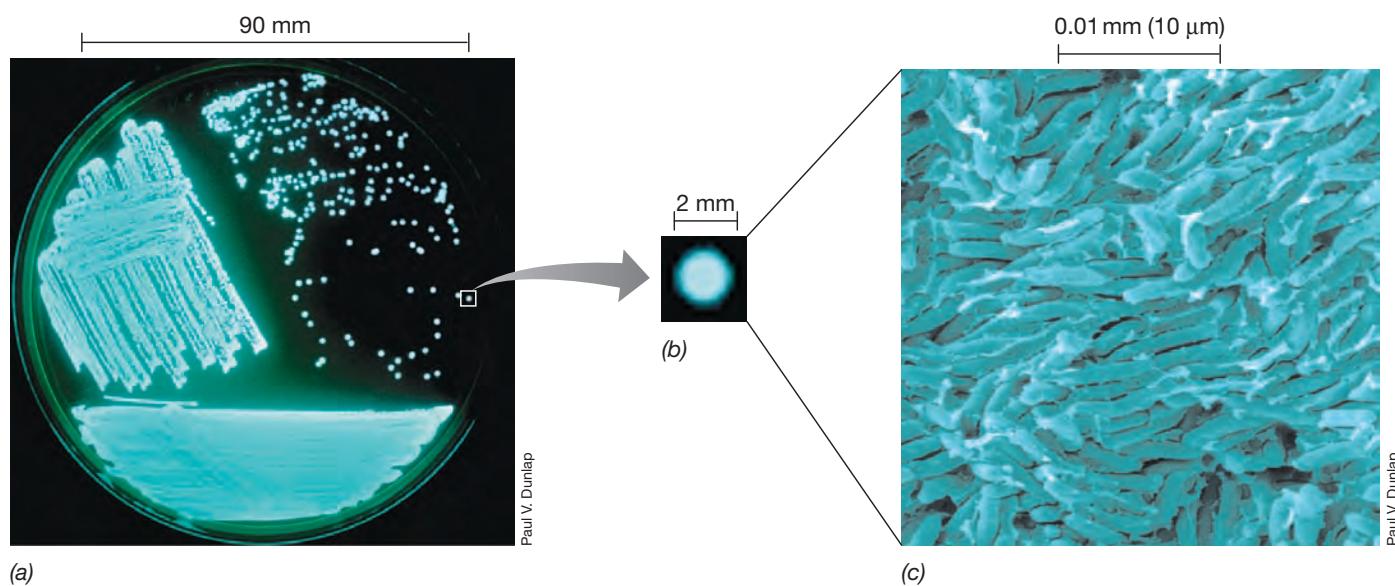

Figure 1.1 Microbial cells. (a) Bioluminescent (light-emitting) colonies of the bacterium *Photobacterium* grown in laboratory culture on a Petri plate. (b) A single colony can contain more than 10 million (10^7) individual cells. (c) Scanning electron micrograph of cells of *Photobacterium*.

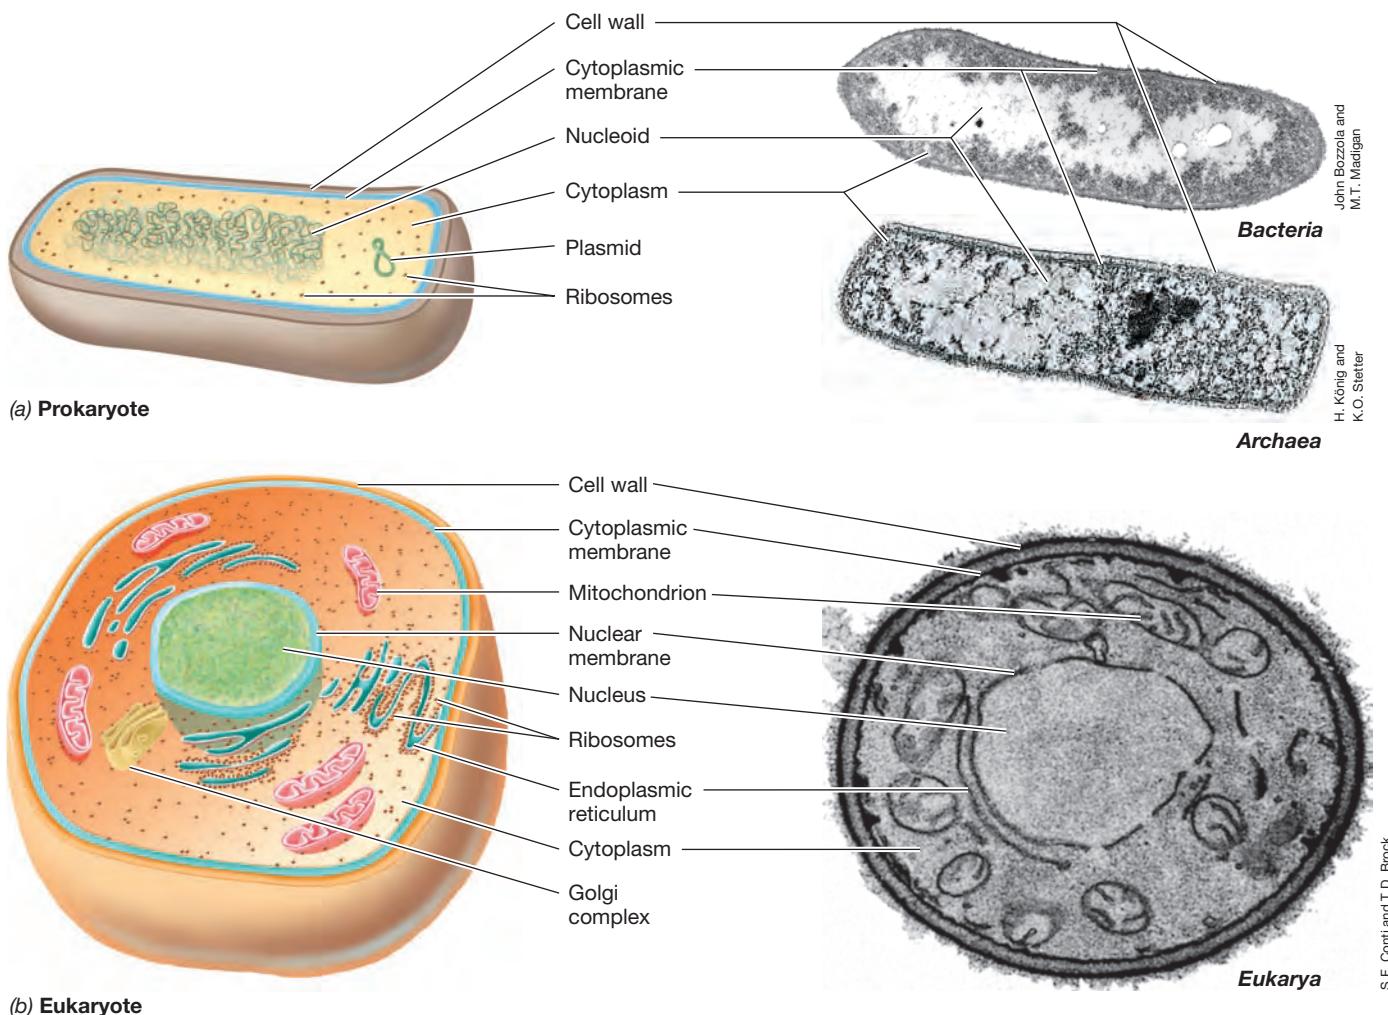

Figure 1.2 Microbial cell structure. (a) (Left) Diagram of a prokaryotic cell. (Right) Electron micrograph of *Heliobacterium modesticaldum* (*Bacteria*, cell is about 1 m in diameter) and *Thermoproteus neutrophilus* (*Archaea*, cell is about 0.5 m in diameter). (b) (Left) Diagram of a eukaryotic cell. (Right) Electron micrograph of a cell of *Saccharomyces cerevisiae* (*Eukarya*, cell is about 8 m in diameter).

microbial structure and activities. We purposely exclude viruses in this discussion because although they resemble cells in many ways, viruses are not cells but instead a special category of microorganism. We consider the structure, diversity, and activities of viruses in Chapters 8 and 9.

Elements of Microbial Structure

All cells have much in common and contain many of the same components (Figure 1.2). All cells have a permeability barrier called the **cytoplasmic membrane** that separates the inside of the cell, the **cytoplasm**, from the outside. The cytoplasm is an aqueous mixture of **macromolecules**—proteins, lipids, nucleic acids, and polysaccharides—small organic molecules (mainly precursors of macromolecules), various inorganic ions, and **ribosomes**, the cell's protein-synthesizing structures. The **cell wall** lends structural strength to a cell; it is a relatively permeable structure located outside the membrane and is a much stronger layer than the membrane itself. Plant cells and most microorganisms have cell walls, whereas animal cells, with rare exceptions, do not.

Examination of the internal structure of cells reveals two patterns, called **prokaryote** and **eukaryote**. Prokaryotes include the *Bacteria* and the *Archaea* and consist of small and structurally rather simple cells (Figure 1.2a). Eukaryotes are typically much larger than prokaryotes and contain an assortment of membrane-enclosed cytoplasmic structures called **organelles** (Figure 1.2b). These include, most prominently, the DNA-containing nucleus but also mitochondria and chloroplasts, organelles that specialize in supplying the cell with energy, and various other organelles. Eukaryotic microorganisms include algae, protozoa and other protists, and the fungi. The cells of plants and animals are also eukaryotic. Despite the clear-cut *structural* differences between prokaryotes and eukaryotes (Figure 1.2), the word “prokaryote” does not imply *evolutionary* relatedness. As we will see in the next section, although species of *Bacteria* and *Archaea* may look similar, they are not closely related in an evolutionary sense.

Genes, Genomes, Nucleus, and Nucleoid

The life processes of a cell are controlled by its complement of genes, its **genome**. A gene is a segment of DNA that encodes a

protein or an RNA molecule. The genome is the living blueprint of an organism; the characteristics, activities, and very survival of a cell are governed by its genome. The genomes of prokaryotes and eukaryotes are organized differently. In eukaryotes, DNA is present as linear molecules within the membrane-enclosed **nucleus**. By contrast, the genome of *Bacteria* and *Archaea* is a closed circular chromosome (a few prokaryotes have linear chromosomes). The chromosome aggregates within the cell to form the **nucleoid**, a mass visible in the electron microscope (Figure 1.2a). Most prokaryotes have only a single chromosome, but many also contain one or more small circles of DNA distinct from that of the chromosome, called *plasmids*. Plasmids typically contain genes that confer a special property on the cell (such as a unique metabolism, or antibiotic resistance) rather than essential genes needed under all growth conditions. This contrasts with genes on the chromosome, most of which are needed for basic survival.

How many genes does a cell have? We know that this number is highly variable because of the many genomes that have been sequenced. The genome of the model bacterium *Escherichia coli* is fairly typical in size; it is a single circular chromosome of 4,639,221 base pairs of DNA arranged into 4288 genes. The genomes of a few prokaryotes are three times this size while the genomes of some others contain as few as one-twentieth as many genes. Eukaryotic cells typically have much larger genomes than do prokaryotes. A human cell, for example, contains over 1000 times as much DNA as a cell of *E. coli* and about 7 times as many genes.

Activities of Microbial Cells

What activities do microbial cells carry out? We will see that in nature, microbial cells typically live in groups called *microbial communities*. Figure 1.3 considers some of the ongoing cellular activities within the microbial community. All cells show some form of **metabolism** by taking up nutrients from the environment and transforming them into new cell materials and waste products. During these transformations, energy is conserved that can be used by the cell to support synthesis of new structures. Production of these new structures culminates in the division of the cell to form two cells. In microbiology, we use the word **growth** to refer to the increase in cell number as a result of cell division.

During metabolism and growth, both genetic and catalytic events occur in cells; biological information flow is initiated and metabolic pathways are engaged. On the genetic side, the cell's genome is replicated, and the proteins needed to support growth under a given set of conditions are biosynthesized in the sequential processes of *transcription* and *translation* (Figure 1.3). These events require that the cell's catalytic machinery—its **enzymes**—carry out reactions that supply the energy and precursors necessary for the biosynthesis of all cell components. Catalytic and genetic events in a microbial cell are coordinated and highly regulated to ensure that new cell materials are made in the proper order and concentrations and that the cell remains optimally tuned to its surroundings.

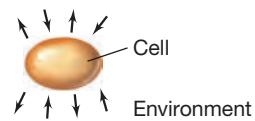

Many microbial cells are capable of **motility**, typically by self-propulsion (Figure 1.3). Motility allows cells to move away from unfavorable conditions and to exploit new resources or growth opportunities. Some microbial cells undergo **differentiation**, which

Properties of all cells:

Metabolism

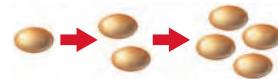

Cells take up nutrients, transform them, and expel wastes.

1. **Genetic** (replication, transcription, translation)
2. **Catalytic** (energy, biosyntheses)

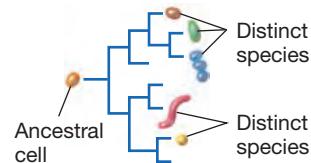

Growth

Nutrients from the environment are converted into new cell materials to form new cells.

Evolution

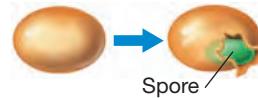

Cells evolve to display new properties. Phylogenetic trees capture evolutionary relationships.

Properties of some cells:

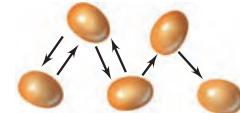

Differentiation

Some cells can form new cell structures such as a spore.

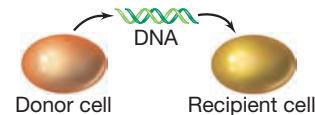

Communication

Cells interact with each other by chemical messengers.

Genetic exchange

Cells can exchange genes by several mechanisms.

Motility

Some cells are capable of self-propulsion.

Figure 1.3 The properties of microbial cells. Major activities ongoing in cells in the microbial community are depicted.

may result in the formation of modified cells specialized for growth, dispersal, or survival. Cells respond to chemical signals in their environment, including those produced by other cells of either the same or different species, and these signals often trigger new cellular activities. Microbial cells thus exhibit intercellular **communication**; they are “aware” of their neighbors and can respond accordingly. Many prokaryotic cells can also transfer genes to or accept genes from neighboring cells, either of the same species or of a different species, in the process of **genetic exchange**.

Evolution (Figure 1.3) is the process of descent with modification in which genetic variants (mutants) are selected based on their reproductive fitness. Although we learn from elementary biology that evolution is a very slow process, evolution in microbial cells can be very rapid when selective pressure is strong. For example, witness today how genes encoding antibiotic resistance in pathogenic (disease-causing) bacteria have been selected and widely distributed by the indiscriminate use of antibiotics in human and veterinary medicine. Genetic exchange between prokaryotic cells, which is independent of evolution (Figure 1.3), can also significantly accelerate the adaptation of cells to new habitats or to rapidly changing conditions.

Not all of the processes depicted in Figure 1.3 occur in all cells. Metabolism, growth, and evolution, however, are universal. We now take a peek at the results of microbial evolution in the form of the enormous diversity of the microbial world that has been unveiled by modern microbiology.

MINIQUIZ

- What important functions do the following play in a cell: cytoplasmic membrane, ribosomes, cell wall?
- What type of cells have a nucleus? Nucleoid? What is a cell's genome and why is it important?
- What do the terms "growth" and "motility" mean in microbiology?

1.3 Evolution and Diversity of Microbial Cells

Microorganisms were the first entities on Earth that showed the properties we associate with life. How did microbial cells originate and how are extant microbial cells related to one other?

The First Cells and the Beginnings of Evolution

Because all cells are constructed in similar ways, it is thought that all cells have descended from a common ancestral cell, the *last universal common ancestor* (LUCA). After the first cells arose from nonliving materials, a process that occurred over hundreds of millions of years, their subsequent growth formed cell populations and these began to interact with other cell populations to form microbial communities. Along the way, evolution and genetic exchange served up variants that could be selected for improvements that made their success and survival more probable. Today we see the grand result of these processes, ongoing for nearly 4 billion years.

Life on Earth through the Ages

Earth is 4.6 billion years old and evidence shows that microbial cells first appeared between 3.8 and 3.9 billion years ago (Figure 1.4). During the first 2 billion years of Earth's existence, its atmosphere was anoxic (O_2 was absent), and only nitrogen (N_2), carbon dioxide (CO_2), and a few other gases were present. Only microorganisms capable of anaerobic metabolism could survive under these conditions. The evolution of phototrophic microorganisms—organisms that harvest energy from sunlight—occurred within 1 billion years of the formation of Earth. The first phototrophs were relatively simple ones, such as purple or green bacteria and other anoxygenic (non-oxygen-evolving) phototrophs (Figure 1.5a). Cyanobacteria (oxygen-evolving phototrophs) (Figure 1.5b) evolved from anoxygenic phototrophs nearly a billion years later and began the slow process of oxygenating Earth's atmosphere. Triggered by increases in O_2 in the atmosphere, multicellular life forms eventually evolved and continued to increase in complexity, culminating in the plants and animals we know today. But plants and animals have only existed for about half a billion years. The timeline of life on Earth (Figure 1.4a) shows that 80% of life's history was exclusively microbial, and thus in many ways, Earth can be considered a microbial planet.

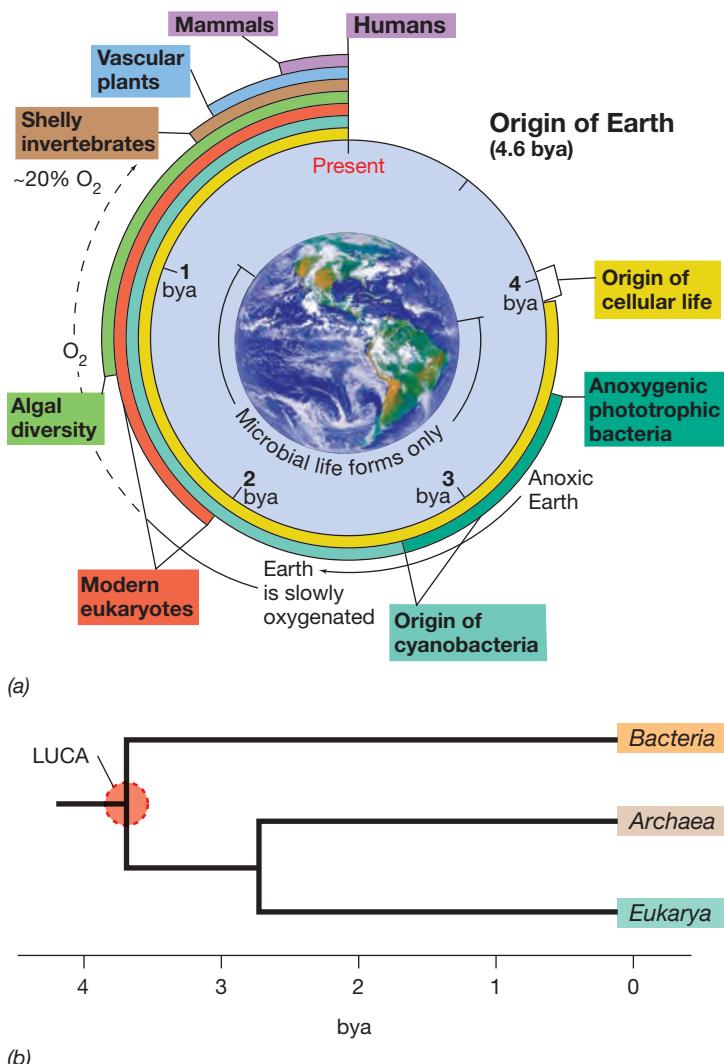

Figure 1.4 A summary of life on Earth through time and origin of the cellular domains. (a) Cellular life was present on Earth by 3.8 billion years ago (bya). Cyanobacteria began the slow oxygenation of Earth about 3 bya, but current levels of O_2 in the atmosphere were not achieved until 500–800 million years ago. Eukaryotes are nucleated cells (Figure 1.2b) and include both microbial and multicellular organisms. (b) The three domains of cellular organisms are *Bacteria*, *Archaea*, and *Eukarya*. *Archaea* and *Eukarya* diverged long before nucleated cells with organelles ("modern eukaryotes" in part a) appear in the fossil record. LUCA, last universal common ancestor.

As evolutionary events unfolded, three major lineages of microbial cells—the *Bacteria*, the *Archaea*, and the *Eukarya* (Figure 1.4b)—were distinguished; microbial *Eukarya* were the ancestors of the plants and animals. These major cell lineages are called **domains**. Over enormous periods of time, natural selection filled every suitable environment on Earth with microorganisms whose ancestry can be traced back to one of these three domains.

Microbial Diversity

Assessing the phylogenetic history of the microbial world—and thus revealing its true diversity—had to wait until tools were available that could do the job. Unlike plants and animals for which bones, fossils, leaves, and the like can be used to help reconstruct

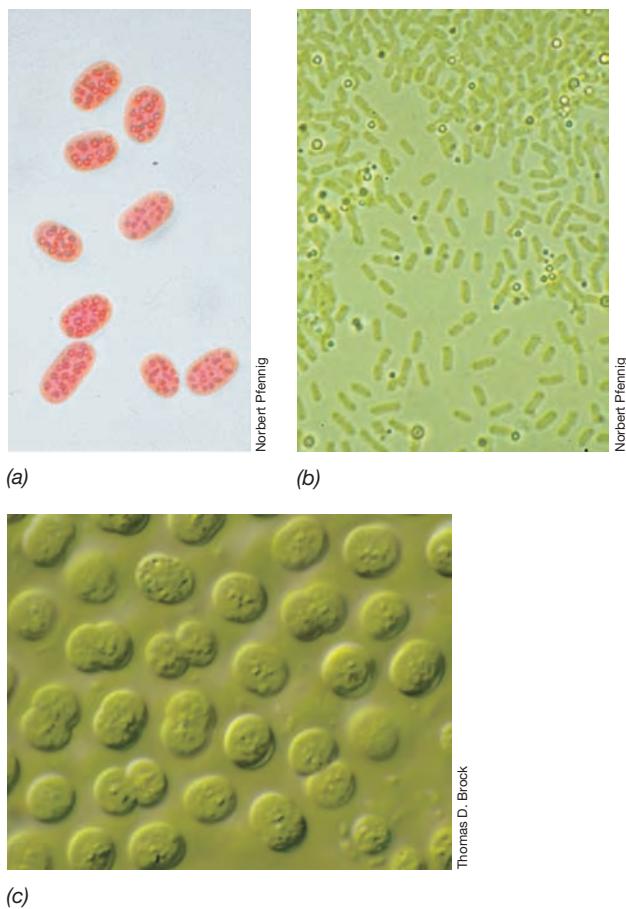

Figure 1.5 Phototrophic microorganisms. (a) Purple sulfur and (b) green sulfur bacteria (both anoxygenic phototrophs). (c) Cyanobacteria (oxygenic phototrophs). Purple and green bacteria appeared on Earth long before oxygenic phototrophs evolved (see Figure 1.4a).

phylogenies, such remains were unavailable to guide the construction of a microbial evolutionary tree. However, discoveries made in the past 40 years or so have clearly shown that each cell contains a record of its evolutionary history embedded in its genes. For reasons that will be presented in later chapters, genes that encode *ribosomal RNAs* have emerged as excellent barometers of microbial diversity. Ribosomal RNAs are components of ribosomes (Figure 1.2), the structures that synthesize new proteins as part of the process of translation. The technology for revealing the phylogeny of a microorganism from its ribosomal RNA genes is well developed, and from only a few cells, a phylogenetic tree that reveals the position of any organism relative to its neighbors can be constructed (Figure 1.6a).

As the ribosomal RNA phylogenetic tree of life has been fleshed out (Figure 1.6b), it has shown that thousands of species of *Bacteria* and *Archaea* exist as well as hundreds of species of microbial *Eukarya* (the tree in Figure 1.6b shows only a few landmark lineages). The tree of life has also revealed two important facts that were previously unsuspected: (1) *Bacteria* and *Archaea* are phylogenetically distinct despite sharing many structural features (Figure 1.2a), and (2) *Archaea* are more closely related to *Eukarya* than to *Bacteria*. From the last universal common

ancestor of all cells (Figure 1.4b), evolution proceeded along two paths to form the domains *Bacteria* and *Archaea*. At some later time, the domain *Archaea* diverged to distinguish the *Eukarya* from the *Archaea* (Figures 1.4b and 1.6b).

The tools for generating microbial phylogenies on pure cultures of microorganisms (Figure 1.6a) have been adapted for use in natural environments in order to probe the diversity of microbial communities. These techniques have greatly improved our picture of microbial diversity and have led to the staggering conclusion that most microorganisms that exist on Earth have yet to be brought into laboratory culture! It now appears that our understanding of microbial diversity is still in its infancy. Nevertheless, the universal tree of life provides us with a roadmap to guide future work on microbial diversity and has unveiled the previously hidden concept of three evolutionary domains of life.

- Why were cyanobacteria so important in the evolution of life on Earth?
- How can the phylogenetic history of microorganisms be determined?
- Name the three domains of life.

1.4 Microorganisms and Their Environments

In nature, microbial cells live in association with other cells. A *population* is a group of cells derived from a single parental cell by successive cell divisions. The immediate environment in which a microbial population lives is called its **habitat**. Populations of cells interact with other populations in **microbial communities** (Figure 1.7). The abundance and diversity of any microbial community is strongly controlled by the *resources* (foods) available and *conditions* (temperature, pH, presence or absence of oxygen, and so on) that prevail in that community.

Microbial Ecosystems

Microbial populations can interact with each other in beneficial, neutral, or harmful ways. For example, the metabolic waste products of one group of organisms can be nutrients or even poisons to other groups of organisms. Habitats differ markedly in their characteristics, and a habitat that is favorable for the growth of one organism may be harmful for another. Collectively, we call all the living organisms, together with the physical and chemical components of their environment, an **ecosystem**. Major microbial ecosystems are *aquatic* (oceans, ponds, lakes, streams, ice, hot springs), *terrestrial* (surface soils, deep subsurface), and *higher organisms* (in or on plants and animals).

An ecosystem is greatly influenced by microbial activities. Microorganisms carrying out metabolic processes remove nutrients from the ecosystem and use them to build new cells. At the same time, they excrete waste products back into the

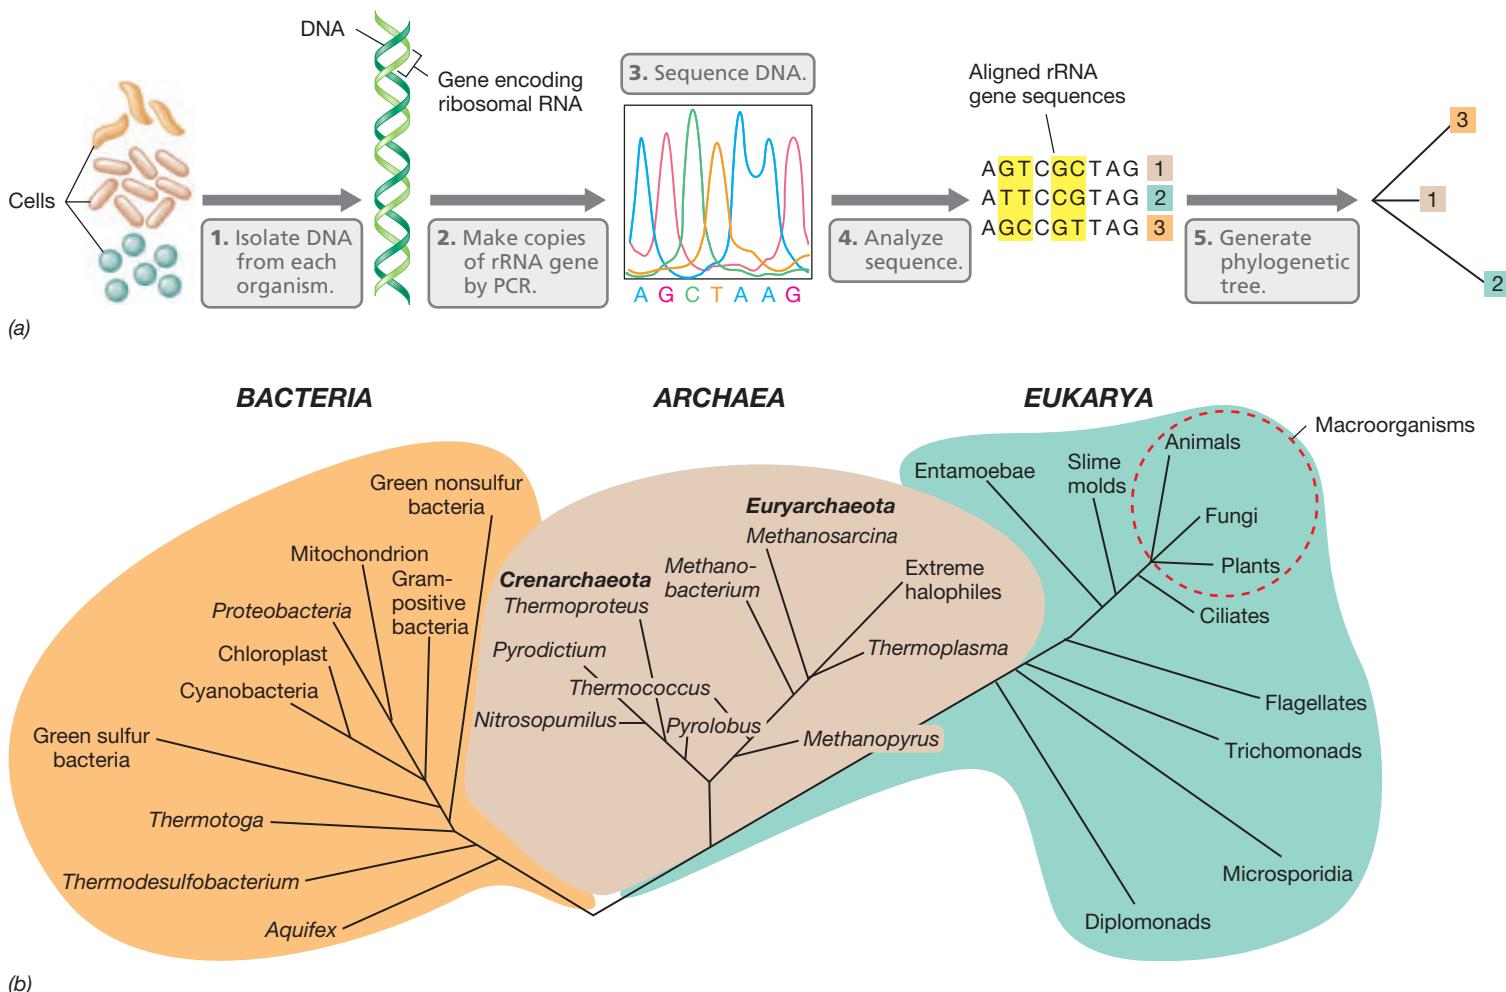

Figure 1.6 Evolutionary relationships and the phylogenetic tree of life. (a) The technology behind ribosomal RNA gene phylogenies. 1. DNA is extracted from cells. 2. Copies of the gene encoding rRNA are made by the polymerase chain reaction (PCR); [Section 11.3](#). 3, 4. The gene is sequenced and

the sequence aligned with sequences from other organisms. A computer algorithm makes pairwise comparisons at each base and generates a phylogenetic tree, 5, that depicts evolutionary relationships. In the example shown, the sequence differences are highlighted in yellow and are as follows: organism 1

versus organism 2, three differences; 1 versus 3, two differences; 2 versus 3, four differences. Thus organisms 1 and 3 are closer relatives than are 2 and 3 or 1 and 2. (b) The phylogenetic tree of life. The tree shows the three domains of organisms and a few representative groups in each domain.

environment. Thus, microbial ecosystems expand and contract, depending on the resources and conditions available and the different populations of organisms they can support. Over time, the metabolic activities of microorganisms can gradually change their ecosystems, both chemically and physically. For example, molecular oxygen (O_2) is a vital nutrient for some microorganisms but a poison to others. If aerobic (oxygen-consuming) microorganisms remove O_2 from a habitat, rendering it anoxic (O_2 -free), the changed conditions may favor the growth of anaerobic microorganisms that were formerly present in the habitat but unable to grow. In other words, as resources and conditions change in a microbial habitat, cell populations rise and fall, changing the makeup of the community and redefining the ecosystem. In later chapters we will return to a consideration of the ways in which microorganisms affect animals, plants, and the whole global ecosystem. This is the science of **microbial**

ecology, perhaps the most exciting subdiscipline of microbiology today.

Microorganisms in Natural Environments

Microorganisms are present everywhere on Earth that will support life. These include habitats we are all familiar with—soil, water, animals, and plants—as well as virtually any structures made by humans. In the human body alone, microbial cells outnumber our body cells by a factor of ten. Sterility (the absence of life forms) in any natural sample is extremely rare.

In some microbial habitats higher organisms cannot survive because the habitat is too hot or too cold, too acidic or too caustic, too salty or otherwise osmotically stressing, or includes enormous pressures. Although one might predict that such “extreme environments” would pose challenges for any life forms, these punishing habitats are often teeming with microorganisms. Such

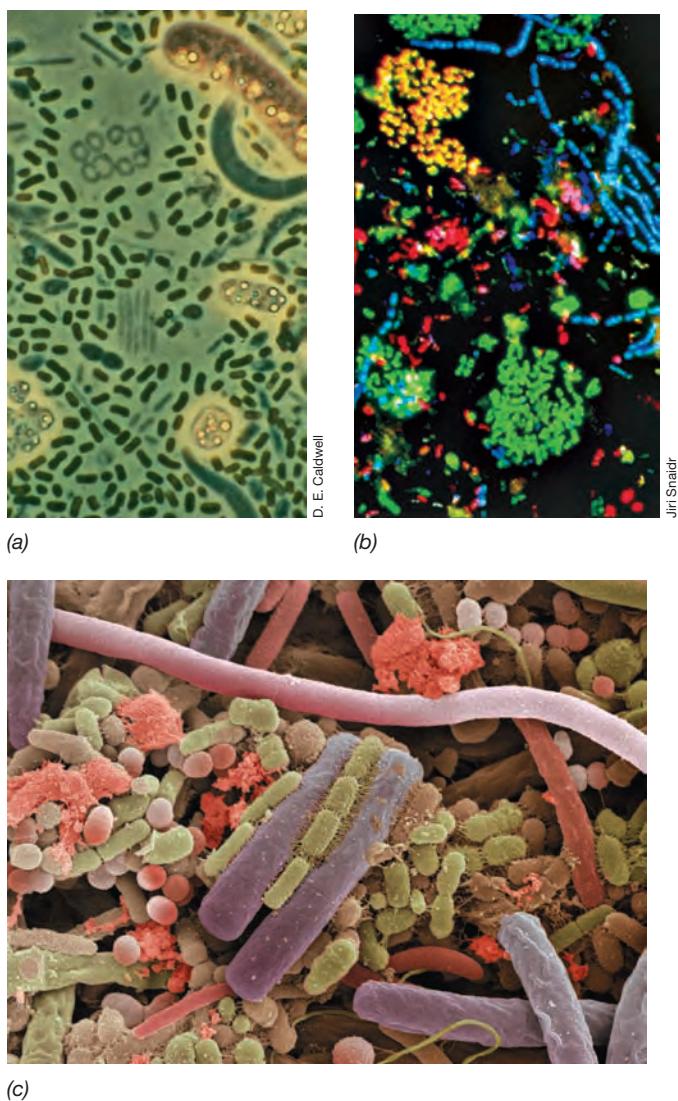

Figure 1.7 Microbial communities. (a) A bacterial community that developed in the depths of a small Michigan lake, showing cells of various green and purple (large cells with sulfur granules) phototrophic bacteria. (b) A bacterial community in a sewage sludge sample. The sample was stained with a series of dyes, each of which stained a specific bacterial group. microorganisms are called **extremophiles** and include a large and remarkable group of mainly *Bacteria* and *Archaea*, whose collective properties define the physiochemical limits to life ([Table 1.1](#)).

Extremophiles abound in such harsh environments as volcanic hot springs; on or in the ice covering lakes (see page 1), glaciers, or the polar seas; in extremely salty bodies of water; in soils and waters having a pH as low as 0 or as high as 12; and in the deep sea or deep in the earth where pressures can exceed atmospheric by over 1000 times. Interestingly, these prokaryotes do not just *tolerate* their particular environmental extreme but actually *require* it in order to grow. That is why they are called extremophiles (the suffix *-phile* means “loving”). Table 1.1 summarizes the current “record holder” extremophiles, lists the term used to describe

each class, and gives examples of their habitats. We will revisit many of these organisms in later chapters and discover the special structural and biochemical properties that allow them to thrive under extreme conditions.

Estimates of the total number of microbial cells on Earth are about 2.5×10^{30} ([Table 1.2](#)). The total amount of carbon present in all of these microbial cells equals that of all plants on Earth, and plant carbon far exceeds animal carbon. Moreover, the collective contents of nitrogen and phosphorus in microbial cells exceed that of all plant biomass by 10-fold. Thus, microbial cells, small as they are, are not inconsequential; they constitute the major fraction of biomass on Earth and are key reservoirs of essential nutrients for life. We will see later that this very large number of very small cells also play important roles in many hot-button global issues such as climate change, agricultural productivity, fuels, and many other issues of importance to humans.

Most microbial cells reside in just a few very large habitats, and strange as it may seem, most do not reside on Earth’s *surface* but instead lie underground in the oceanic and terrestrial subsurfaces at depths up to about 10 km ([Table 1.2](#)). By comparison to the subsurface, surface soils and waters contain a relatively small percentage of the total microbial cells on Earth. Animals (including humans), which are heavily colonized with microorganisms, collectively contain only a tiny fraction of the total microbial population of Earth ([Table 1.2](#)). Because almost everything we know about microbial life has emerged from the study of surface-dwelling microorganisms, many new discoveries are likely in store for future microbiologists who dig into Earth’s most populated microbial habitats—those which we cannot see.

MINIQUIZ

- How does a microbial community differ from a microbial population?
- What is a habitat? How can microorganisms change the characteristics of their habitats?
- What is an extremophile?
- Where do most microorganisms live in nature?

1.5 The Impact of Microorganisms on Humans

Through the years microbiologists have made great strides in discovering how microorganisms work, and application of this knowledge has greatly advanced human health and welfare. Besides understanding microorganisms as agents of disease, microbiology has made great advances in understanding the important role that microorganisms play in food and agriculture, and microbiologists have been able to exploit microbial activities to produce valuable human products, generate energy, and clean up the environment.

Microorganisms as Agents of Disease

The statistics summarized in [Figure 1.8](#) show how microbiologists and clinical medicine have combined to conquer infectious diseases

Table 1.1 Classes and examples of extremophiles^a

Extreme	Descriptive term	Genus/species	Domain	Habitat	Minimum	Optimum	Maximum	
Temperature	High	Hyperthermophile	<i>Methanopyrus kandleri</i>	Archaea	Undersea hydrothermal vents	90°C	106°C	122°C ^b
	Low	Psychrophile	<i>Psychromonas ingrahamii</i>	Bacteria	Sea ice	-12°C	5°C	10°C
pH	Low	Acidophile	<i>Picrophilus oshimae</i>	Archaea	Acidic hot springs	-0.06	0.7 ^c	4
	High	Alkaliphile	<i>Natronobacterium gregoryi</i>	Archaea	Soda lakes	8.5	10 ^d	12
Pressure	Barophile (piezophile)	<i>Moritella yayanosii</i>	Bacteria	Deep ocean sediments	500 atm	700 atm ^e	>1000 atm	
Salt (NaCl)	Halophile	<i>Halobacterium salinarum</i>	Archaea	Salterns	15%	25%	32% (saturation)	

^aThe organisms listed are the current “record holders” for growth in laboratory culture at the extreme condition listed.

^bAnaerobe showing growth at 122°C only under several atmospheres of pressure.

^c*P. oshimae* is also a thermophile, growing optimally at 60°C.

^d*N. gregoryi* is also an extreme halophile, growing optimally at 20% NaCl.

^e*M. yayanosii* is also a psychrophile, growing optimally near 4°C.

in the past 100 years. At the beginning of the twentieth century, the major causes of human death were infectious diseases caused by bacterial and viral **pathogens**. In those days children and the aged in particular succumbed in large numbers to microbial diseases. Today, however, infectious diseases are much less deadly, at least in developed countries. Control of infectious disease has come from a combination of advances including our increased understanding of disease processes, improved sanitary and public health practices, active vaccine campaigns, and the widespread use of antimicrobial agents, such as antibiotics. As we will see in the second part of this chapter, the development of microbiology as a science can be traced to pioneering studies of infectious disease.

Although many infectious diseases are now controlled, many others can still be a threat, particularly in developing countries. For example, diseases such as malaria, tuberculosis, cholera, African sleeping sickness, measles, pneumonia and other respiratory diseases, and diarrheal syndromes are still common in developing countries. Moreover, humans worldwide are under threat from diseases that could quickly emerge, such as bird or swine flu, or Ebola hemorrhagic fever; these are primarily animal diseases that under certain circumstances can be transmitted to humans and spread quickly through a population. Thus, microorganisms can still be serious health threats to humans in all parts of the world.

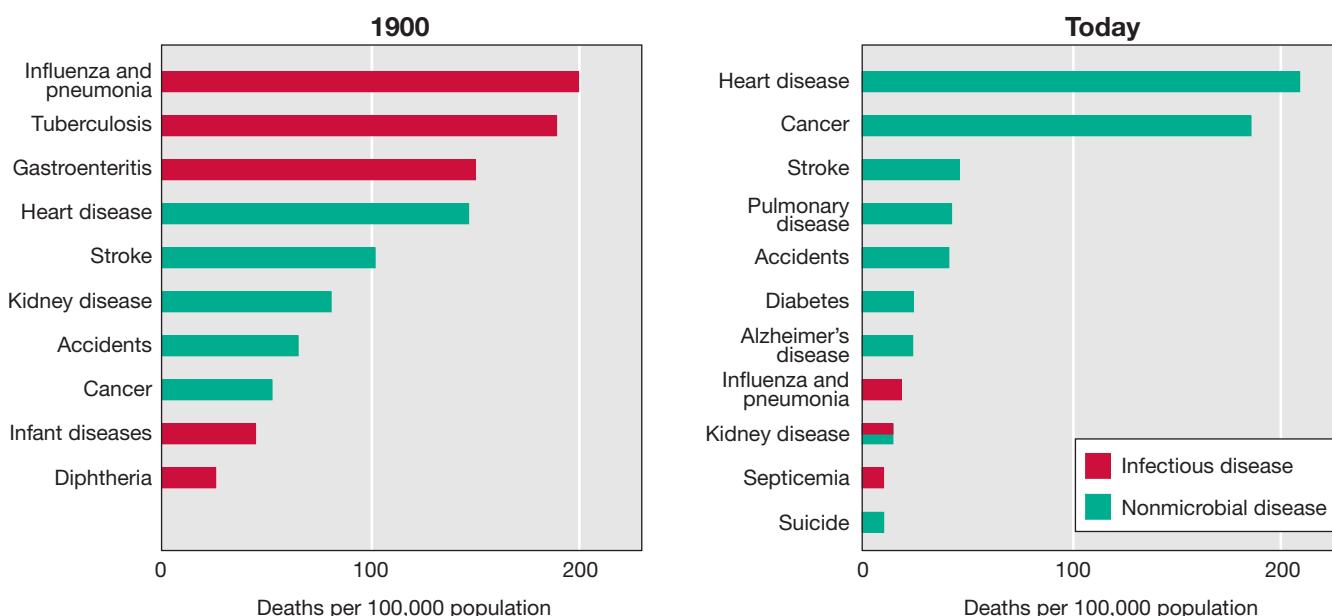

Figure 1.8 Death rates for the leading causes of death in the United States: 1900 and today. Infectious diseases were the leading causes of death in 1900, whereas today they account for relatively few deaths. Kidney diseases can be caused by microbial infections or systemic sources (diabetes, cancers, toxicities, metabolic diseases, etc.). Data are from the United States National Center for Health Statistics and the Centers for Disease Control and Prevention.

Table 1.2 Distribution of microorganisms in and on Earth^a

Habitat	Percent of total
Marine subsurface	66
Terrestrial subsurface	26
Surface soil	4.8
Oceans	2.2
All other habitats ^b	1.0

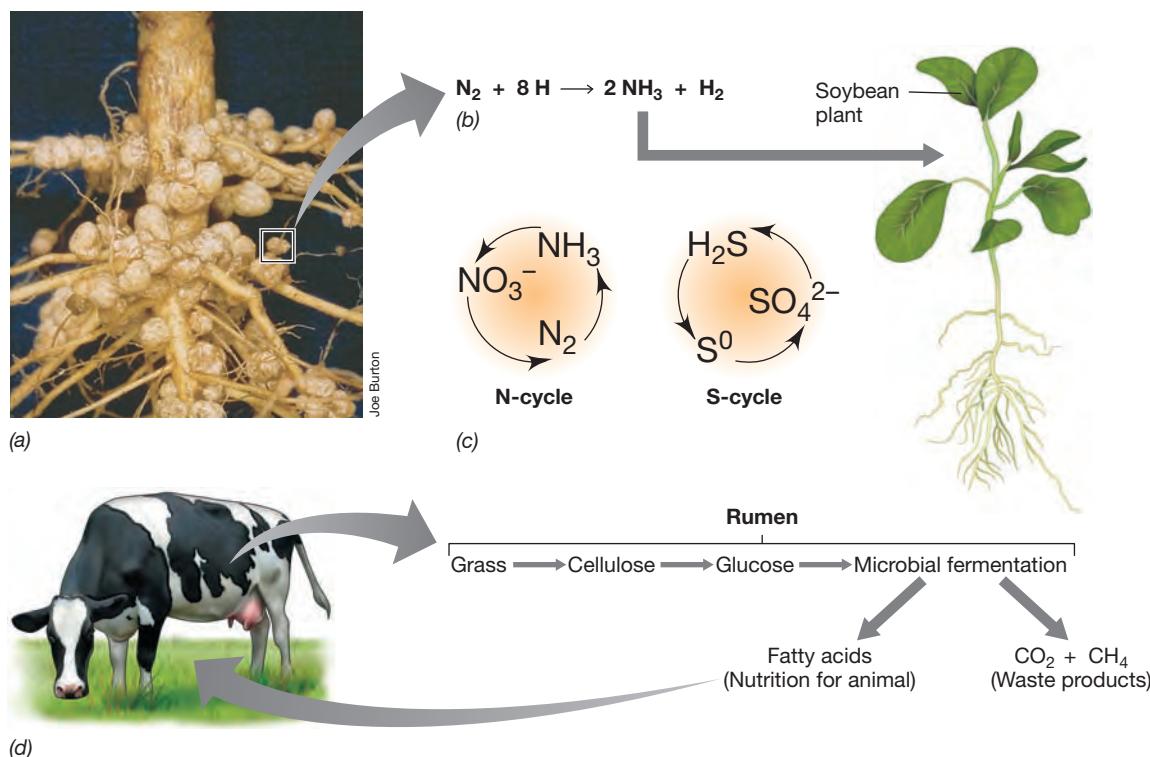

^aData compiled by William Whitman, University of Georgia, USA; refer to total numbers (estimated to be about 2.5×10^{30} cells) of *Bacteria* and *Archaea*. This enormous number of cells contains, collectively, about 5×10^{17} grams of carbon.

^bIncludes, in order of decreasing numbers: freshwater and salt lakes, domesticated animals, sea ice, termites, humans, and domesticated birds.

Although we must appreciate the powerful threat posed by pathogenic microorganisms, in reality, most microorganisms are not harmful to humans. In fact, most microorganisms cause no harm but instead are beneficial, and in many cases are even essential, to human welfare and the functioning of the planet. We turn our attention to these microorganisms now.

Microorganisms, Agriculture, and Human Nutrition

Agriculture benefits from the cycling of nutrients by microorganisms. For example, a number of major crop plants that feed humans and domesticated animals are legumes. Legumes live in close association with bacteria that form structures called *nodules* on their roots. In the nodules, these bacteria convert atmospheric nitrogen (N_2) into ammonia (NH_3 , the process of *nitrogen fixation*) that the plants use as a nitrogen source for growth (Figure 1.9).

Nitrogen fixation also eliminates the need for farmers to apply costly and polluting nitrogen fertilizers. Other bacteria cycle sulfur, oxidizing toxic sulfur compounds such as hydrogen sulfide (H_2S) into sulfate (SO_4^{2-}), which is nontoxic and an essential plant nutrient (Figure 1.9c).

Also of major agricultural importance are microorganisms that inhabit the *rumen* of ruminant animals, such as cattle and sheep. The rumen is a microbial ecosystem in which large populations of microorganisms digest and ferment the polysaccharide cellulose, the major component of plant cell walls (Figure 1.9d). Without these symbiotic microorganisms, ruminants could not thrive on cellulose-rich (but otherwise nutrient-poor) food, such as grass and hay. Many domesticated and wild herbivorous mammals—including deer, bison, camels, giraffes, and goats—are also ruminants.

The human gastrointestinal (GI) tract lacks a rumen, and microbial numbers comparable to those in the rumen (about 10^{11} microbial cells per gram of contents) occur only in the colon (large intestine). The colon (Figure 1.10) follows the stomach and small intestine in the digestive tract, but unlike the rumen, the colon lacks significant numbers of cellulose-degrading microorganisms. Microbial cell numbers are low in the highly acidic (pH 2) stomach (about 10^4 per gram) but increase to about 10^8 per gram near the end of the small intestine (pH 5) and then reach maximal numbers in the colon (pH 7) (Figure 1.10). Microorganisms in the colon assist in digestive processes by synthesizing certain vitamins and other essential nutrients but also compete for space and resources with pathogenic microorganisms that may enter the GI tract in contaminated food and water. Thus by their sheer numbers alone, the colonic microflora help prevent pathogens from gaining a foothold.

In addition to benefiting agriculture, microorganisms also have negative effects on the industry. Microbial diseases of plants and

Figure 1.9 Microorganisms in modern agriculture. (a) Root nodules on this soybean plant contain bacteria that fix molecular nitrogen (N_2) for use by the plant. (b) The nitrogen and sulfur cycles, key nutrient cycles in nature. (c) Ruminant animals. Microorganisms in the rumen of the cow convert cellulose from grass into fatty acids that can be used by the animal. The other products are not so desirable, as CO_2 and CH_4 are the major gases that cause global warming.

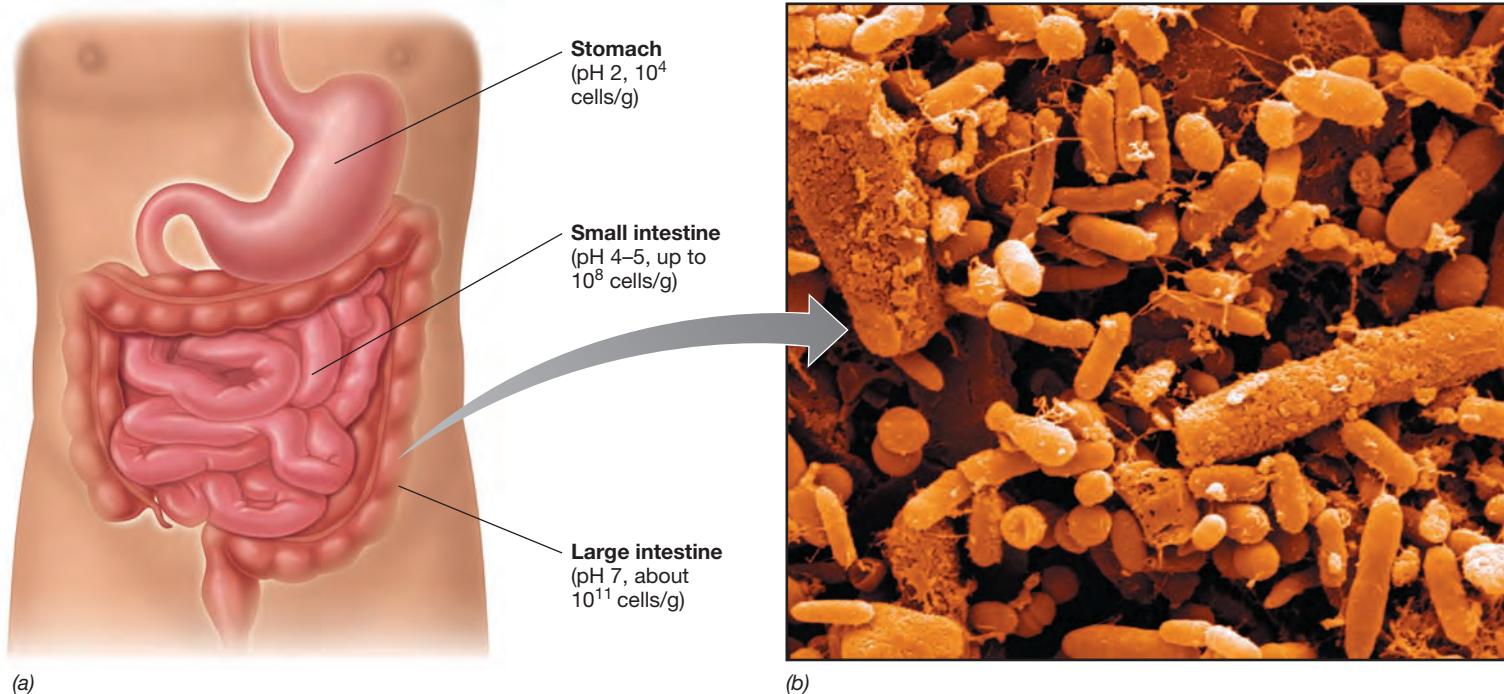

Figure 1.10 The human gastrointestinal tract. (a) Diagram of the human GI tract showing the major organs. (b) Scanning electron micrograph of microbial cells in the human colon (large intestine). Cell numbers in the colon can reach as high as 10^{11} per gram. As well as cell numbers, the microbial diversity in the colon is also quite high.

animals used for human food cause major economic losses every year. Occasionally a food product causes serious human disease, such as when pathogenic *Escherichia coli* or *Salmonella* is transmitted from infected meat, or when microbial pathogens are ingested with contaminated fresh fruits and vegetables. Microorganisms thus significantly impact the agriculture industry in both positive and negative ways.

Microorganisms and Food, Energy, and the Environment

Microorganisms play important roles in the food industry, including food spoilage, safety, and production. Food spoilage alone results in huge economic losses each year, and the canning, frozen food, and dried-food industries were developed as means to preserve foods that would otherwise undergo microbial spoilage. Food safety requires the constant monitoring of food products to ensure that they are free of pathogens and the tracking of disease outbreaks to identify the source(s) of the pathogens. Fresh foods such as meats, fruits, and vegetables are most vulnerable to microbial contamination and typically have brief “shelf lives” for the very reason that contamination is virtually impossible to prevent.

Although food safety is a major problem in the food industry, not all microorganisms

in foods cause harm to the food products or to those who eat them. Many are desirable or even essential, such as those that grow in fermented foods (Figure 1.11). For example, many dairy products depend on the activities of microorganisms to produce key acids characteristic of the products, such as in the fermentations that yield cheeses, yogurt, and buttermilk. Sauerkraut, pickles, and some sausages are also subject to microbial fermentations. Moreover, baked goods and alcoholic beverages rely on the fermentative activities of yeast, which generate carbon dioxide (CO_2)

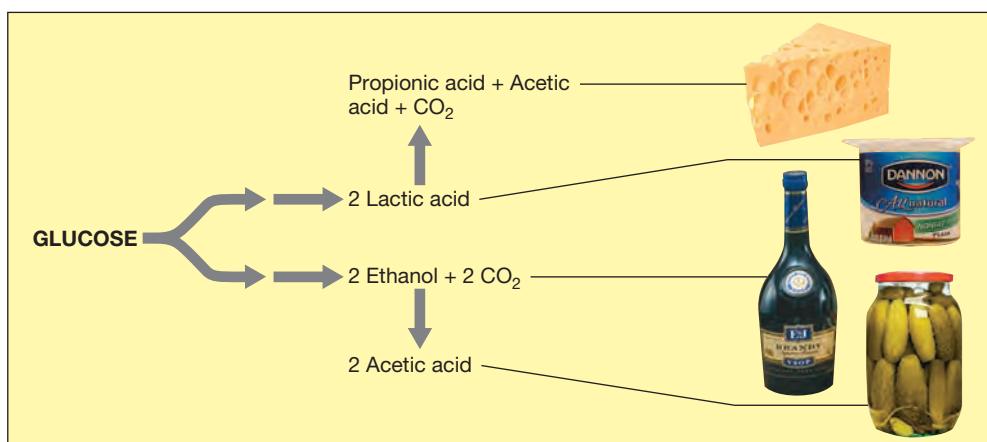

Figure 1.11 Fermented foods. (a) Major fermentations in various fermented foods. It is the fermentation product (ethanol, or lactic, propionic, or acetic acids) that both preserves the food and renders it a characteristic flavor. (b) Photo of several fermented foods showing the characteristic fermentation product in each.

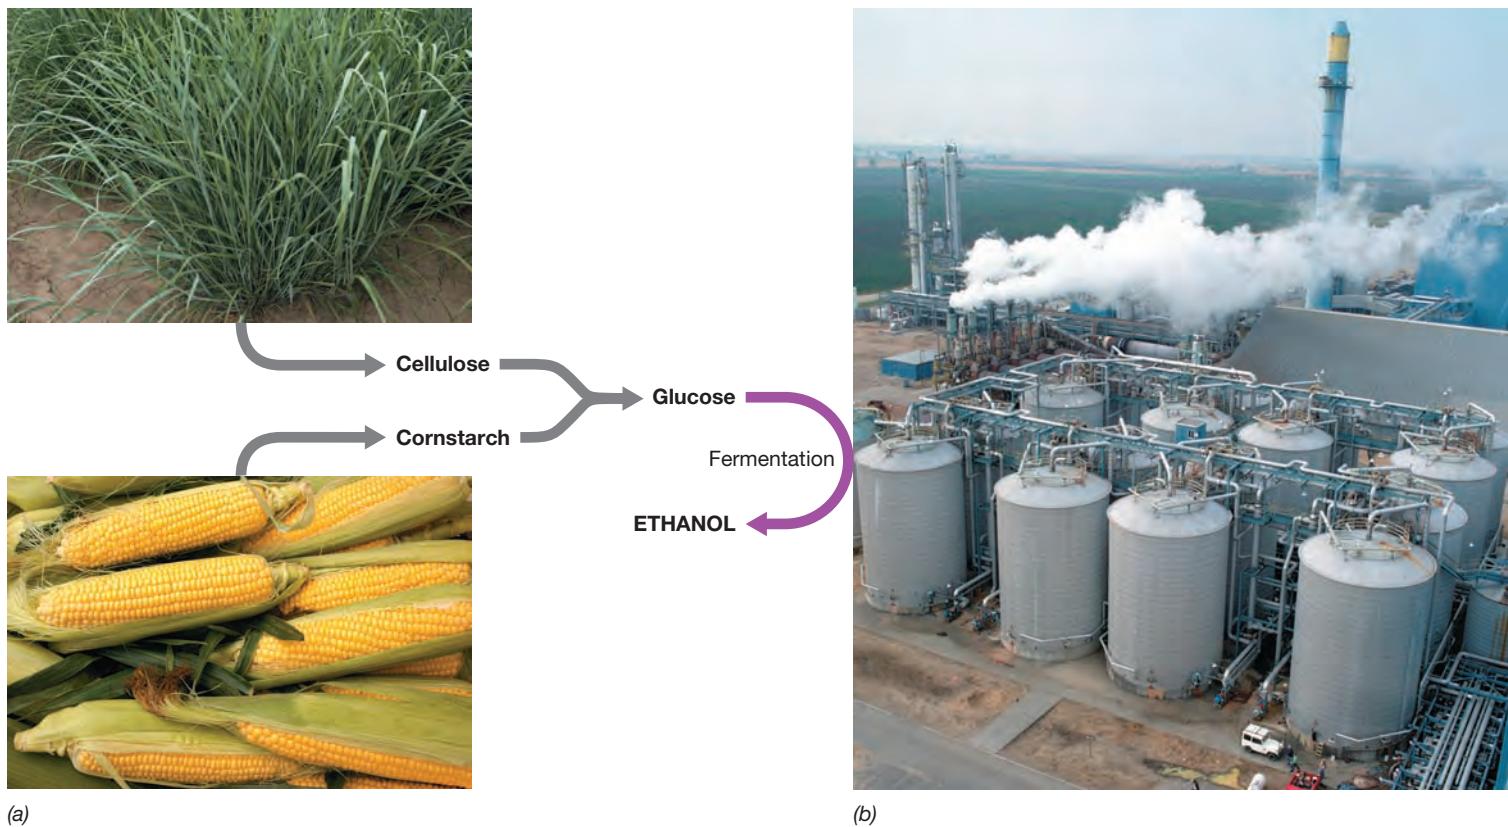

Figure 1.12 Ethanol as a biofuel. (a) Major crop plants used as feedstocks for biofuel ethanol production. Top: switchgrass, a source of cellulose. Bottom: corn, a source of cornstarch. Both cellulose and starch are composed of glucose, which is fermented to ethanol by yeast. (b) An ethanol plant in the United States. Ethanol produced by fermentation is distilled and then stored in the tanks.

to raise the dough and alcohol as a key ingredient, respectively (Figure 1.11). These products of fermentation are not only desirable chemicals but also function to preserve the food product from deleterious microbial growth.

Some microorganisms produce *biofuels*. For example, natural gas (methane, CH_4) is a product of the anaerobic metabolism of a group of *Archaea* called *methanogens*. Ethyl alcohol (ethanol), which is produced by the microbial fermentation of glucose obtained from feedstocks such as sugarcane, corn, or rapidly growing grasses, is a major motor fuel or fuel supplement (Figure 1.12). Waste materials such as domestic refuse, animal wastes, and cellulose can also be converted to ethanol and methane; and soybeans (Figure 1.9) contain oils that can be converted into fuel for diesel engines.

Microorganisms can be used to clean up pollution in a process called *bioremediation*. In bioremediation, microorganisms are used to consume spilled oil, solvents, pesticides, and other environmentally toxic pollutants. Bioremediation accelerates the cleanup process by either adding special microorganisms to a polluted environment or by adding nutrients that stimulate indigenous microorganisms to degrade the pollutants. In either case the goal is to accelerate disappearance of the pollutant.

Microorganisms can also be harnessed to produce commercially valuable products. In *industrial microbiology*, naturally occurring microorganisms are grown on a massive scale to make large amounts of products of relatively low value, such as antibiotics,

enzymes, and certain chemicals. By contrast, *biotechnology* employs genetically engineered microorganisms to synthesize products of high value, such as insulin or other human proteins, usually on a small scale. Genomics has greatly enhanced both industrial microbiology and biotechnology by making it possible to inspect the genome of virtually any organism for genes of potential commercial interest.

As the above discussion shows, the influence of microorganisms on humans is great and their activities essential for functioning of the planet. Or, as the eminent French chemist and early microbiologist Louis Pasteur so aptly put it: “The role of the infinitely small in nature is infinitely large.” We continue our introduction to the microbial world in the second half of this chapter with an historical overview of the contributions of Pasteur and a few other key scientists who were instrumental in developing the science of microbiology.

MINIQUIZ

- List two ways in which microorganisms are important in the food and agricultural industries.
- Give some examples of biofuels. How can nitrogen fixation in root nodules help biofuel production?
- What is biotechnology and how can it improve the lives of humans?

II • Microbiology in Historical Context

The future of any science is rooted in its past accomplishments. Although microbiology claims very early roots, the science did not really develop in a systematic way until the nineteenth century because technology such as microscopes and culturing techniques had to catch up with the already strong scientific curiosity. In the past 150 years or so, microbiology has moved forward in a way unprecedented by any other biological science and has spawned several new fields in modern biology. We retrace some highlights in the history of microbiology now and describe a few of the major contributors.

1.6 The Discovery of Microorganisms

Although the existence of creatures too small to be seen with the naked eye had been suspected for centuries, their discovery had to await invention of the microscope. The English mathematician and natural historian Robert Hooke (1635–1703) was an excellent microscopist. In his famous book *Micrographia* (1665), the first book devoted to microscopic observations, Hooke illustrated, among many other things, the fruiting structures of molds (Figure 1.13). This was the first known description of microorganisms.

The first person to see bacteria, the smallest microbial cells, was the Dutch draper and amateur microscopist Antoni van Leeuwenhoek (1632–1723). Van Leeuwenhoek constructed extremely simple microscopes containing a single lens to examine various natural substances for microorganisms (Figure 1.14). These microscopes were crude by today's standards, but by careful manipulation and focusing, van Leeuwenhoek was able to see bacteria. He discovered bacteria in 1676 while studying pepper–water infusions, and reported his observations in a series of letters to the prestigious Royal Society of London, which published them in English translation in 1684. Drawings of some of van Leeuwenhoek's "wee animalcules," as he referred to them, are shown in Figure 1.14b, and a photo taken through a van Leeuwenhoek microscope is shown in Figure 1.14c.

Because experimental tools to study microorganisms were crude at this time, little progress in understanding the nature and importance of bacteria was made for the next 150 years. However, in the mid-nineteenth century, microbiology reawakened. A major contributor during this period was the German–Polish scientist, Ferdinand Cohn. Cohn (1828–1898) was trained as a botanist, and his interests in microscopy led him to the study of unicellular algae and later to bacteria, including the large sulfur bacterium *Beggiatoa* (Figure 1.15). Cohn was particularly interested in heat resistance in bacteria, which led to his discovery that some bacteria form *endospores*. We now know that bacterial endospores are formed by differentiation from the mother (vegetative) cell and are extremely heat-resistant structures. Cohn described the life cycle of the endospore-forming bacterium *Bacillus* (vegetative cell → endospore → vegetative cell) and showed that vegetative cells but not endospores were killed by boiling.

Cohn also laid the groundwork for a system of bacterial classification and devised many highly effective methods for preventing the contamination of culture media, such as the use of cotton for

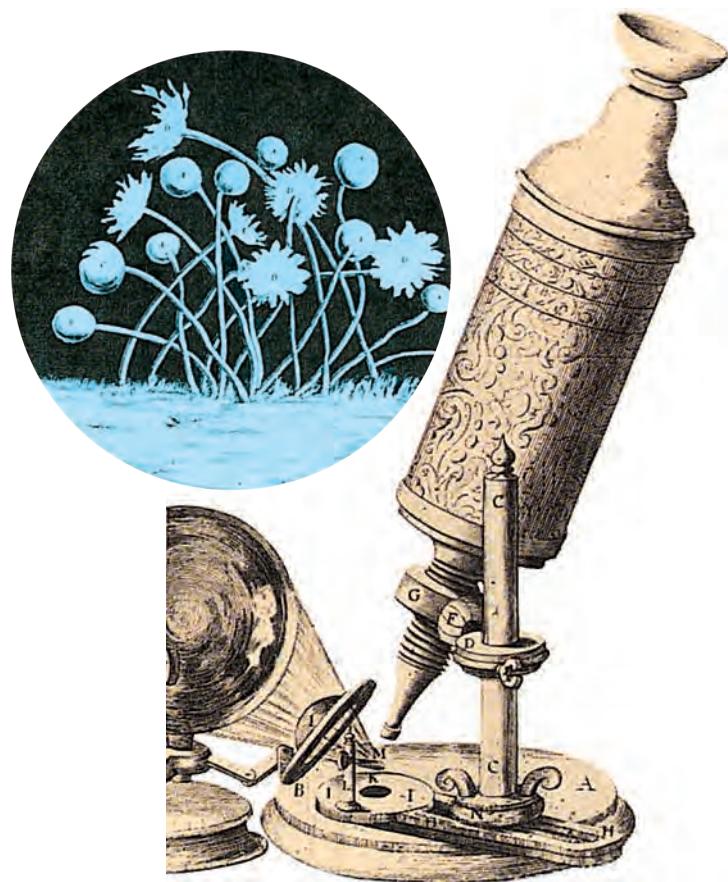

Figure 1.13 Robert Hooke and early microscopy. A drawing of the microscope used by Robert Hooke in 1664. The lens was fitted at the end of an adjustable bellows (G) and light focused on the specimen by a separate lens (I). Inset: Hooke's drawing of a bluish mold he found degrading a leather surface; the round structures contain spores of the mold.

closing flasks and tubes. These methods were later adopted by Robert Koch, the first medical microbiologist, and allowed him to make rapid progress in the isolation and characterization of several disease-causing bacteria. Cohn was also a contemporary of Louis Pasteur, and we consider the contributions of Pasteur and Koch in the next two sections.

MINIQUIZ

- What prevented the science of microbiology from developing before the era of Hooke and van Leeuwenhoek?
- What major discovery emerged from Cohn's study of heat resistance in microorganisms?

1.7 Pasteur and Spontaneous Generation

Major advances in microbiology were made in the nineteenth century because of the interest in two major questions of the day: (1) Does spontaneous generation occur? and (2) What is the nature of infectious disease? Answers to these seminal questions

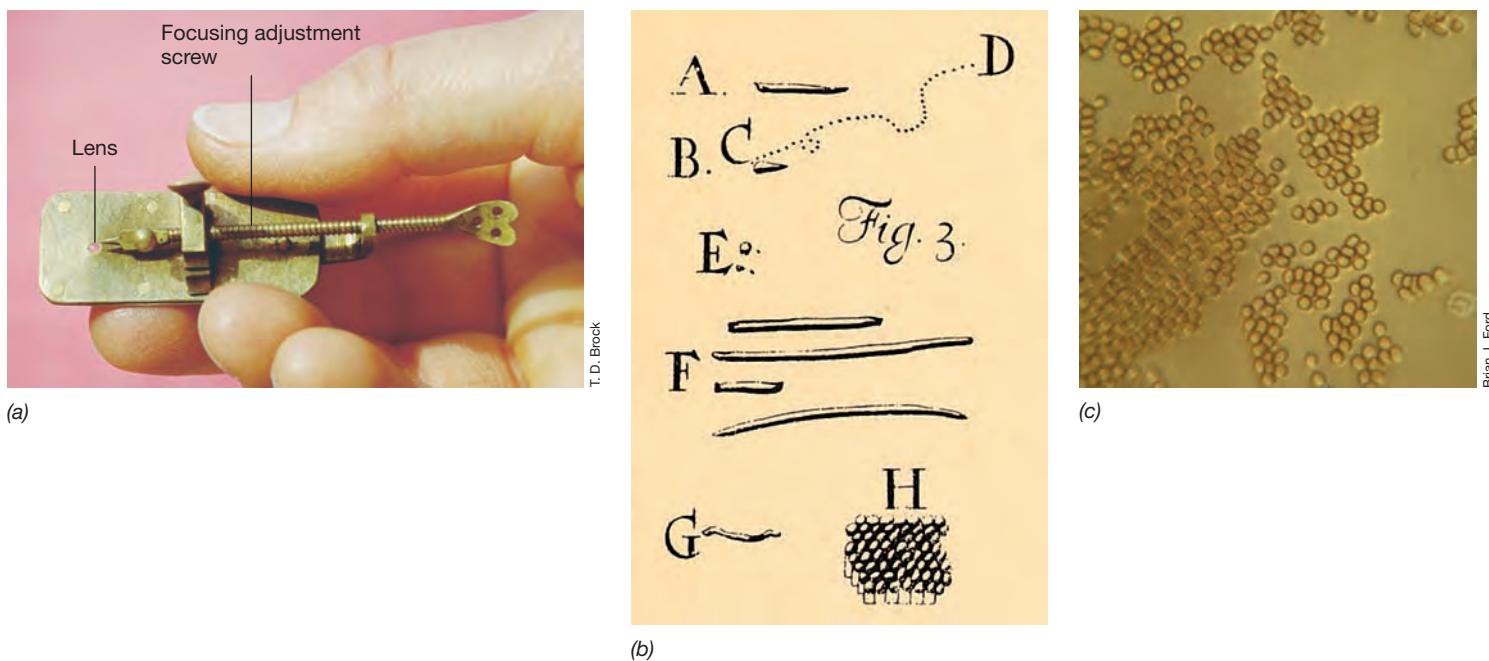

Figure 1.14 The van Leeuwenhoek microscope. (a) A replica of Antoni van Leeuwenhoek's microscope. (b) Van Leeuwenhoek's drawings of bacteria, published in 1684. Even from these simple drawings we can recognize several shapes of common bacteria: A, C, F, and G, rods; E, cocci; H, packets of cocci. (c) Photomicrograph of a human blood smear taken through a van Leeuwenhoek microscope. Red blood cells are clearly apparent.

emerged from the work of two giants in the fledgling field of microbiology: the French chemist Louis Pasteur and the German physician Robert Koch. We begin with the work of Pasteur.

Optical Isomers and Fermentations

Pasteur was a chemist by training and was one of the first to recognize the significance of *optical isomers*. A molecule is optically active if a pure solution or crystal diffracts light in only one

direction. Pasteur studied crystals of tartaric acid that he separated by hand into those that bent a beam of polarized light to the left and those that bent the beam to the right. Pasteur discovered that the mold *Aspergillus* metabolized D-tartrate, which bent light to the right, but did not metabolize its optical isomer, L-tartrate (Figure 1.16). The fact that a living organism could discriminate between optical isomers was not lost on Pasteur, and he began to suspect that some chemical activities were actually catalyzed by microorganisms and that these could be distinct from purely chemical reactions.

Pasteur initiated studies on the mechanism of the alcoholic fermentation, which in the mid-nineteenth century was assumed to be a strictly chemical process. The yeast cells in the fermenting broth were thought to be some sort of chemical substance formed by the fermentation. However, microscopic observations and other simple but rigorous experiments convinced Pasteur that the alcoholic fermentation was catalyzed by living microorganisms, the yeast cells. From these foundational studies, Pasteur began a series of classic experiments on spontaneous generation, experiments that are forever linked to his name and to the science of microbiology.

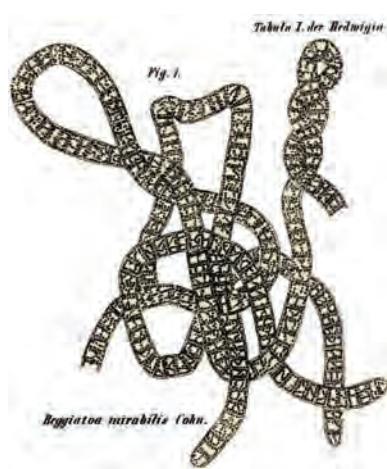

Figure 1.15 Drawing by Ferdinand Cohn of the large filamentous sulfur-oxidizing bacterium *Beggiatoa*. The small granules inside the cells consist of elemental sulfur, produced from the oxidation of hydrogen sulfide (H_2S). Cohn was the first to identify the granules as sulfur in 1866. A cell of *Beggiatoa* is about 15 μm in diameter. *Beggiatoa* moves on solid surfaces by a gliding mechanism, and in so doing, cells often twist about one another. Compare this drawing with Winogradsky's drawings of *Beggiatoa* in Figure 1.24b.

Spontaneous Generation

The concept of **spontaneous generation** had existed since biblical times and its basic tenet can be easily grasped. If food or some other perishable material is allowed to stand for some time, it putrefies. When examined microscopically, the putrefied material is teeming with microorganisms. From where do these organisms arise? Some people said they developed from seeds or germs that entered the food from air. Others said they arose spontaneously

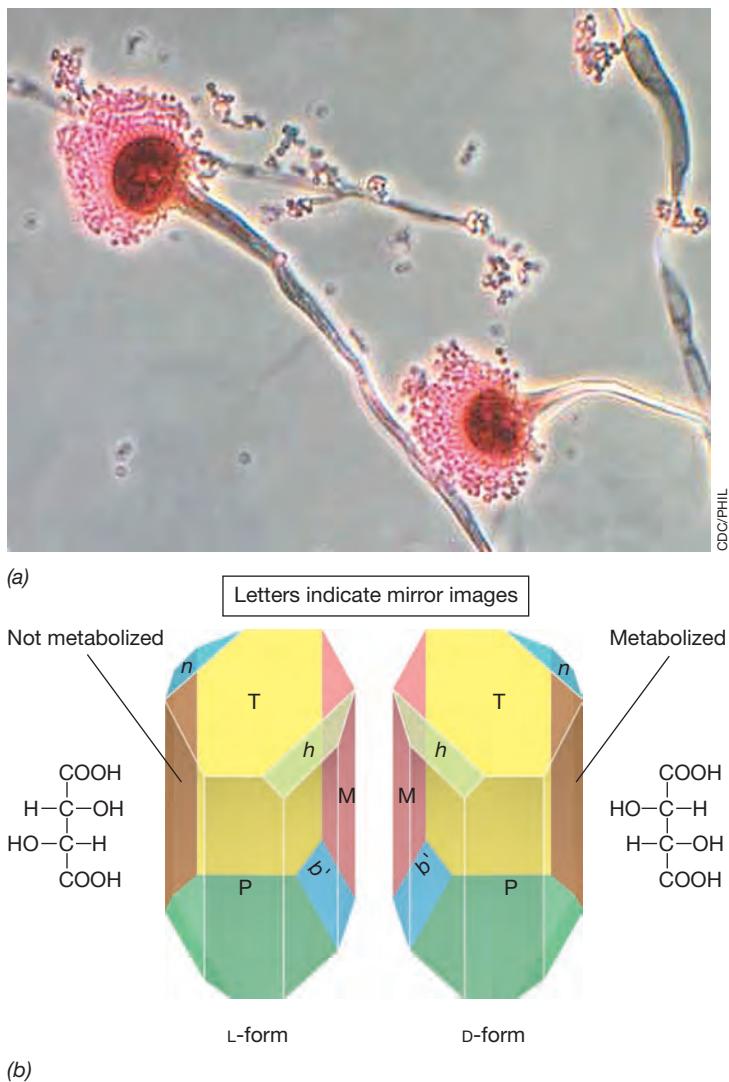

Figure 1.16 Louis Pasteur and optical isomers. (a) Light micrograph of cells of the mold *Aspergillus*. (b) Pasteur's drawings of crystals of tartaric acid. Left-handed L-form crystals bend light to the left, and right-handed crystals bend light to the right. Note that the two crystals are mirror images of one another, a hallmark of optical isomers. Pasteur found that only D-tartarate was metabolized by *Aspergillus*.

from nonliving materials, that is, by *spontaneous generation*. Who was right? Keen insight was necessary to solve this controversy, and this was exactly the kind of problem that appealed to Louis Pasteur.

Pasteur became a powerful opponent of spontaneous generation. Following his discoveries on the tartaric acid and alcoholic fermentations, Pasteur predicted that microorganisms in putrefying materials were descendants of cells that entered from the air or cells that had been on the decaying materials to begin with. Pasteur further reasoned that if food were treated in such a way as to destroy all living organisms present—that is, if it were rendered **sterile**—and then protected from further contamination, it should not putrefy.

Pasteur used heat to kill contaminating microorganisms, and he found that extensive heating of a nutrient solution followed

by sealing kept it from putrefying. Proponents of spontaneous generation criticized these experiments by declaring that “fresh air” was necessary for the phenomenon to occur. In 1864 Pasteur countered this objection simply and brilliantly by constructing a swan-necked flask, now called a *Pasteur flask* (Figure 1.17). In such a flask nutrient solutions could be heated to boiling and sterilized. However, after the flask was cooled, air could reenter but the bend in the neck prevented particulate matter (including microorganisms) from entering the nutrient solution and initiating putrefaction. Nutrient solutions in such flasks remained sterile indefinitely.

The microbial growth was observed only after particulate matter from the neck of the flask was allowed to enter the liquid in the flask (Figure 1.17c), which settled the spontaneous generation controversy forever. Pasteur's work on spontaneous generation naturally led to the development of effective sterilization procedures that were eventually standardized and carried over into both basic and applied microbiological research as well as clinical medicine. The food industry also benefited from the work of Pasteur, as his principles were quickly adapted for the preservation of milk and many other foods by heat treatment (pasteurization).

Other Accomplishments of Pasteur

Pasteur went on from his famous work on spontaneous generation to many other triumphs in microbiology and medicine. Some highlights include his development of vaccines for the diseases anthrax, fowl cholera, and rabies. Pasteur's work on rabies was his most famous success, culminating in July 1885 with the first administration of a rabies vaccine to a human, a young French boy named Joseph Meister who had been bitten by a rabid dog. In those days, a bite from a rabid animal was invariably fatal. News spread quickly of the success of Meister's vaccination, and of one administered shortly thereafter to a young shepherd boy, Jean-Baptiste Jupille (Figure 1.18a). Within a year several thousand people bitten by rabid animals had traveled to Paris to be treated with Pasteur's rabies vaccine.

Pasteur's fame from his rabies research was legendary and led the French government to establish the Pasteur Institute in Paris in 1888 (Figure 1.18b). Originally established as a clinical center for the treatment of rabies and other contagious diseases, the Pasteur Institute today is a major biomedical research center focused on antiserum and vaccine research and production. The medical and veterinary breakthroughs of Pasteur were not only highly significant in their own right but helped solidify the concept of the germ theory of disease, whose principles were being developed at about the same time by a second giant of this era, Robert Koch.

MINIQUIZ

- Define the term **sterile**. How did Pasteur's experiments using swan-necked flasks defeat the theory of spontaneous generation?
- Besides ending the controversy over spontaneous generation, what other accomplishments do we credit to Pasteur?

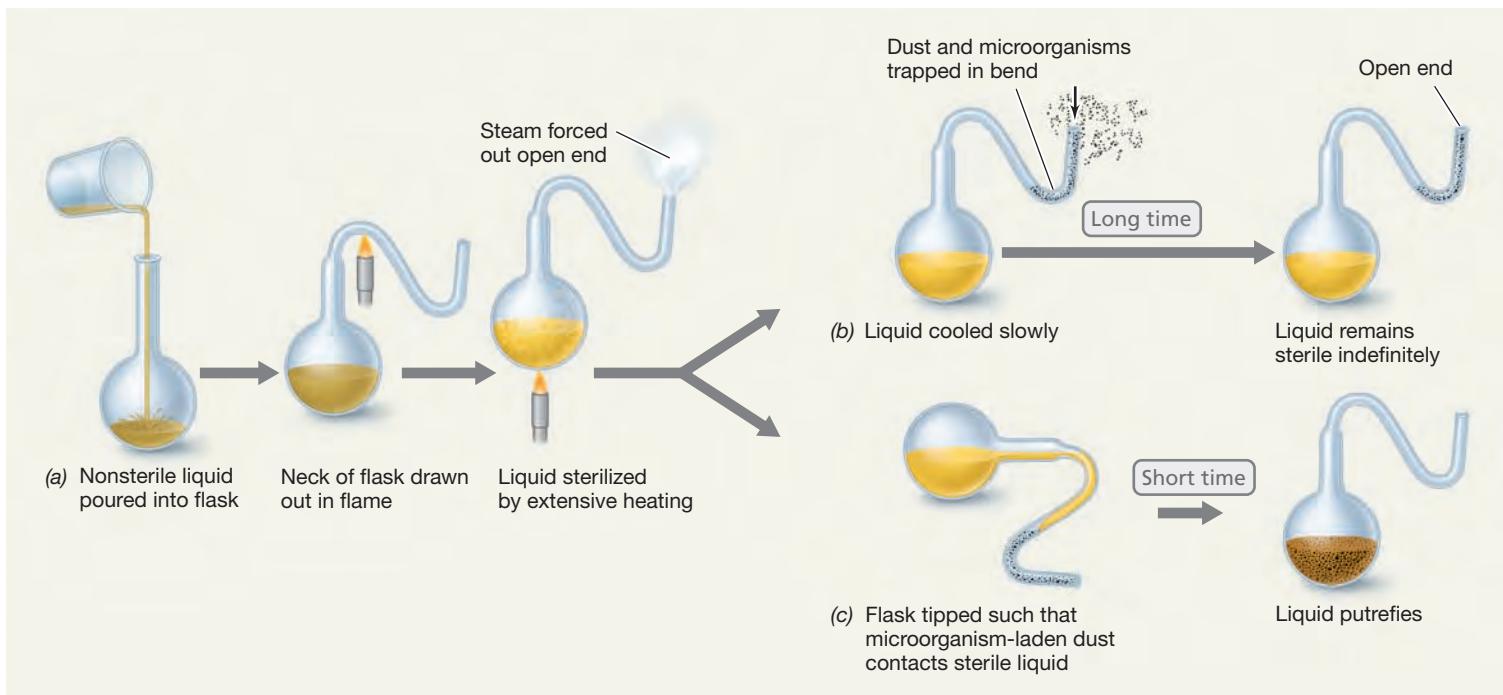

Figure 1.17 The defeat of spontaneous generation: Pasteur's swan-necked flask experiment. In (c) the liquid putrefies because microorganisms enter with the dust. The bend in the flask allowed air to enter (a key objection of Pasteur's sealed flasks) but prevented microorganisms from entering.

1.8 Koch, Infectious Disease, and Pure Cultures

Proof that some microorganisms cause disease provided the greatest impetus for the development of microbiology as an independent biological science. Even as early as the sixteenth century it was thought that something that induced disease could be transmitted from a diseased person to a healthy person. After the discovery of microorganisms, it was widely believed that they were responsible, but definitive proof was lacking. Improvements in sanitation by the Hungarian physician Ignaz Semmelweis (attempts to control hospital-associated infections, 1847) and the British physician Joseph Lister (introduction of aseptic techniques for surgeries, 1867) provided indirect evidence for the importance of microorganisms in causing human diseases. But it was not until the work of the German physician Robert Koch (1843–1910) (Figure 1.19) that the concept of infectious disease was developed and given direct experimental support.

The Germ Theory of Disease and Koch's Postulates

In his early work Koch studied anthrax, a disease of cattle and occasionally of humans. Anthrax is caused by an endospore-forming bacterium called *Bacillus anthracis*. By careful microscopy and staining, Koch established that the bacteria were always present in the blood of an animal that was succumbing to the disease. However, Koch reasoned that the mere *association* of

the bacterium with the disease was not actual proof of *cause and effect*, and he seized the opportunity to study cause and effect experimentally using anthrax and laboratory animals. The results of this study formed the standard by which infectious diseases have been studied ever since.

Koch used mice as experimental animals. Using appropriate controls, Koch demonstrated that when a small drop of blood from a mouse with anthrax was injected into a healthy mouse, the latter quickly developed anthrax. He took blood from this second animal, injected it into another, and again observed the characteristic disease symptoms. However, Koch carried this experiment a critically important step further. He discovered that the anthrax bacteria could be grown in nutrient fluids *outside the host* and that even after many transfers in laboratory culture, the bacteria still caused the disease when inoculated into a healthy animal.

On the basis of these experiments and others on the causative agent of tuberculosis, Koch formulated a set of rigorous criteria, now known as **Koch's postulates**, for definitively linking cause and effect in an infectious disease. Koch's postulates, summarized in Figure 1.20, stressed the importance of *laboratory culture* of the putative infectious agent followed by introduction of the suspected agent into virgin animals and recovery of the pathogen from diseased or dead animals. With these postulates as a guide, Koch, his students, and those that followed them discovered the causative agents of most of the important infectious diseases of humans and domestic animals. These discoveries also led to the

Today this structure, built for Pasteur by the French government, houses a museum that displays some of the original swan-necked flasks used in his experiments and a chapel containing Pasteur's crypt.

development of successful treatments for the prevention and cure of many of these diseases, thereby greatly improving the scientific basis of clinical medicine and human health and welfare (Figure 1.8).

The modern genomic era has also weighed in on the question of cause and effect in infectious diseases by developing molecular methods for identifying potential pathogens. Using these methods, a pathogen can be identified even if it cannot be cultured, or even if the pathogen itself is long since dead (see Explore the Microbial World, “The Black Death Decoded”). Such methods have revolutionized infectious disease diagnosis and treatment.

Koch, Pure Cultures, and Microbial Taxonomy

The second of Koch's postulates states that the suspected pathogen must be isolated and grown away from other microorganisms

Figure 1.19 Robert Koch. The German physician and microbiologist is credited with founding medical microbiology and formulating his famous postulates.

in laboratory culture (Figure 1.20); in microbiology we say that such a culture is *pure*. To accomplish this important goal, Koch and his associates developed several simple but ingenious methods of obtaining and growing bacteria in **pure culture**, and many of these methods are still used today.

Koch started by using natural surfaces such as a potato slice to obtain pure cultures, but quickly developed more reliable and reproducible growth media employing liquid nutrient solutions solidified with gelatin, and later with agar, an algal polysaccharide with excellent properties for this purpose. Along with his associate Walther Hesse, Koch observed that when a solid surface was incubated in air, masses of bacterial cells called *colonies* developed, each having a characteristic shape and color (Figure 1.21). He inferred that each colony had arisen from a single bacterial cell that had grown to yield the mass of cells. Koch reasoned that each colony harbored a population of identical cells, that is, a *pure culture*, and Koch quickly realized that solid media provided an easy way to obtain pure cultures. Richard Petri, another associate of Koch's, developed the transparent double-sided “Petri dish” in 1887 and this quickly became the standard tool for obtaining pure cultures.

KOCH'S POSTULATES

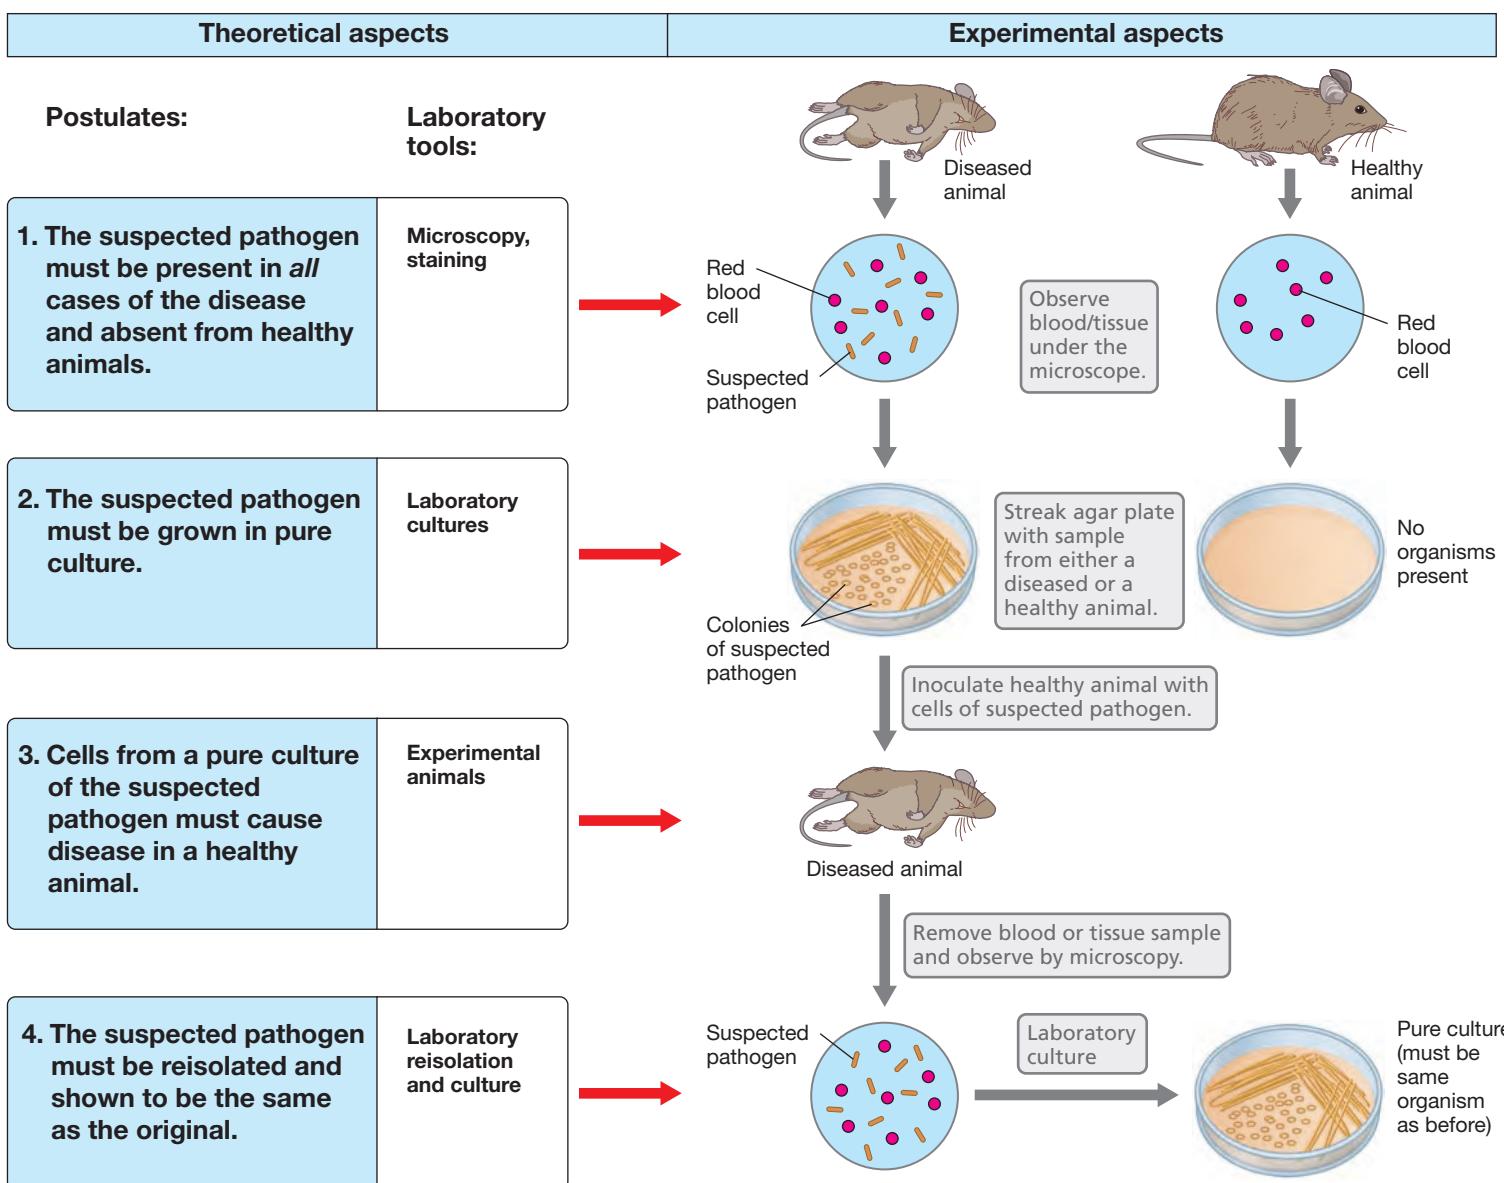

Figure 1.20 Koch's postulates for proving cause and effect in infectious diseases. Note that following isolation of a pure culture of the suspected pathogen, the cultured organism must both initiate the disease and be recovered from the diseased animal. Establishing the correct conditions for growing the pathogen is essential; otherwise it will be missed.

Koch was keenly aware of the implications his pure culture methods had for classifying microorganisms. He observed that colonies that differed in color and size (Figure 1.21) bred true and that cells from different colonies typically differed in size and shape and often in their nutrient requirements as well. Koch realized that these differences were analogous to the criteria taxonomists had established for the classification of larger organisms, such as plant and animal species, and he suggested that the different types of bacteria should be considered as “species, varieties, forms, or other suitable designation.” Such insightful thinking was important for the rapid acceptance of microbiology as a new biological science, rooted as biology was in classification during Koch’s era.

Koch and Tuberculosis

Koch's crowning scientific accomplishment was his discovery of the causative agent of tuberculosis. At the time Koch began this work (1881), one-seventh of all reported human deaths were caused by tuberculosis (Figure 1.8). There was a strong suspicion that tuberculosis was a contagious disease, but the suspected agent had never been seen, either in diseased tissues or in culture. Following his successful studies of anthrax, Koch set out to demonstrate the cause of tuberculosis, and to this end he brought together all of the methods he had so carefully developed in his previous studies with anthrax: microscopy, staining, pure culture isolation, and an animal model system (Figure 1.20).

EXPLORE THE MICROBIAL WORLD

The Black Death Decoded

It is sometimes impossible to satisfy Koch's postulates, and in such cases, genomics may be able to link cause with effect in a different way. Thousands of microbial genomes have been sequenced and have revealed that pathogens often contain "signature" genes that can be used to positively identify them in a clinical specimen without the need for laboratory culture. This technology has greatly improved both the rapidity and accuracy of disease diagnoses. Although such genomic methods have been used primarily to diagnose disease in sick but still living patients, the technology has also been used to solve ancient medical mysteries where both sick patients and a recoverable pathogen are long gone. An excellent example is research that revealed the causative agent of the "Black Death."

The Black Death swept through Europe in the middle of the fourteenth century from origins near the Crimean Peninsula (present-day Ukraine). It has long been thought that the Black Death was a massive outbreak of bubonic plague, a typically fatal disease whose causative agent, *Yersinia pestis* (Figure 1), was discovered by the Swiss microbiologist Alexandre Yersin in 1894 and later linked to the disease through animal model studies. However, in the case of the Black Death, the connection to *Y. pestis* was uncertain for at least two major reasons. First, this deadly and widespread disease outbreak (the Black Death killed nearly one-third of the European

population) occurred 660 years ago, and second, historical descriptions of victims' symptoms were often ambiguous, leaving open the possibility that other pathogens could have been responsible. Genomic studies confirmed that the Black Death was a severe outbreak of plague, and the published study¹ has become a model for how genomics can contribute to disease sleuthing.

How was the Black Death–plague link confirmed? At the height of the Black Death outbreak in the year 1349, a new cemetery was dug in East Smithfield, England. According to burial records, the cemetery was prepared specifically to inter Black Death victims, and in a little more than a year, the graveyard was filled with nearly 2500 bodies. No further burials occurred. A team of scientists examined corpses removed from the East Smithfield cemetery knowing in hindsight that all of the bodies were of Black Death victims. Because of this, the scientists could rule out other causes of death.¹

Bubonic plague is an infection of the lymphatic system caused by cells of *Y. pestis* transmitted to a person from the bite of an infected flea. The bacteria multiply in the lymph nodes, forming painful swellings called *bubo*es, and from there cells travel throughout the body and cause tissues to hemorrhage and then blacken (thus the term "Black Death") (Figure 2). Using tooth and bone samples from corpses disinterred from East Smithfield and employing a method for *Y. pestis* "DNA capture" developed from previous genomic studies of the pathogen, the international research team¹ fished out enough ancient DNA to reconstruct the genome of the bacterium that caused the Black Death. By comparing this genome with that from isolates of *Y. pestis* obtained from recent localized outbreaks, the mystery behind this devastating medieval disease was solved: The Black Death was indeed bubonic plague.

Further analyses of the Black Death *Y. pestis* genome showed that the Black Death strain was the ancestor of all modern *Y. pestis* strains and that the genomes of modern strains have evolved very little from the Black Death strain during the intervening 660 years. This points to the heightened importance of other factors—extremely poor sanitation, an influx of rats (rats harbor

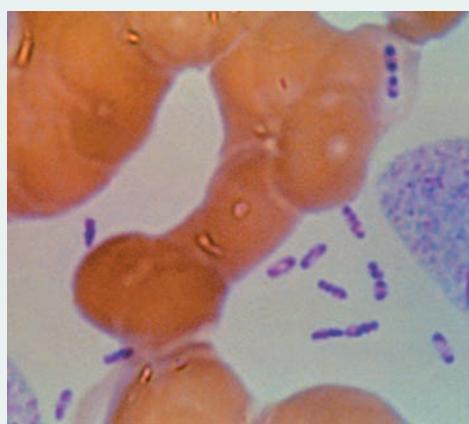

Figure 1 Light micrograph of cells of the bacterium *Yersinia pestis* in a blood smear. This bacterium is the causative agent of bubonic plague.

Figure 2 Symptoms of bubonic plague. Blackened skin on the toes of this plague victim comes from internal bleeding (hemorrhaging) due to systemic infection with *Yersinia pestis*.

the fleas that carry *Y. pestis*), and poor nutrition—in intensifying the Black Death outbreak compared with less pervasive waves of plague that visited Europe in earlier times. Indeed, the Black Death was the most devastating plague pandemic the world has ever seen. And because the Black Death touched such a wide geographic area, the Black Death strain of *Y. pestis* was able to infect a very large population of fleas and rats. From these sources, this ferocious pathogen became firmly entrenched and has periodically reemerged to trigger localized outbreaks of bubonic plague, all of which can be traced back to the Black Death bacterium that took its gruesome toll more than half a century ago.

In the United States, a handful of plague cases are observed each year. However, plague today carries two concerns. In addition to dealing with the natural disease, we must also be on guard against the use of *Y. pestis* as an agent of bioterrorism!

¹Bos, K.I., et al. 2011. A draft genome of *Yersina pestis* from victims of the Black Death. *Nature* 478: 506–510.

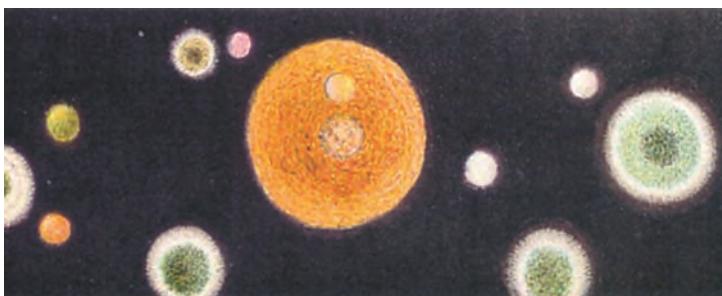

Figure 1.21 A hand-colored photograph taken by Walther Hesse of colonies formed on agar. The colonies include those of molds and bacteria obtained during Hesse's studies of the microbial content of air in Berlin, Germany, in 1882. From Hesse, W. 1884. "Ueber quantitative Bestimmung der in der Luft enthaltenen Mikroorganismen." *Mittheilungen aus dem Kaiserlichen Gesundheitsamte*. 2: 182–207.

The bacterium that causes tuberculosis, *Mycobacterium tuberculosis*, is very difficult to stain because *M. tuberculosis* cells contain large amounts of a waxlike lipid in their cell walls. Nevertheless, Koch devised a staining procedure for *M. tuberculosis* cells in lung tissue samples. Using this method, he observed the blue, rod-shaped cells of *M. tuberculosis* in tubercular tissues but not in healthy tissues (Figure 1.22). Obtaining cultures of *M. tuberculosis* was not easy, but eventually Koch succeeded in growing colonies of this organism on a solidified nutrient solution containing blood serum. Under the best of conditions, *M. tuberculosis* grows slowly in culture, but Koch's persistence and patience eventually led to pure cultures of this organism from human and animal sources.

From this point Koch used his postulates (Figure 1.20) to obtain definitive proof that the organism he had isolated was the cause

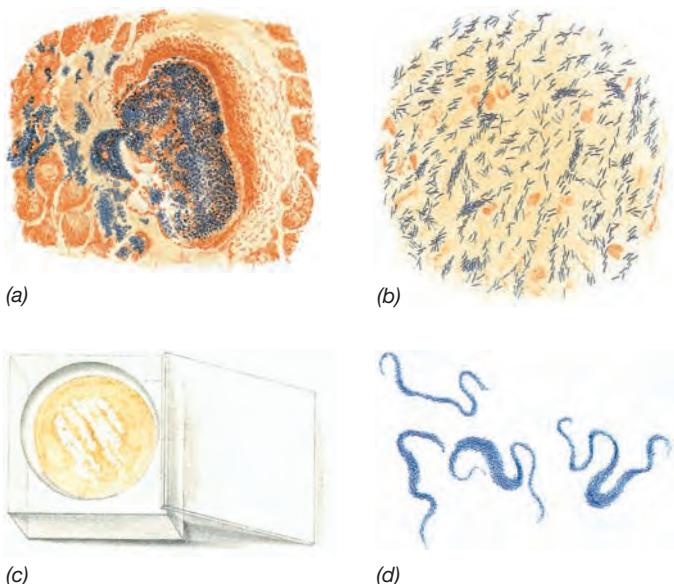

Figure 1.22 Robert Koch's drawings of *Mycobacterium tuberculosis*. (a) Section through infected lung tissue showing cells of *M. tuberculosis* (blue). (b) *M. tuberculosis* cells in a sputum sample from a tubercular patient. (c) Growth of *M. tuberculosis* on a glass plate of coagulated blood serum stored inside a glass box to prevent contamination. (d) *M. tuberculosis* cells taken from the plate in part c and observed microscopically; cells appear as long cordlike forms. Original drawings from Koch, R. 1884. of the disease tuberculosis. Guinea pigs can be readily infected with *M. tuberculosis* and eventually succumb to systemic tuberculosis. Koch showed that tuberculous guinea pigs contained masses of *M. tuberculosis* cells in their lungs and that pure cultures obtained from such animals transmitted the disease to healthy animals. In this way, Koch successfully satisfied all four of his postulates, and the cause of tuberculosis was understood. Koch announced his discovery of the cause of tuberculosis in 1882, and for this accomplishment he was awarded the 1905 Nobel Prize for Physiology or Medicine. Koch had many other triumphs in the growing field of infectious diseases, including the discovery of the causative agent of cholera (the bacterium *Vibrio cholerae*) and developing methods to diagnose infection with *M. tuberculosis* (the tuberculin skin test).

MINIQUIZ

- How do Koch's postulates ensure that cause and effect of a given disease are clearly differentiated?
- What advantages do solid media offer for the isolation of microorganisms?
- What is a pure culture?

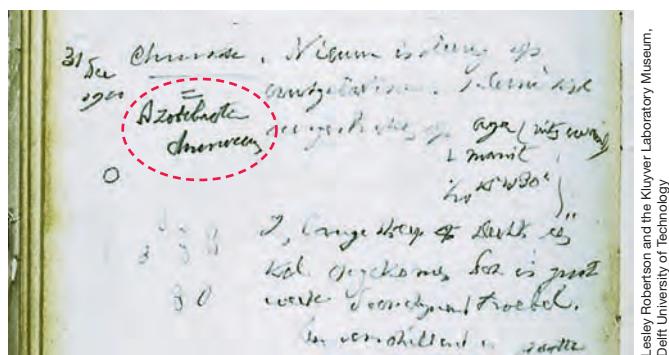

1.9 The Rise of Microbial Diversity

As microbiology entered the twentieth century, its initial focus on basic principles, methods, and medical aspects broadened to include studies of the microbial diversity of soil and water and the metabolic processes that microorganisms carried out in these habitats. Major contributors in this era included the Dutchman Martinus Beijerinck and the Russian Sergei Winogradsky.

Martinus Beijerinck and the Enrichment Culture Technique

Martinus Beijerinck (1851–1931) was a professor at the Delft Polytechnic School in Holland and was originally trained in botany, so he began his career in microbiology studying plants. Beijerinck's greatest contribution to the field of microbiology was his clear formulation of the **enrichment culture technique**. In enrichment cultures, microorganisms are isolated from natural samples using highly selective nutrient and incubation conditions to favor a particular metabolic group of organisms. Beijerinck's skill with the enrichment method was readily apparent when, following Winogradsky's discovery of the process of nitrogen fixation, he isolated the aerobic nitrogen-fixing bacterium *Azotobacter* from soil (Figure 1.23). Nitrogen-fixing bacteria can use atmospheric nitrogen (N_2) to make important nitrogenous substances in the cell, such as amino acids to make proteins and nucleotides to make nucleic acids.

Using the enrichment culture technique, Beijerinck isolated the first pure cultures of many soil and aquatic microorganisms, including sulfate-reducing and sulfur-oxidizing bacteria, nitrogen-fixing root nodule bacteria (Figure 1.9), lactic acid bacteria, green algae, various anaerobic bacteria, and many others. In addition, in his classic studies of "mosaic disease" of tobacco, Beijerinck used selective filters to show that the infectious agent in this disease (a virus) was smaller than a bacterium and that it

Beijerinck dated 31 December 1900 describing the aerobic nitrogen-fixing bacterium *Azotobacter chroococcum* (name circled in red). Compare Beijerinck's drawings of pairs of *A. chroococcum* cells with the photomicrograph of cells of *Azotobacter* in Figure 14.32. (b) A painting by M. Beijerinck's sister, Henriëtte Beijerinck, showing cells of *Azotobacter chroococcum*. Beijerinck used such paintings to illustrate his lectures.

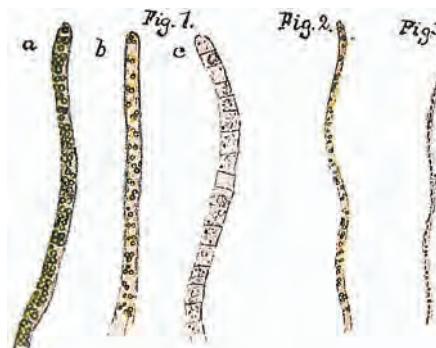

somehow became incorporated into cells of the living host plant. In this insightful work, Beijerinck not only described the first virus, but also the basic principles of virology, which we present in Chapter 8.

Sergei Winogradsky, Chemolithotrophy, and Nitrogen Fixation

Like Beijerinck, Sergei Winogradsky (1856–1953) was interested in the bacterial diversity of soils and waters and was highly successful in isolating several notable bacteria from natural samples. Winogradsky was particularly interested in bacteria that cycle nitrogen and sulfur compounds, such as the nitrifying bacteria and the sulfur bacteria (Figure 1.24). He showed that these bacteria catalyze specific chemical transformations in nature and proposed the important concept of **chemolithotrophy**, the oxidation of *inorganic* compounds to yield energy. Winogradsky further

(a)

(b)

Figure 1.24 Sulfur bacteria. The original drawings were made by Sergei Winogradsky in the late 1880s and then copied and hand-colored by his wife Hélène. (a) Purple sulfur phototrophic bacteria. Figures 3 and 4 show cells of *Chromatium okenii* (compare with photomicrographs of *C. okenii* in Figures 1.5a and 1.7a). (b) *Beggiatoa*, a sulfur chemolithotroph (compare with Figures 1.15 and 14.27).

showed that these organisms, which he called *chemolithotrophs* (meaning, literally, “earth eaters”), are widespread in nature and obtain their carbon from CO₂. Winogradsky thus revealed that, like photosynthetic organisms, chemolithotrophic bacteria are *autotrophs*.

Winogradsky performed the first isolation of a nitrogen-fixing bacterium, the anaerobe *Clostridium pasteurianum*, and as just mentioned, Beijerinck used this discovery to guide his isolation of *aerobic* nitrogen-fixing bacteria years later (Figure 1.23). Winogradsky lived to be almost 100, publishing many scientific papers and a major monograph, *Microbiologie du Sol* (*Soil Microbiology*). This work, a milestone in microbiology, contains drawings of many of the organisms Winogradsky studied during his lengthy career (Figure 1.24).

MINIQUIZ

- What is meant by the term “enrichment culture”?
- What is meant by the term “chemolithotrophy”? In what way are chemolithotrophs like plants?

1.10 Modern Microbiology and Genomics

In the twentieth century the field of microbiology developed quickly, as many new laboratory tools became available and the science matured to spawn new subdisciplines. Most of these subdisciplines had both discovery (basic) and problem-solving (applied) components (Table 1.3). In the mid-twentieth century an exciting new emphasis emerged in microbiology with studies of the genetic properties of microorganisms. From these roots in microbial genetics, the fields of molecular biology, genetic engineering, and genomics developed. These molecular subdisciplines have revolutionized the life sciences and spawned new generations of experimental tools to attack the most compelling and complex problems in biology.

Many advances in microbiology today are fueled by **genomics**, the mapping, sequencing, and analysis of genomes. New methods for DNA sequencing and improved computational capacities have unleashed huge amounts of genomic data for attacking problems in medicine, agriculture, and the environment. The fast-paced field of genomics has itself spawned several highly focused new subdisciplines such as *transcriptomics*, *proteomics*, and *metabolomics*; these explore the patterns of RNA, protein,

and metabolic pathway expression in cells, respectively. The concepts of genomics, transcriptomics, proteomics, metabolomics, and other “omics” are all presented in Chapter 6.

Genomics today is very close to defining the minimum complement of genes necessary for a cell to be alive. With such information, microbiologists should be able to define the biochemical prerequisites for life in precise genetic terms. When that day arrives, and it is likely not far off, the laboratory creation of a living cell from nonliving components—in essence, spontaneous generation—should be possible. Obviously, much exciting science is in store for the next generation of microbiologists, and your continued journey through this book will position you to both understand it and appreciate it. Good luck, and welcome to the exciting field of microbiology!

MINIQUIZ

- Identify the subdiscipline of microbiology that deals with each of these topics: metabolism, enzymology, nucleic acid and protein synthesis, microorganisms and their natural environments, microbial classification, inheritance of characteristics, gene complements of different organisms.

Table 1.3 The major subdisciplines of microbiology

Subdiscipline	Focus
I. Basic emphases^a	
Microbial physiology	Nutrition, metabolism
Microbial genetics	Genes, heredity, and genetic variation
Microbial biochemistry	Enzymes and chemical reactions in cells
Microbial systematics	Classification and nomenclature
Virology	Viruses and subviral particles
Molecular biology	Nucleic acids and protein
Microbial ecology	Microbial diversity and activity in natural habitats; biogeochemistry
Genomics	Genome sequencing and comparative analyses
II. Applied emphases^a	
Medical microbiology	Infectious disease
Immunology	Immune systems
Agricultural/soil microbiology	Microbial diversity and processes in soil
Industrial microbiology	Large-scale production of antibiotics, alcohol, and other chemicals
Biotechnology	Production of human proteins by genetically engineered microorganisms
Aquatic microbiology	Microbial processes in waters and wastewaters, drinking water safety

^aNone of these subdisciplines are devoted entirely to basic science or applied science. However, the subdisciplines listed in I tend to be more focused on discovery and those in II more focused on solving problems or making commercial products.

BIG IDEAS

1.1 • Microorganisms are single-celled microscopic organisms that are essential for the well-being and functioning of other life forms and the planet. As a science, microbiology has its basic and applied components, which generate new knowledge and solve problems, respectively.

1.2 • Like houses, cells are constructed of many parts, all of which interact to yield the intact living organism. Prokaryotic and eukaryotic cells differ in cellular architecture, and an organism's characteristics are defined by its complement of genes—its genome. Many activities are carried out by all cells, including metabolism, growth, and evolution.

1.3 • Diverse microbial populations were widespread on Earth for billions of years before higher organisms appeared, and cyanobacteria in particular were important because they oxygenated the atmosphere. *Bacteria*, *Archaea*, and *Eukarya* are the major phylogenetic lineages (domains) of cells.

1.4 • Microorganisms live in populations that interact with other populations to form microbial communities. The activities of microorganisms in microbial communities can greatly affect the chemical and physical properties of their habitats. Microbial biomass on Earth exceeds that of higher organisms, although most microbial cells actually reside in the terrestrial and oceanic deep subsurface.

1.5 • Microorganisms can be both beneficial and harmful to humans, although many more microorganisms are beneficial (or even essential) than are harmful. Agriculture, food,

energy, and the environment are all impacted in major ways by microorganisms.

1.6 • Robert Hooke was the first to describe microorganisms, and Antoni van Leeuwenhoek was the first to describe bacteria. Ferdinand Cohn founded the field of bacteriology and discovered bacterial endospores.

1.7 • Louis Pasteur devised ingenious experiments proving that living organisms do not arise spontaneously from nonliving matter. Pasteur developed many concepts and techniques central to the science of microbiology, including sterilization, and developed a number of key vaccines for humans and other animals.

1.8 • Robert Koch developed a set of criteria called Koch's postulates for linking cause and effect in infectious diseases. Koch also developed the first reliable and reproducible means for obtaining and maintaining microorganisms in pure culture.

1.9 • Martinus Beijerinck and Sergei Winogradsky explored soil and water for microorganisms that carry out important natural processes, such as nutrient cycling and the biodegradation of particular substances. Out of their work came the enrichment culture technique and the concepts of chemolithotrophy and nitrogen fixation.

1.10 • In the middle to latter part of the twentieth century, various basic and applied subdisciplines of microbiology emerged. These paved the way for the current era of molecular microbiology, with genomic sciences currently on center stage.

KEY TERMS

Cell wall a rigid layer present outside the cytoplasmic membrane; it confers structural strength on the cell and prevents osmotic lysis

Chemolithotrophy a form of metabolism in which energy is generated from the oxidation of inorganic compounds

Communication interactions between cells using chemical signals

Cytoplasm the fluid portion of a cell, bounded by the cytoplasmic membrane

Cytoplasmic membrane a semipermeable barrier that separates the cell interior (cytoplasm) from the environment

Differentiation modification of cellular components to form a new structure, such as a spore

Domain one of the three main evolutionary lineages of cells: the *Bacteria*, the *Archaea*, and the *Eukarya*

Ecosystem organisms plus their nonliving environment

Enrichment culture technique a method for isolating specific microorganisms from nature using specific culture media and incubation conditions

Enzyme a protein (or in some cases an RNA) catalyst that functions to speed up chemical reactions

Eukaryote a cell having a membrane-enclosed nucleus and various other membrane-enclosed organelles; *Eukarya*

Evolution descent with modification leading to new forms or species

Extremophiles microorganisms that inhabit environments unsuitable for higher life forms, such as environments that are extremely hot or cold, or environments that are acidic, alkaline, or extremely salty

Genetic exchange the transfer of genes or the acceptance of genes between prokaryotic cells

Genome an organism's full complement of genes

Genomics the mapping, sequencing, and analysis of genomes

Growth in microbiology, an increase in cell number with time

Habitat the environment in which a microbial population resides

Koch's postulates a set of criteria for proving that a given microorganism causes a given disease

Macromolecules a polymer of monomeric units that includes the proteins, nucleic acids, polysaccharides, and lipids

Metabolism all biochemical reactions in a cell

Microbial community two or more populations of cells that coexist and interact in a habitat

Microbial ecology the study of microorganisms in their natural environments

Microorganism a microscopic organism consisting of a single cell or cell cluster or a virus

Motility the movement of cells by some form of self-propulsion

Nucleoid the aggregated mass of DNA that makes up the chromosome of prokaryotic cells

Nucleus a membrane-enclosed structure in eukaryotic cells that contains the cell's DNA genome

Organelles a bilayer-membrane-enclosed structure such as the mitochondrion, found in eukaryotic cells

Pathogen a disease-causing microorganism

Prokaryote a cell that lacks a membrane-enclosed nucleus and other organelles; *Bacteria* or *Archaea*

Pure culture a culture containing a single kind of microorganism

Ribosomes a structure composed of RNAs and proteins upon which new proteins are made

Spontaneous generation the hypothesis that living organisms can originate from nonliving matter

Sterile free of all living organisms (cells) and viruses

REVIEW QUESTIONS

- What are the two major themes of microbiology and how do they differ in their focus? (Section 1.1)
- How can prokaryotic and eukaryotic cells be distinguished? List the major activities carried out by cells, and in each case, describe why the activity occurs. (Section 1.2)
- Why did the evolution of cyanobacteria change Earth forever? How many domains of life are there and how are they related? (Section 1.3)
- What is an ecosystem? What effects can microorganisms have on their ecosystems? (Section 1.4)
- How would you convince a friend that microorganisms are much more than just agents of disease? (Section 1.5)
- For what contributions are Robert Hooke and Antoni van Leeuwenhoek most remembered in microbiology? What time period were these scientists active? (Section 1.6)
- Explain the principle behind the Pasteur flask in studies on spontaneous generation. Why were the results of this experiment inconsistent with the theory of spontaneous generation? (Section 1.7)
- What is a pure culture and how can one be obtained? Why are pure cultures important for medical microbiology and other areas of microbiology? (Section 1.8)
- What are Koch's postulates and how did they influence the development of microbiology? Why are Koch's postulates still relevant today? (Section 1.8)
- What were the major microbiological interests of Martinus Beijerinck and Sergei Winogradsky? It can be said that both men discovered nitrogen fixation. Explain. (Section 1.9)
- Select one major subdiscipline of microbiology from each of the two major categories of Table 1.3. Why do you think the subdiscipline is "basic" or "applied"? (Section 1.10)

APPLICATION QUESTIONS

- Pasteur's experiments on spontaneous generation contributed to the methodology of microbiology, understanding of the origin of life, and techniques for the preservation of food. Explain briefly how Pasteur's experiments affected each of these topics.
- Describe the lines of proof Robert Koch used to definitively associate the bacterium *Mycobacterium tuberculosis* with the disease tuberculosis. How would his proof have been flawed if any of the tools he developed for studying bacterial diseases had not been available for his study of tuberculosis?
- Imagine that all microorganisms suddenly disappeared from Earth. From what you have learned in this chapter, why do you think that animals would eventually disappear from Earth? Why would plants disappear? By contrast, if all higher organisms suddenly disappeared, what in Figure 1.4a tells you that a similar fate would not befall microorganisms?

2 • Microbial Cell Structure and Function

microbiologynow

Archaeal Tortoise and Hare

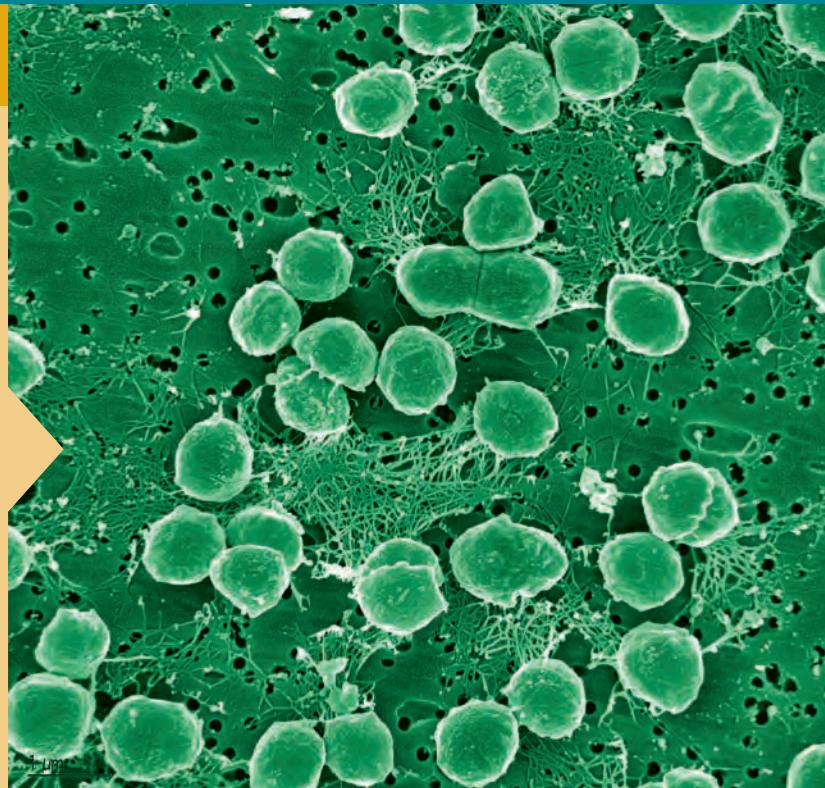

Motility is important for microorganisms because the ability to move allows cells to explore new habitats and exploit their resources. Motility has been studied for over 50 years in the flagellated bacterium *Escherichia coli*. It is with *E. coli* that scientists first discovered that the bacterial flagellum functions by rotating and that when speed is expressed in terms of body lengths traveled per second, swimming *E. coli* cells are actually moving faster than the fastest animals.

Studies of the archaeon *Halobacterium* showed that its flagella also rotate but that they were thinner than their bacterial counterparts and were composed of a protein distinct from flagellin, the protein that makes up bacterial flagella. Moreover, observations of swimming cells showed that *Halobacterium* was a slowpoke, moving at less than one-tenth the speed of *E. coli*. This raised the interesting question of whether this was true of all Archaea; are they naturally joggers instead of sprinters?

Microbiologists recently zeroed in on the movements of swimming Archaea and showed that *Halobacterium* was the slowest of all species examined.¹ By contrast, cells of the archaeon *Methanocaldococcus* (cells with flagellar tufts in photo) swam nearly 50 times faster than cells of *Halobacterium* and 10 times faster than cells of *E. coli*. Astonishingly, *Methanocaldococcus* moves at nearly 500 cell lengths per second, which makes it the fastest organism on Earth!

The thin diameter of the archaeal flagellum obviously does not mandate a slow swimming speed as some had predicted from the *Halobacterium* work. Instead, swimming speeds of Archaea can and do vary greatly.¹ Indeed, the existence of both a “tortoise” and a “hare” within the Archaea shows that there is still much to learn about the structure and function of microbial cells.

I • Microscopy

Historically, the science of microbiology has taken its greatest leaps forward as new tools for the study of microorganisms are developed and old tools improve. The microscope is the microbiologist's oldest and most basic tool for studying microbial structure. Many types of microscopy are used and some are extremely powerful. So as a prelude to our study of cell structure, let's first take a look at some common tools for visualizing cells with a goal of understanding how they work and what they can tell us.

2.1 Discovering Cell Structure: Light Microscopy

To see microorganisms, one needs a microscope of some sort, either a *light* microscope or an *electron* microscope. In general, light microscopes are used to examine cells at relatively low magnifications, and electron microscopes are used to examine cells and cell structures at very high magnification.

All microscopes employ lenses that magnify the image. Magnification, however, is not the limiting factor in our ability to see small objects. It is instead **resolution**—the ability to distinguish two adjacent objects as distinct and separate—that governs our ability to see the very small. Although magnification can be increased virtually without limit, resolution cannot, because resolution is a function of the physical properties of light.

We begin with the light microscope, for which the limits of resolution are about $0.2 \text{ } \mu\text{m}$ (μm is the abbreviation for micrometer, 10^{-6} m). We then proceed to the electron microscope, for which resolution is considerably greater.

The Compound Light Microscope

The light microscope uses visible light to illuminate cell structures. Several types of light microscopes are used in microbiology: *bright-field*, *phase-contrast*, *differential interference contrast*, *dark-field*, and *fluorescence*.

With the bright-field microscope, specimens are visualized because of the slight differences in contrast that exist between them and their surroundings, differences that arise because cells absorb or scatter light to varying degrees. The modern compound light microscope contains two lenses, *objective* and *ocular*, that function in combination to form the image. The light source is focused on the specimen by the condenser (Figure 2.1). Bacterial cells are typically difficult to see well with the bright-field microscope because the cells themselves lack significant contrast with their surrounding medium. Cells visualized by a form of light microscopy called phase-contrast (Section 2.2; see inset Figure 2.1) overcome these limitations. Pigmented microorganisms are also an exception because the color of the organism itself adds contrast, which makes them easier to visualize by bright-field optics (Figure 2.2).

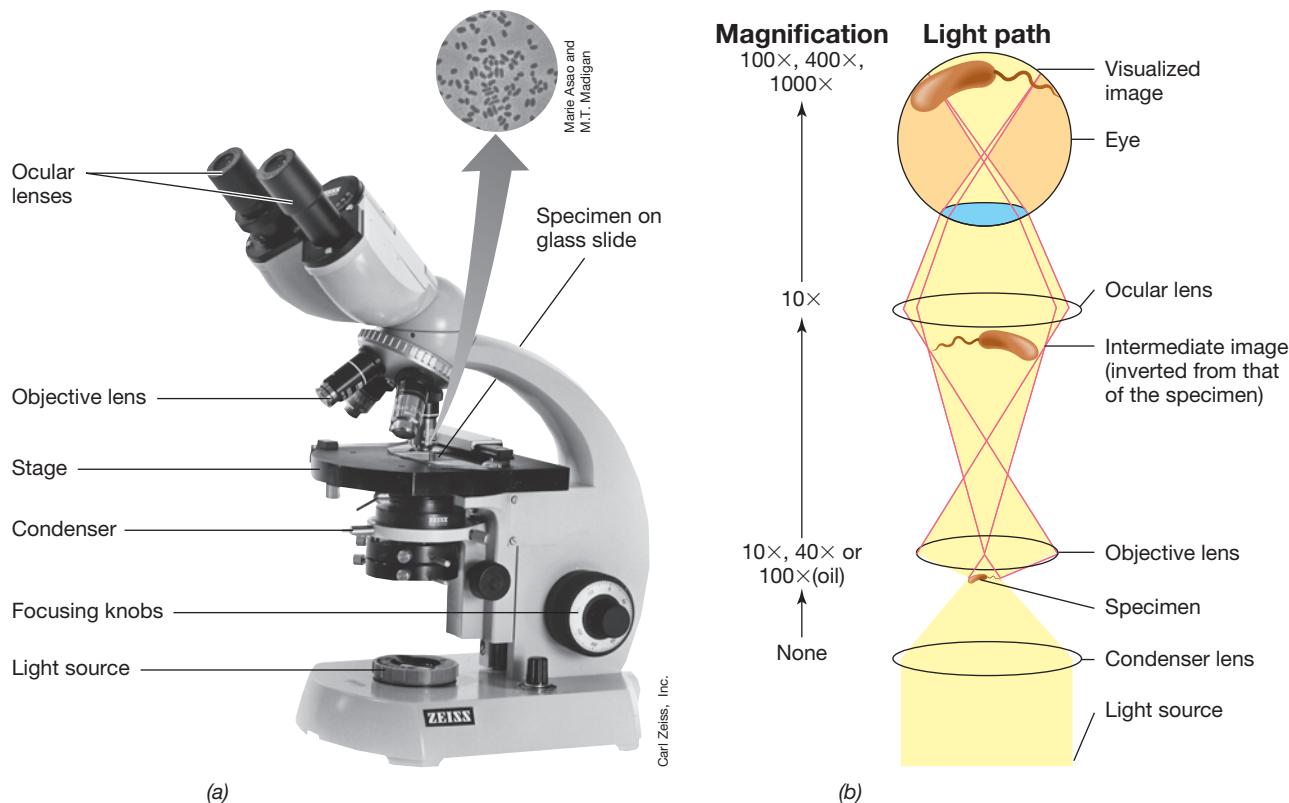

Figure 2.1 Microscopy. (a) A compound light microscope (inset photomicrograph of unstained cells taken through a phase-contrast light microscope). (b) Path of light through a compound light microscope. Besides 10 \times , ocular lenses are available in 15–30 \times magnifications. Figure 2.5 compares cells visualized by bright field with those by phase contrast.

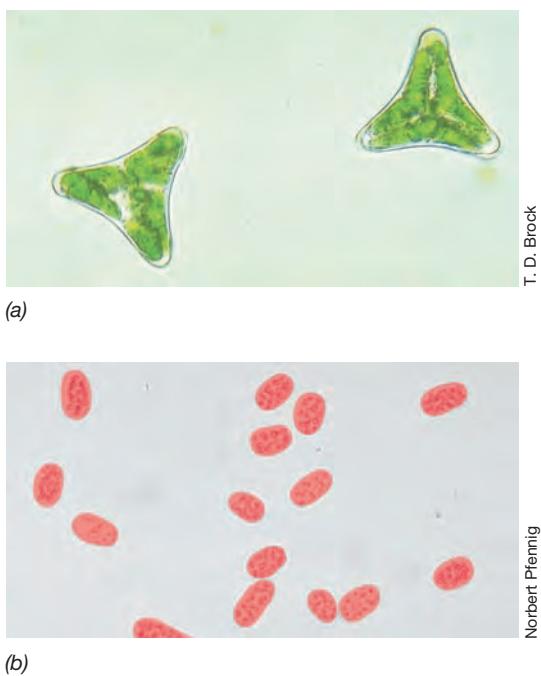

Figure 2.2 Bright-field photomicrographs of pigmented microorganisms. (a) A green alga (eukaryote). The green structures are chloroplasts. (b) Purple phototrophic bacteria (prokaryote). The algal cell is about 15 μm wide, and the bacterial cells are about 5 μm wide.

For cells lacking pigments there are several ways to boost contrast, and we consider these methods in the next section.

Magnification and Resolution

The total magnification of a compound light microscope is the *product* of the magnification of its objective and ocular lenses (Figure 2.1b). Magnifications of about 2000 \times are the upper limit for light microscopes, and at magnifications above this, resolution does not improve. Resolution is a function of the wavelength of light used and a characteristic of the objective lens known as its *numerical aperture*, a measure of light-gathering ability. There is a correlation between the magnification of a lens and its numerical aperture; lenses with higher magnification typically have higher numerical apertures. The diameter of the smallest object resolvable by any lens is equal to $0.5\lambda/\text{numerical aperture}$, where λ is the wavelength of light used. This formula reveals that resolution is highest when blue light is used to illuminate a specimen (blue light has shorter wavelengths than white or red light) and the objective has a very high numerical aperture.

As mentioned, the highest resolution possible in a compound light microscope is about 0.2 μm . What this means is that two objects that are closer together than 0.2 μm cannot be resolved as distinct and separate. Microscopes used in microbiology have ocular lenses that magnify 10–20 \times and objective lenses that magnify 10–100 \times (Figure 2.1b). At 1000 \times , objects 0.2 μm in diameter can just be resolved. With the 100 \times objective, and with certain other objectives of very high numerical aperture, an optical grade oil is placed between the microscope slide and the objective. Lenses on which oil is used are called *oil-immersion* lenses. Immersion oil increases the light-gathering ability of a lens

by allowing some of the light rays emerging from the specimen at angles (that would otherwise be lost to the objective lens) to be collected and viewed.

MINIQUIZ

- Define the terms magnification and resolution.
- What is the upper limit of magnification for a bright-field microscope? Why is this so?

2.2 Improving Contrast in Light Microscopy

In light microscopy, improving contrast improves the final image. Staining is a quick and easy way to improve contrast, but there are many other ways to do this.

Staining: Increasing Contrast for Bright-Field Microscopy

Dyes can be used to stain cells and increase their contrast so that they can be more easily seen in the bright-field microscope. Dyes are organic compounds, and each class of dye has an affinity for specific cellular materials. Many dyes used in microbiology are positively charged, and for this reason they are called *basic dyes*. Examples of basic dyes include methylene blue, crystal violet, and safranin. Basic dyes bind strongly to negatively charged cell components, such as nucleic acids and acidic polysaccharides. Because cell surfaces tend to be negatively charged, these dyes also combine with high affinity to the surfaces of cells, and hence are very useful general-purpose stains.

To perform a simple stain one begins with dried preparations of cells (Figure 2.3). A clean glass slide containing a dried suspension of cells is flooded for a minute or two with a dilute solution of a basic dye, rinsed several times in water, and blotted dry. Because their cells are so small, it is common to observe dried, stained preparations of *Bacteria* or *Archaea* with a high-power (oil-immersion) lens.

Differential Stains: The Gram Stain

Stains that render different kinds of cells different colors are called *differential stains*. An important differential-staining procedure used in microbiology is the **Gram stain** (Figure 2.4). On the basis of their reaction in the Gram stain, *Bacteria* can be divided into two major groups: **gram-positive** and **gram-negative**. After Gram staining, gram-positive bacteria appear purple-violet and gram-negative bacteria appear pink (Figure 2.4b). The color difference in the Gram stain arises because of differences in the cell wall structure of gram-positive and gram-negative cells, a topic we will consider later. After staining with a basic dye such as crystal violet that renders cells purple in color, treatment with ethanol decolorizes gram-negative cells but not gram-positive cells. Following counterstaining with a different-colored stain, typically the red stain safranin, the two cell types can be distinguished microscopically by their different colors (Figure 2.4b).

The Gram stain is the most common staining procedure used in microbiology, and it is often done to begin the characterization of a

Figure 2.3 Staining cells for microscopic observation. Stains improve the contrast between cells and their background. Center: Same cells as shown in Figure 2.1 inset but stained with a basic dye.

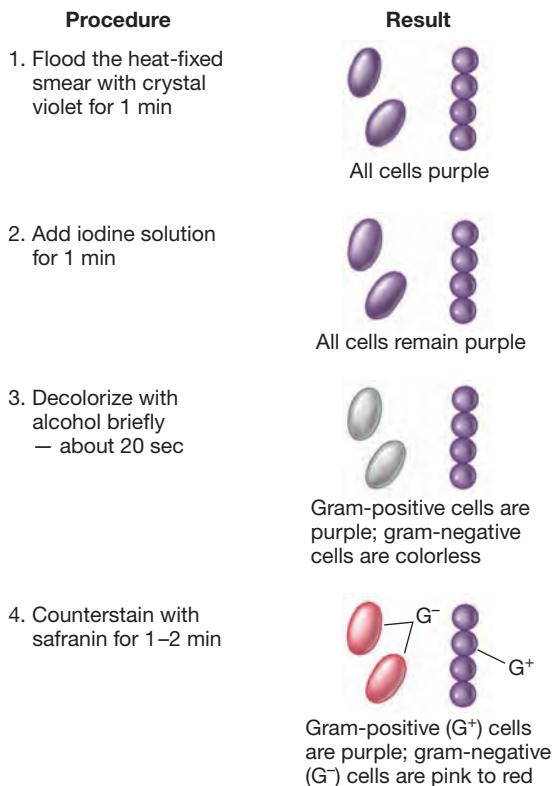

newly isolated bacterium. If a fluorescent microscope is available, the Gram stain can be reduced to a one-step procedure; gram-positive and gram-negative cells fluoresce different colors when treated with a special chemical (Figure 2.4c).

Phase-Contrast and Dark-Field Microscopy

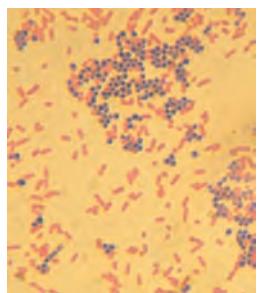

Although staining is widely used in light microscopy, staining kills cells and can distort their features. Two forms of light microscopy improve image contrast of unstained (and thus live) cells. These are phase-contrast microscopy and dark-field microscopy (Figure 2.5). The phase-contrast microscope in particular is widely used in teaching and research for the observation of living preparations.

Phase-contrast microscopy is based on the principle that cells differ in refractive index (a factor by which light is slowed as it passes through a material) from their surroundings. Light passing through a cell thus differs in phase from light passing through the surrounding liquid. This subtle difference is amplified by a device in the objective lens of the phase-contrast microscope called the *phase ring*, resulting in a dark image on a light background (Figure 2.5b; see also inset to Figure 2.1). The ring consists of a phase plate that amplifies the variation in phase to produce the higher-contrast image.

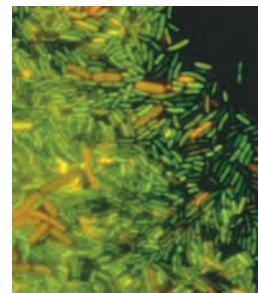

In the dark-field microscope, light reaches the specimen from the sides only. The only light that reaches the lens is that scattered by the specimen, and thus the specimen appears light on a dark

This method allows for differentiating gram-positive from gram-negative cells in a single staining step.

background (Figure 2.5c). Resolution by dark-field microscopy is often better than by light microscopy, and some objects can be resolved by dark-field that cannot be resolved by bright-field or even by phase-contrast microscopes. Dark-field microscopy is a particularly good way to observe microbial motility, as bundles of flagella (the structures responsible for swimming motility) are often resolvable with this technique (see Figure 2.50a).

Fluorescence Microscopy

The fluorescence microscope is used to visualize specimens that fluoresce, emitting light of one color after absorbing light

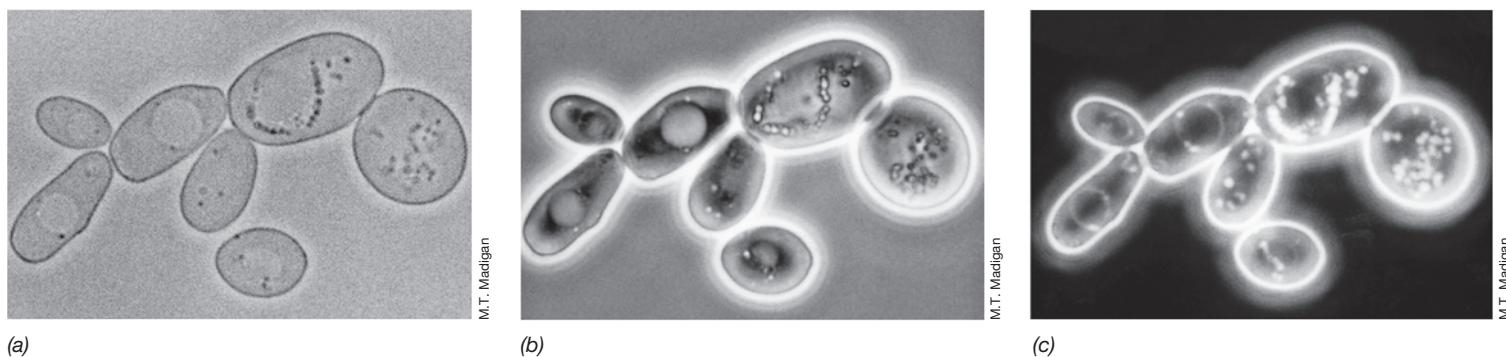

Figure 2.5 Cells visualized by different types of light microscopy. The same field of cells of the yeast *Saccharomyces cerevisiae* visualized by (a) bright-field microscopy, (b) phase-contrast microscopy, and (c) dark-field microscopy. Cells average 8–10 μm wide.

of another color (Figure 2.6). Cells fluoresce because they either contain naturally fluorescent substances such as chlorophyll or other fluorescing components (autofluorescence, Figure 2.6a, b), or because they have been stained with a fluorescent dye (Figure 2.6c). DAPI (4',6-diamidino-2-phenylindole) is a widely used fluorescent dye. DAPI stains cells bright blue because it complexes with the cell's DNA (Figure 2.6c). DAPI can be used to visualize cells in their natural habitats, such as soil, water, food, or a clinical specimen. Fluorescence microscopy using DAPI is therefore widely used in clinical diagnostic microbiology and also in microbial ecology for enumerating bacteria in a natural environment or in a cell suspension.

MINIQUIZ

- What major advantage does phase-contrast microscopy have over staining?
- How can cells be made to fluoresce?

electron microscope offers one solution to this problem, but certain forms of light microscopy can also improve the three-dimensional perspective of an image.

Differential Interference Contrast Microscopy

Differential interference contrast (DIC) microscopy is a form of light microscopy that employs a polarizer in the condenser to produce polarized light (light in a single plane). The polarized light then passes through a prism that generates two distinct beams. These beams pass through the specimen and enter the objective lens where they are recombined into one. Because the two beams pass through substances that differ in refractive index, the combined beams are not totally in phase but instead interfere with each other, and this effect enhances subtle differences in cell structure. Thus, by DIC microscopy, cellular structures such as the nucleus of eukaryotic cells (Figure 2.7) or endospores, vacuoles, and inclusions of bacterial cells, appear more three-dimensional. DIC microscopy is typically used on unstained cells as it can reveal internal cell structures that are nearly invisible by bright-field without the need for staining (compare Figure 2.5a with Figure 2.7).

Confocal Scanning Laser Microscopy

A confocal scanning laser microscope (CSLM) is a computer-controlled microscope that couples a laser to a fluorescent microscope. The laser generates a bright three-dimensional

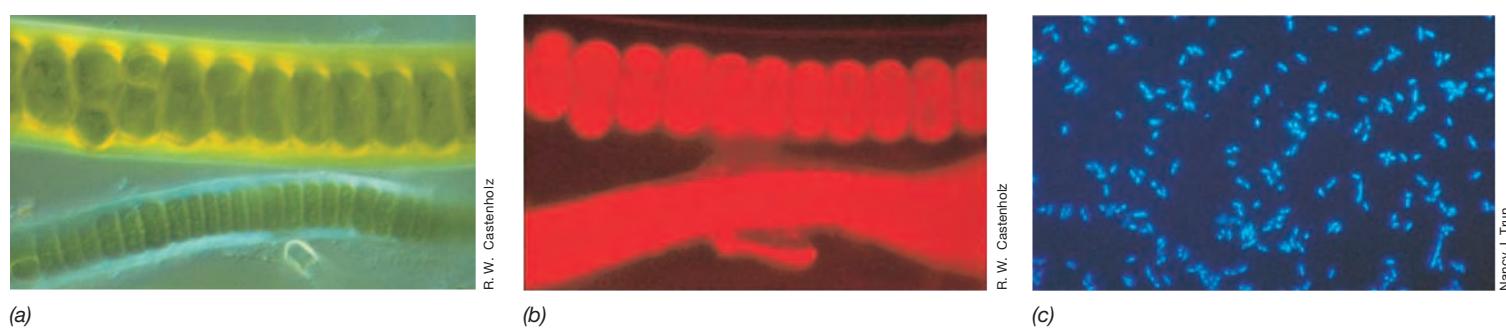

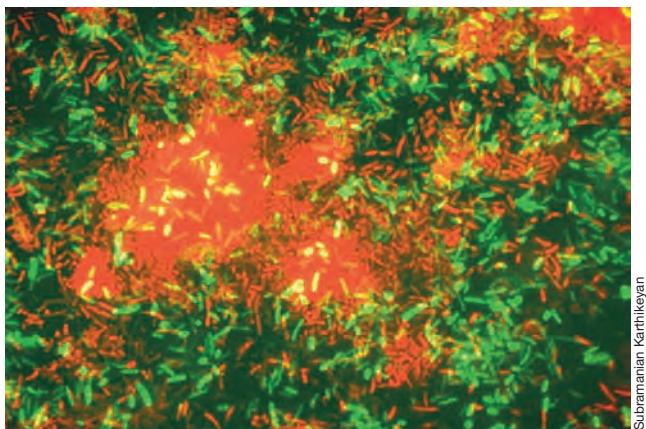

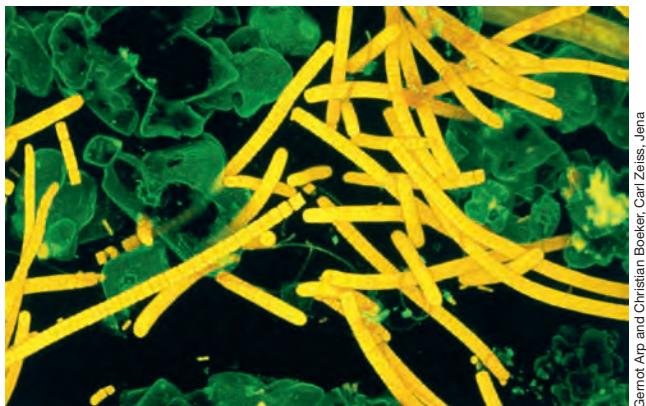

Figure 2.6 Fluorescence microscopy. (a, b) Cyanobacteria. The same cells are observed by bright-field microscopy in part a and by fluorescence microscopy in part b. The cells fluoresce red because they contain chlorophyll *a* and other pigments. (c) Fluorescence photomicrograph of cells of *Escherichia coli* made fluorescent by staining with the fluorescent dye DAPI, which binds to DNA.

Figure 2.7 Differential interference contrast microscopy. Cells of the yeast *Saccharomyces cerevisiae* are given a three-dimensional effect by this form of microscopy. The yeast cells are about 8 μm wide. Note the clearly visible nucleus and compare to the bright-field image of yeast cells in Figure 2.5a.

image and allows the viewer to access several planes of focus in the specimen (Figure 2.8). To do this, the laser beam is precisely adjusted such that only a particular layer within a specimen is in perfect focus at one time. By precisely illuminating only this single plane, the CSLM eliminates stray light from other focal planes. Thus, when observing a relatively thick specimen such as a bacterial biofilm (Figure 2.8a), not only can cells on the surface of the biofilm be observed, as would be the case with conventional light microscopy, but cells in the various layers can also be observed by adjusting the plane of focus of the laser beam. Using CSLM it has been possible to improve on the 0.2- μm resolution of the compound light microscope to a limit of about 0.1 μm .

Cells in CSLM preparations can be stained with fluorescent dyes to make them more distinct (Figure 2.8a). Alternatively, false color can be added to unstained preparations such that different layers in the specimen have different colors (Figure 2.8b). A CSLM employs a computer to assemble digital images for subsequent image processing. Images obtained from the different layers can then be digitally reconstructed to yield a three-dimensional image of the entire specimen.

CSLM is widely used in microbial ecology, especially for identifying specific populations of cells in a microbial habitat or for resolving the different components of a structured microbial community, such as a biofilm (Figure 2.8a) or a microbial mat. In general, CSLM is particularly useful anywhere thick specimens need to be examined for their microbial content with depth.

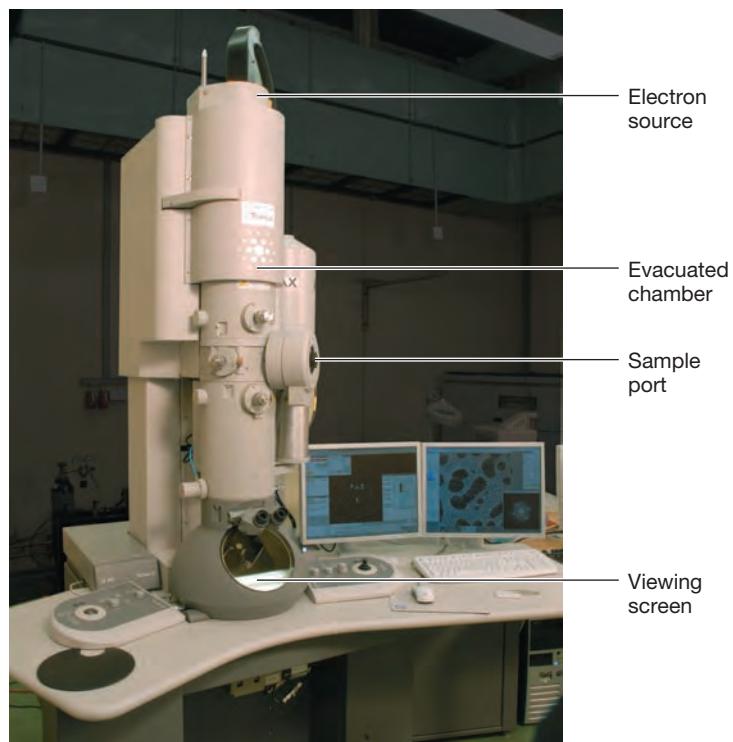

Figure 2.9 The electron microscope. This instrument encompasses both transmission and scanning electron microscope functions.

MINIQUIZ

- What structure in eukaryotic cells is more easily seen in DIC than in bright-field microscopy? (*Hint:* Compare Figures 2.5a and 2.7).
- Why is CSLM able to view different layers in a thick preparation while bright-field microscopy cannot?

2.4 Probing Cell Structure: Electron Microscopy

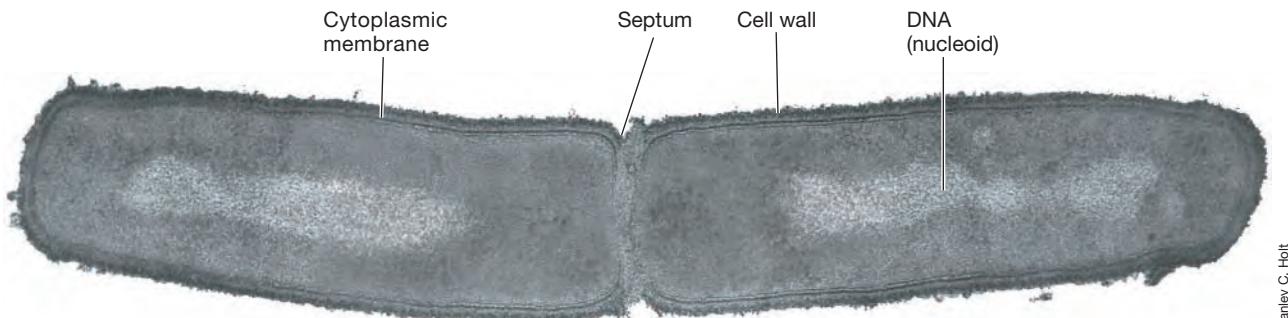

Electron microscopes use electrons instead of visible light (photons) to image cells and cell structures. In the electron microscope, electromagnets function as lenses, and the whole system operates in a vacuum (Figure 2.9). Electron microscopes are fitted with cameras to allow a photograph, called an *electron micrograph*, to be taken. Two types of electron microscopy are in routine use in microbiology: transmission and scanning.

Transmission Electron Microscopy

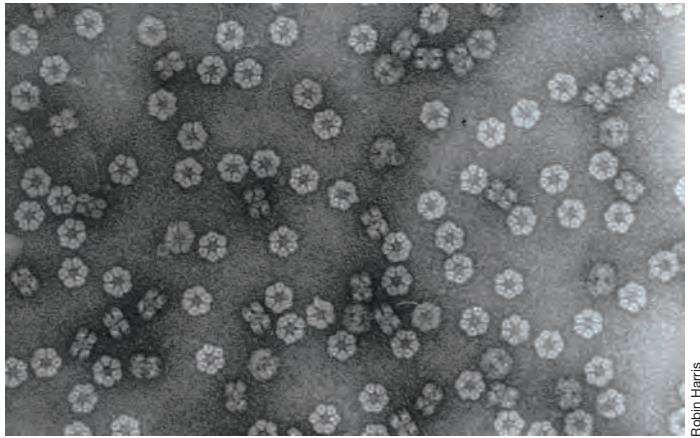

The *transmission electron microscope* (TEM) is used to examine cells and cell structure at very high magnification and resolution. The resolving power of a TEM is much greater than that

of the light microscope, even allowing one to view structures at the molecular level (Figure 2.10). This is because the wavelength of electrons is much shorter than the wavelength of visible light, and, as we have learned, wavelength affects resolution (Section 2.1). For example, whereas the resolving power of a light microscope is about 0.2 *micrometer*, the resolving power of a TEM is about 0.2 *nanometer*, a thousandfold improvement. With such powerful resolution, objects as small as individual protein and nucleic acid molecules can be visualized by transmission electron microscopy (Figure 2.10).

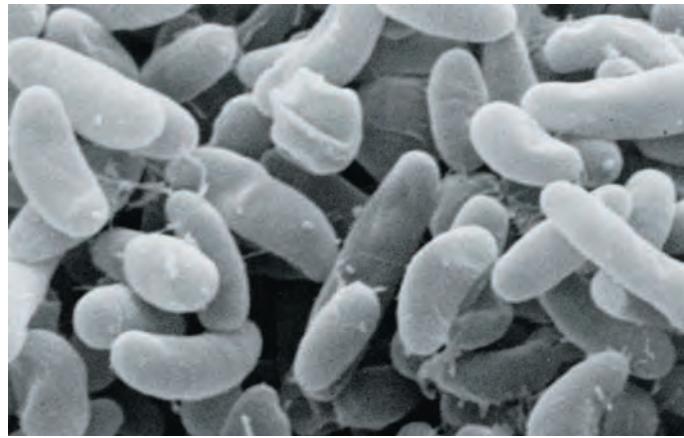

Unlike photons, electrons are very poor at penetrating; even a single cell is too thick to penetrate with an electron beam. Consequently, to view the internal structure of a cell, *thin sections* of the cell are needed, and the sections must be stabilized and stained with various chemicals to make them visible. A single bacterial cell, for instance, is cut into extremely thin (20–60 nm) slices, which are then examined individually by TEM (Figure 2.10a). To obtain sufficient contrast, the sections are treated with stains such as osmic acid, or permanganate, uranium, lanthanum, or lead salts. Because these substances are composed of atoms of high atomic weight, they scatter electrons well and thus improve contrast. If only the *external* features of an organism are to be

(a)

(b)

(c)

(b) TEM of negatively stained molecules of hemoglobin. Each hexagonal-shaped molecule is about 25 nanometers (nm) in diameter and consists of two doughnut-shaped rings, a total of 15 nm wide. (c) Scanning electron micrograph of bacterial cells. A single cell is about 0.75 μm wide.

observed, thin sections are unnecessary. Intact cells or cell components can be observed directly in the TEM by a technique called *negative staining* (Figure 2.10b).

Scanning Electron Microscopy

For optimal three-dimensional imaging of cells, a *scanning electron microscope* (SEM) is used (Figure 2.9). In scanning electron microscopy, the specimen is coated with a thin film of a heavy metal, typically gold. An electron beam then scans back and forth across the specimen. Electrons scattered from the metal coating are collected and projected on a monitor to produce an image (Figure 2.10c). In the SEM, even fairly large specimens can be observed, and the depth of field (the portion of the image that remains in sharp focus) is extremely good. A wide range of magnifications can be obtained with the SEM, from as low as $15\times$ up to about $100,000\times$, but only the *surface* of an object is typically visualized.

Electron micrographs taken by either TEM or SEM are originally taken as black-and-white images. Although the original

image contains the maximum amount of scientific information that is available, color is often added to electron micrographs by manipulating them in a computer. However, such false color does not improve resolution of a micrograph. Its primary value is to increase the artistic value of the image for public consumption in the mass media. The maximum scientific content and detail in an electron micrograph is set at the moment the micrograph is taken, and thus false color will be used sparingly in electron micrographs in this book so as to present the micrographs in their original scientific context.

MINIQUIZ

- What is an electron micrograph? Why do electron micrographs have greater resolution than light micrographs?
- What type of electron microscope would be used to view a cluster of cells? What type would be used to observe internal cell structure?

II • Cells of Bacteria and Archaea

Two features of prokaryotic cells that are immediately obvious upon microscopic examination are their shape and small size. A variety of shapes are possible, and in general, prokaryotes are extremely small relative to eukaryotic cells. Cell shape can be useful for distinguishing different cells and undoubtedly has some ecological significance, but cell shape rarely has phylogenetic relevance. By contrast, the typically small size of prokaryotes affects many aspects of their biology.

2.5 Cell Morphology

In microbiology, the term **morphology** means cell shape. Several morphologies are known among prokaryotes, and the most common ones are described by terms that are part of the essential lexicon of the microbiologist.

Major Cell Morphologies

Examples of bacterial morphologies are shown in Figure 2.11. A cell that is spherical or ovoid in morphology is called a *coccus* (plural, *cocci*). A cylindrically shaped cell is called a *rod* or a *bacillus*. Some rods form spiral shapes and are called *spirilla*. The cells of some prokaryotes remain together in groups or clusters after cell division, and the arrangements are often characteristic. For instance, some cocci form long chains (for example, the bacterium *Streptococcus*), others occur in three-dimensional cubes (*Sarcina*), and still others in grapelike clusters (*Staphylococcus*).

A few bacterial groups are immediately recognizable by the unusual shapes of their individual cells. Examples include the spirochetes, which are tightly coiled bacteria; appendaged bacteria, which possess extensions of their cells as long tubes or stalks; and filamentous bacteria, which form long, thin cells or chains of cells (Figure 2.11).

The cell morphologies described here should only be considered representative; many variations of these morphologies are

known. For example, there are fat rods, thin rods, short rods, and long rods, a rod simply being a cell that is longer in one dimension than in the other. As we will see, there are even square bacteria and star-shaped bacteria! Cell morphologies thus form a continuum, with some shapes, such as rods, being very common, whereas others are more unusual.

Morphology and Biology

Although cell morphology is easily determined, it is a poor predictor of other properties of a cell. For example, under the microscope many rod-shaped *Archaea* look identical to rod-shaped *Bacteria*, yet we know they are of different phylogenetic domains (☞ Section 1.3). With very rare exceptions, it is impossible to predict the physiology, ecology, phylogeny, pathogenic potential, or virtually any other property of a prokaryotic cell by simply knowing its morphology.

Why is a cell the shape it is? Although we know something about *how* cell shape is controlled, we know little about *why* a particular cell evolved the morphology it has. Several selective forces undoubtedly help shape the morphology of a given species. Some examples of these might include optimization for nutrient uptake (small cells and others with high surface-to-volume ratios, such as appendaged cells), swimming motility in viscous environments or near surfaces (helical- or spiral-shaped cells), gliding motility (filamentous bacteria), and so on. Morphology is not a trivial feature of a microbial cell but instead a genetically encoded property that maximizes fitness of the organism for success in its particular habitat.

MINIQUIZ

- How do cocci and rods differ in morphology?
- Is cell morphology a good predictor of other properties of the cell?

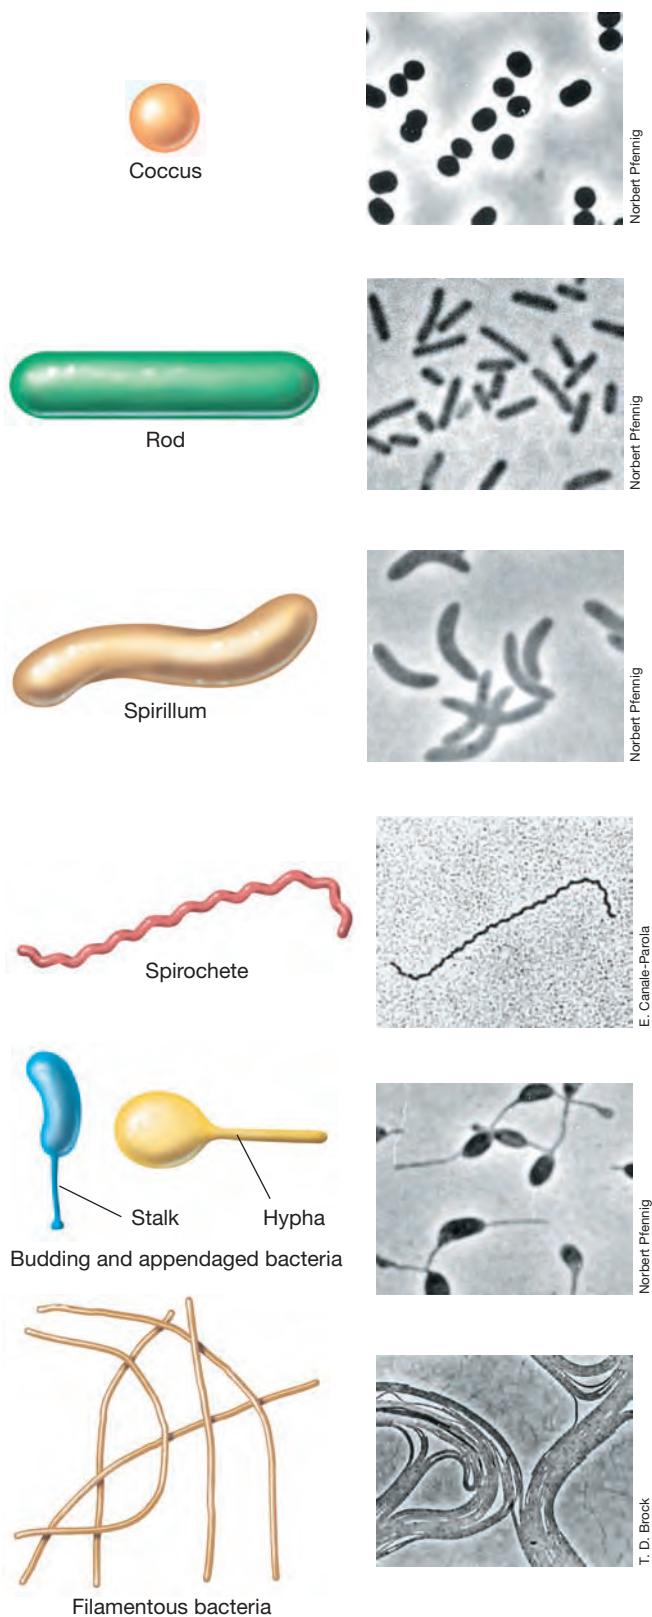

Figure 2.11 Cell morphologies. Beside each drawing is a phase-contrast photomicrograph of cells showing that morphology. Coccus (cell diameter in photomicrograph, 1.5 μm); rod (1 μm); spirillum (1 μm); spirochete, (0.25 μm); budding (1.2 μm); filamentous (0.8 μm). All photomicrographs are of species of *Bacteria*. Not all of these morphologies are known among the *Archaea*.

2.6 Cell Size and the Significance of Being Small

Prokaryotes vary in size from cells as small as about 0.2 μm in diameter to those more than 700 μm in diameter (Table 2.1). The vast majority of rod-shaped prokaryotes that have been cultured are between 0.5 and 4 μm wide and less than 15 μm long. But a few very large prokaryotes, such as *Epulopiscium fishelsoni*, are known, with cells longer than 600 μm (0.6 millimeter) (Figure 2.12). This bacterium, phylogenetically related to the endospore-forming bacterium *Clostridium* and found in the gut of tropical marine fish called surgeonfish, contains multiple copies of its genome. The many copies are apparently necessary because the volume of an *Epulopiscium* cell is so large (Table 2.1) that a single copy of its

Figure 2.12 Some very large prokaryotes. Dark-field photomicrograph of two giant prokaryotes, species of *Bacteria*. (a) *Epulopiscium fishelsoni*. The rod-shaped cell is about 600 μm (0.6 mm) long and 75 μm wide and is shown with four cells of the protist *Paramecium* (a eukaryote), each of which is about 150 μm long. (b) *Thiomargarita namibiensis*, a large sulfur chemolithotroph and currently the largest known prokaryote. Cell widths vary from 400 to 750 μm .

Table 2.1 Cell size and volume of some cells of *Bacteria*, from the largest to the smallest

Organism	Characteristics	Morphology	Size ^a (μm)	Cell volume (μm^3)	E. coli volumes
<i>Thiomargarita namibiensis</i>	Sulfur chemolithotroph	Cocci in chains	750	200,000,000	100,000,000
<i>Epulopiscium fishelsoni</i> ^a	Chemoorganotroph	Rods with tapered ends	80 × 600	3,000,000	1,500,000
<i>Beggiatoa species</i> ^a	Sulfur chemolithotroph	Filaments	50 × 160	1,000,000	500,000
<i>Achromatium oxaliferum</i>	Sulfur chemolithotroph	Cocci	35 × 95	80,000	40,000
<i>Lyngbya majuscula</i>	Cyanobacterium	Filaments	8 × 80	40,000	20,000
<i>Thiovulum majus</i>	Sulfur chemolithotroph	Cocci	18	3,000	1,500
<i>Staphylothermus marinus</i> ^a	Hyperthermophile	Cocci in irregular clusters	15	1,800	900
<i>Magnetobacterium bavaricum</i>	Magnetotactic bacterium	Rods	2 × 10	30	15
<i>Escherichia coli</i>	Chemoorganotroph	Rods	1 × 2	2	1
<i>Pelagibacter ubique</i> ^a	Marine chemoorganotroph	Rods	0.2 × 0.5	0.014	0.007
<i>Mycoplasma pneumoniae</i>	Pathogenic bacterium	Pleomorphic ^b	0.2	0.005	0.0025

^aWhere only one number is given, this is the diameter of spherical cells. The values given are for the largest cell size observed in each species. For example, for *T. namibiensis*, an average cell is only about 200 μm in diameter. But on occasion, giant cells of 750 μm are observed. Likewise, an average cell of *S. marinus* is about 1 μm in diameter. The species of *Beggiatoa* here is unclear and *E. fishelsoni*, *Magnetobacterium bavaricum*, and *P. ubique* are not formally recognized names in taxonomy.

^b*Mycoplasma* is a bacterium that lacks a cell wall and can thus take on many shapes (*pleomorphic* means “many shapes”).

Source: Data obtained from Schulz, H.N., and B.B. Jørgensen. 2001. *Ann. Rev. Microbiol.* 55: 105–137.

genome would be insufficient to support its transcriptional and translational demands.

Cells of the largest known prokaryote, the sulfur chemolithotroph *Thiomargarita* (Figure 2.12b), are even larger than those of *Epulopiscium*, about 750 μm in diameter; such cells are just visible to the naked eye. Why these cells are so large is not well understood, although for sulfur bacteria a large cell size may be a mechanism for storing inclusions of sulfur (an energy source). It is hypothesized that the upper size limit for prokaryotic cells results from the decreasing ability of larger and larger cells to transport nutrients (their surface-to-volume ratio is very small; see the next subsection). Since the metabolic rate of a cell varies inversely with the square of its size, for very large cells, nutrient uptake would eventually limit metabolism to the point that the cell would no longer be competitive with smaller cells.

Very large cells are uncommon in the prokaryotic world. In contrast to *Thiomargarita* or *Epulopiscium* (Figure 2.12), the dimensions of an average rod-shaped prokaryote, the bacterium *E. coli*, for example, are about 1 × 2 μm ; these dimensions are typical of the cells of most prokaryotes. By contrast, eukaryotic cells can be 2 to more than 600 μm in diameter, although very small eukaryotes are uncommon, most being 8 μm in diameter or greater. In general, then, it can be said that prokaryotes are very small cells compared with eukaryotes.

Surface-to-Volume Ratios, Growth Rates, and Evolution

There are significant advantages to being small. Small cells have more surface area relative to cell volume than do large cells; that is, they have a higher *surface-to-volume ratio*. Consider a coccus. The volume of a coccus is a function of the cube of its radius ($V = \frac{4}{3}\pi r^3$), while its surface area is a function of the square of the radius ($S = 4\pi r^2$). Therefore, the *S/V* ratio of a coccus is $3/r$

(Figure 2.13). As a cell increases in size, its *S/V* ratio decreases. To illustrate this, consider the *S/V* ratio for some of the cells of different sizes listed in Table 2.1: *Pelagibacter ubique*, 22; *E. coli*, 4.5; and *E. fishelsoni* (Figure 2.12a), 0.05.

The *S/V* ratio of a cell affects several aspects of its biology, including even its evolution. Because how fast a cell can grow depends, among other things, on the rate of nutrient exchange, the higher *S/V* ratio of smaller cells supports a faster rate of nutrient exchange per unit of cell volume compared with larger cells. As a result, smaller cells tend to grow faster than larger cells, and for a given amount of resources (nutrients available to support

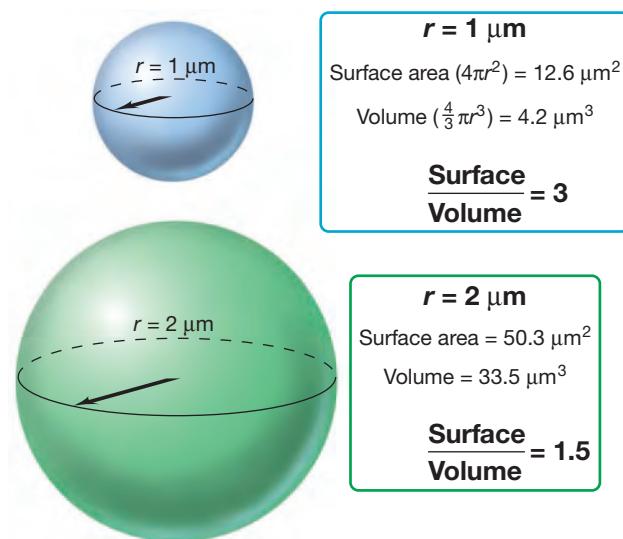

Figure 2.13 Surface area and volume relationships in cells. As a cell increases in size, its *S/V* ratio decreases.

growth), a larger population of small cells than of large cells is possible. This in turn can affect evolution.

Each time a cell divides, its chromosome replicates. As DNA is replicated, occasional errors, called *mutations*, occur. Because mutation rates appear to be about the same in all cells, large or small, the more chromosome replications that occur, the greater the total number of mutations in the cell population. Mutations are the “raw material” of evolution; the larger the pool of mutations, the greater the evolutionary possibilities. Thus, because prokaryotic cells are quite small and are also genetically haploid (allowing mutations to be expressed immediately), they have, in general, the capacity for more rapid growth and faster evolution than larger, genetically diploid cells. In the latter, not only is the *S/V* ratio smaller, but the effects of a mutation in one gene can be masked by a second, unmutated gene copy. These fundamental differences in size and genetics between prokaryotic and eukaryotic cells is a major reason why prokaryotes adapt rapidly to changing environmental conditions and more easily exploit new habitats than eukaryotic cells. We will illustrate this concept in later chapters when we consider, for example, the enormous diversity of prokaryotes (Chapters 13–16) and the rapidity of their evolution (☞ Section 12.6).

Lower Limits of Cell Size

From the foregoing, one could imagine that smaller and smaller bacteria would have greater and greater selective advantages in

nature. However, this is not true, as there are lower limits to cell size. If one considers the volume needed to house the essential components of a free-living cell—proteins, nucleic acids, ribosomes, and so on—a structure 0.1 m in diameter or less is insufficient to do the job, and structures 0.15 m in diameter are marginal. Thus, structures observed in natural samples that are 0.1 m or even smaller and “look” like bacterial cells are almost certainly not so. Despite this, some very small prokaryotic cells are known and many have been grown in the laboratory. Open ocean water, for example, contains 10^5 – 10^6 prokaryotic cells per milliliter, and these tend to be very small cells, 0.2–0.4 m in diameter. We will see later that many pathogenic bacteria are also very small. When the genomes of these pathogens are examined, they are found to be highly streamlined and missing many genes whose functions are supplied to them by their hosts.

MINIQUIZ

- What physical property of cells increases as cells become smaller?
- How can the small size and haploid state of prokaryotes accelerate their evolution?
- What are the approximate limits to how small a cell can be? Why is this so?

III • The Cytoplasmic Membrane and Transport

We now consider the structure and function of one of a cell’s most critical structures, the cytoplasmic membrane. The cytoplasmic membrane plays many roles, chief among them as the “gatekeeper” for dissolved substances that enter and exit the cell.

2.7 Membrane Structure

The **cytoplasmic membrane** surrounds the cytoplasm and separates it from the environment. If the cytoplasmic membrane is compromised, the integrity of the cell is destroyed, the cytoplasm leaks into the environment, and the cell dies. The cytoplasmic membrane is structurally weak and confers little protection from osmotic lysis, but it is an ideal structure for its major function on the cell: selective permeability.

Composition of Membranes

The general structure of the cytoplasmic membrane is a phospholipid bilayer. Phospholipids are composed of both hydrophobic (fatty acid) and hydrophilic (glycerol–phosphate) components (Figure 2.14). As phospholipids aggregate in an aqueous solution, they naturally form bilayers. In a phospholipid membrane, the fatty acids point inward toward each other to form a hydrophobic environment, and the hydrophilic portions remain exposed to the external environment or the cytoplasm (Figure 2.14b). Common fatty acids in the cytoplasmic membrane include those with 14 to 20 carbon atoms.

The cytoplasmic membrane is only 8–10 nanometers wide but is still visible in the transmission electron microscope, where it appears as two dark lines separated by a light line (Figure 2.14c). This *unit membrane*, as it is called (because each phospholipid leaf forms half of the “unit”), consists of a phospholipid bilayer with proteins embedded in it (Figure 2.15). Although in a diagram the cytoplasmic membrane appears rigid, it is actually somewhat fluid, having a consistency approximating that of a low-viscosity oil. Thus, some freedom of movement exists for proteins embedded in the membrane. The cytoplasmic membranes of some *Bacteria* are strengthened by sterol-like molecules called *hopanoids*. Sterols are rigid and planar molecules that function to strengthen the membranes of eukaryotic cells, and hopanoids serve a similar function in *Bacteria*.

Membrane Proteins

The protein content of the cytoplasmic membrane is quite high, and membrane proteins typically have hydrophobic surfaces in regions that span the membrane and hydrophilic surfaces in regions that contact the environment and the cytoplasm (Figures 2.14 and 2.15). The *outer* surface of the cytoplasmic membrane faces the environment and in gram-negative bacteria interacts with a variety of proteins that bind substrates or process larger molecules for transport into the cell (periplasmic proteins, Section 2.11). The *inner* surface of the cytoplasmic membrane touches the cytoplasm and interacts with proteins and other molecules in this milieu.

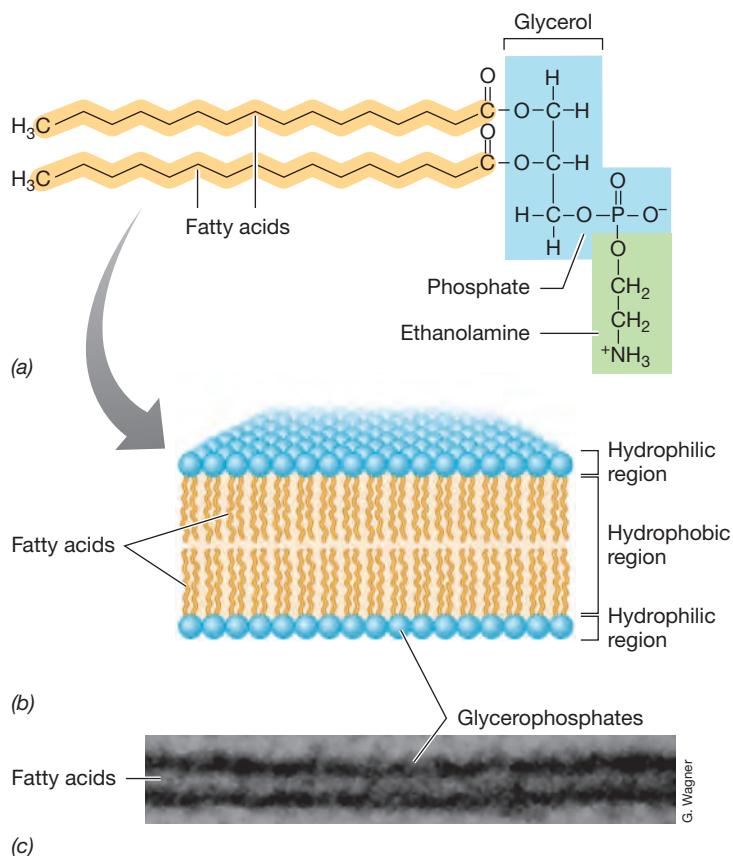

Figure 2.14 Phospholipid bilayer membrane. (a) Structure of the phospholipid phosphatidylethanolamine. (b) General architecture of a bilayer membrane; the blue spheres depict glycerol with phosphate and/or other hydrophilic groups. (c) Transmission electron micrograph of a membrane. The light inner area is the hydrophobic region of the model membrane shown in part b.

Many membrane proteins are firmly embedded in the membrane and are called *integral* membrane proteins. Other proteins have one portion anchored in the membrane and extramembrane regions that point into or out of the cell (Figure 2.15). Still other proteins, called *peripheral* membrane proteins, are not membrane-embedded but nevertheless remain associated with membrane surfaces. Some of these peripheral membrane proteins are lipoproteins, molecules that contain a lipid tail that anchors the protein into the membrane. Peripheral membrane proteins typically interact with integral membrane proteins in important cellular processes such as energy metabolism and transport. Membrane proteins that need to interact with each other in some process are typically grouped together into clusters to allow them to remain adjacent to one another in the semifluid environment of the membrane.

Archaeal Membranes

In contrast to the lipids of *Bacteria* and *Eukarya* in which *ester* linkages bond fatty acids to glycerol, the lipids of *Archaea* contain *ether* bonds between glycerol and their hydrophobic side chains (Figure 2.16). Archaeal lipids thus lack fatty acids, per se, although the hydrophobic side chains play the same functional role as fatty acids. Archaeal lipids are formed from multiple units of the five-carbon hydrocarbon isoprene (Figure 2.16c).

The cytoplasmic membrane of *Archaea* is formed from either glycerol diethers, which have 20-carbon side chains (the 20-C unit is called a *phytanyl* group composed of 5 isoprene units), or diglycerol tetraethers, which have 40-carbon side chains (Figure 2.17). In the tetraether lipid, the ends of the phytanyl side chains that point inward from each glycerol molecule are covalently linked. This forms a lipid *monolayer* instead of a lipid *bilayer* membrane (Figure 2.17d, e). In contrast to lipid bilayers, lipid monolayer membranes are extremely resistant to heat and are therefore widely distributed among hyperthermophilic *Archaea*, organisms that grow best at temperatures above 80°C. Membranes with a mixture of bilayer and monolayer character are also possible, with some of the opposing hydrophobic groups covalently bonded and others not.

Many archaeal lipids contain rings within the hydrocarbon side chains. For example, *crenarchaeol*, a lipid widespread among species of *Thaumarchaeota*, a major phylum of *Archaea*, contains four 5-carbon (cyclopentyl) rings and one 6-carbon (cyclohexyl) ring (Figure 2.17c). Rings in the hydrocarbon side chains affect the chemical properties of the lipids and thus overall membrane function. Sugars can also be present in archaeal lipids. For example, the predominant membrane lipids of many *Euryarchaeota*, a major group of *Archaea* that includes the methanogens and extreme halophiles (Figure 1.6b), are glycerol diether glycolipids.

Despite the differences in chemistry between the cytoplasmic membranes of *Archaea* and organisms in the other domains, the fundamental construction of the archaeal cytoplasmic membrane—inner and outer hydrophilic surfaces and a hydrophobic interior—is the same as that of membranes in *Bacteria* and *Eukarya*. Evolution has selected this design as the best solution to the main function of the cytoplasmic membrane—permeability—and we consider this problem now.

MINIQUIZ

- Draw the basic structure of a lipid bilayer and label the hydrophilic and hydrophobic regions.
- How are the membrane lipids of *Bacteria* and *Archaea* similar, and how do they differ?

2.8 Membrane Function

The cytoplasmic membrane has several functions. First and foremost, the membrane is a permeability barrier, preventing the passive leakage of solutes into or out of the cell (Figure 2.18). Second, the membrane is an anchor for many proteins. Some of these are enzymes that function in energy conservation, and others transport solutes into and out of the cell. The cytoplasmic membrane is a major site of energy conservation in the prokaryotic cell. The membrane can exist in an energetically charged form in which protons (H^+) are separated from hydroxyl ions (OH^-) across the membrane surface (Figure 2.18c). Charge separation forms an energized state, analogous to the potential energy present in a charged battery. This energy source, called the *proton motive force*, is responsible for driving many energy-requiring functions in the cell, including many transport reactions, swimming motility, and the biosynthesis of ATP.

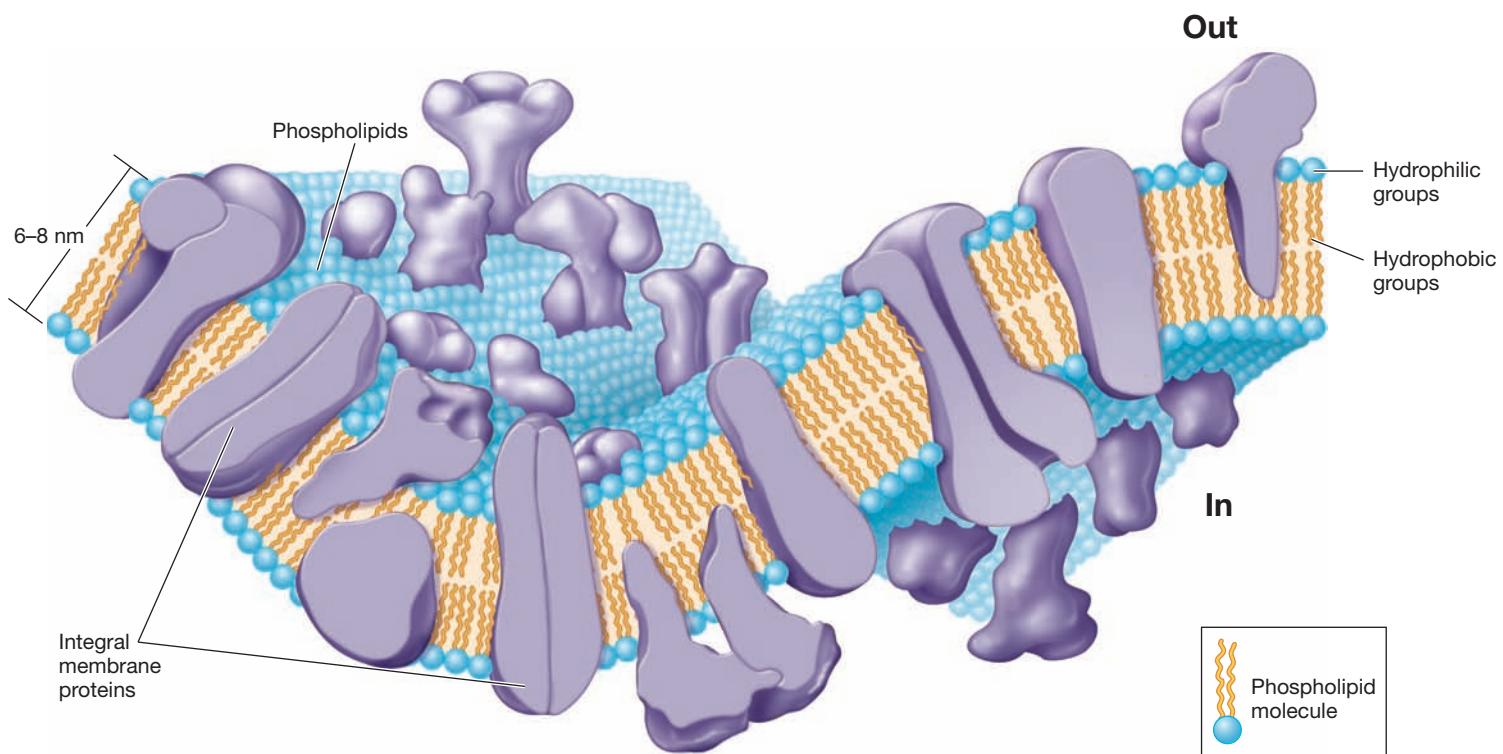

Figure 2.15 Structure of the cytoplasmic membrane. The inner surface (**In**) faces the cytoplasm and the outer surface (**Out**) faces the environment. Phospholipids compose the matrix of the cytoplasmic membrane with proteins embedded or surface associated. The general architecture of the cytoplasmic membrane is similar in both prokaryotes and eukaryotes, although there are chemical differences.

Permeability

The cytoplasm is a solution of salts, sugars, amino acids, nucleotides, and many other substances. The hydrophobic portion of the cytoplasmic membrane (Figures 2.14 and 2.15) is a tight barrier to diffusion of these substances. Although some small hydrophobic molecules pass the cytoplasmic membrane by diffusion, polar and charged molecules do not diffuse but instead must be transported. Even a substance as small as a proton (H^+) cannot diffuse across the membrane. The relative permeability of the membrane to some biologically relevant substances is shown in **Table 2.2**. As

can be seen, most substances cannot diffuse into the cell and thus must be transported.

One substance that does freely pass the membrane in both directions is water, a molecule that is somewhat polar but sufficiently small to pass between phospholipid molecules in the lipid bilayer (Table 2.2). In addition to water that enters by diffusion, membrane proteins called *aquaporins* function to accelerate the movement of water across the membrane. For example, aquaporin AqpZ of *Escherichia coli* imports water to or exports water from the cytoplasm, depending on osmotic conditions.

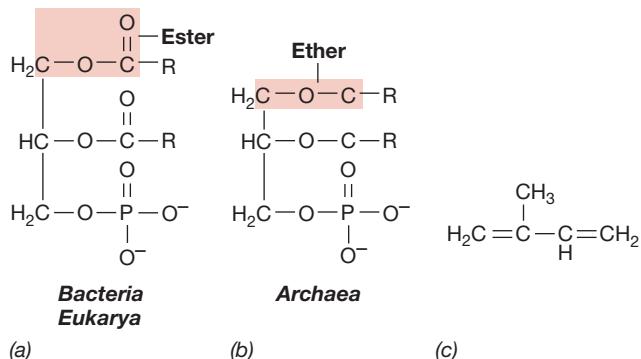

Figure 2.16 General structure of lipids. (a) The ester linkage and (b) the ether linkage. (c) Isoprene, the parent structure of the hydrophobic side chains of archaeal lipids. By contrast, in lipids of *Bacteria* and *Eukarya*, the side chains are composed of fatty acids (see Figure 2.14a).

Table 2.2 Comparative permeability of membranes to various molecules

Substance	Rate of permeability ^a	Potential for diffusion into a cell
Water	100	Excellent
Glycerol	0.1	Good
Tryptophan	0.001	Fair/Poor
Glucose	0.001	Fair/Poor
Chloride ion (Cl^-)	0.000001	Very poor
Potassium ion (K^+)	0.0000001	Extremely poor
Sodium ion (Na^+)	0.0000001	Extremely poor

^aRelative scale—permeability with respect to permeability to water given as 100. Permeability of the membrane to water may be affected by aquaporins.

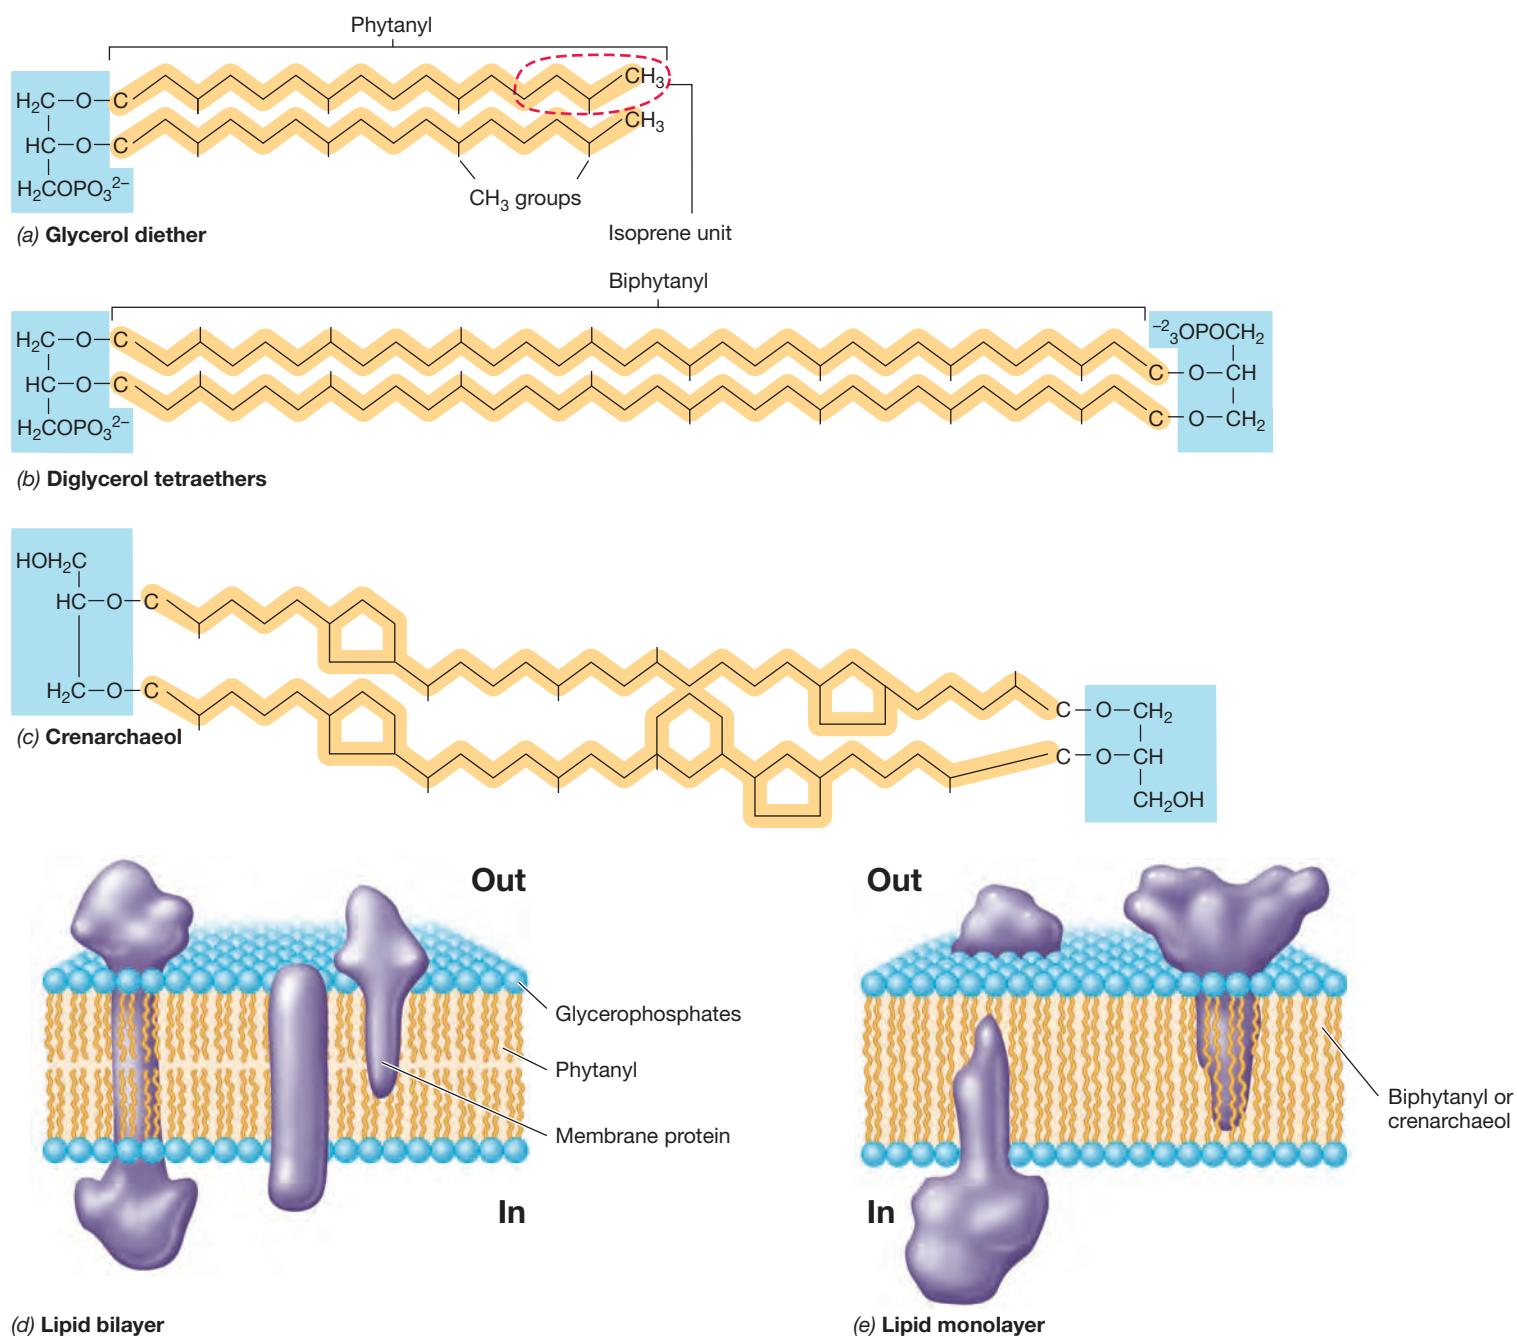

Figure 2.17 Major lipids of *Archaea* and the architecture of archaeal membranes. (a, b) Note that the hydrocarbon of the lipid is bonded to the glycerol by an ether linkage in both cases. The hydrocarbon is phytanyl (C_{20}) in part a and biphytanyl (C_{40}) in part b. (c) A major lipid of *Thaumarchaeota* is crenarchaeol, a lipid containing 5- and 6-carbon rings. (d, e) Membrane structure in *Archaea* may be bilayer or monolayer (or a mix of both).

Transport Proteins

Transport proteins do more than just carry solutes across the membrane—they function to *accumulate* solutes against the concentration gradient. The necessity for carrier-mediated transport is easy to understand. If diffusion were the only mechanism by which solutes entered a cell, the intracellular concentration of nutrients would never exceed that of the external concentration, which for most nutrients in nature is often quite low (Figure 2.19). This would be insufficient for cells to carry out biochemical reactions. Transport reactions move nutrients from low concentration

to high concentration, and as we will see in the next section, this costs the cell energy.

Transport systems show several characteristic properties. First, in contrast with diffusion, transport systems show a *saturation effect*. If the concentration of a substrate is high enough to saturate the transporter, which often occurs at very low substrate concentrations, the rate of uptake becomes maximal and the addition of more substrate does not increase the rate (Figure 2.19). This feature of transport proteins is essential for concentrating nutrients from very dilute environments. A second characteristic

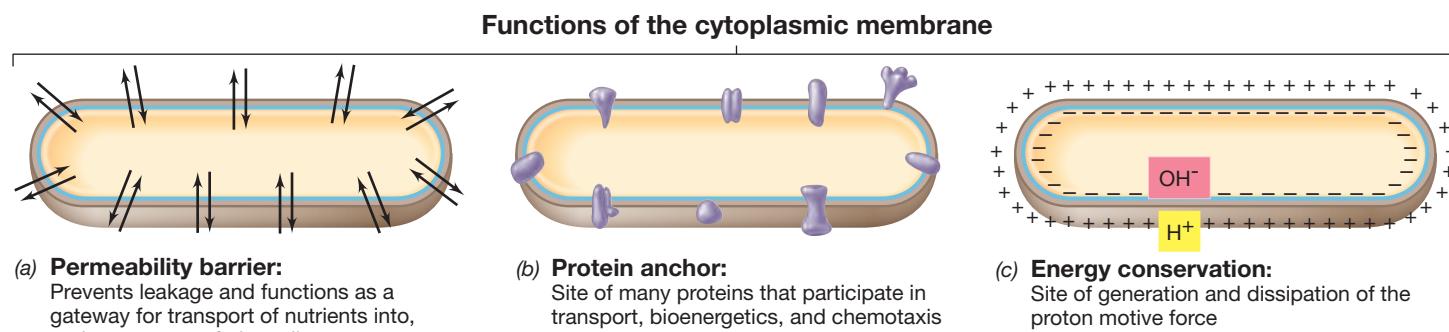

Figure 2.18 The major functions of the cytoplasmic membrane. Although structurally weak, the cytoplasmic membrane has many important cellular functions.

of carrier-mediated transport is *high specificity*. Many transport proteins carry only a single kind of molecule, whereas a few carry a related class of molecules, such as several different sugars or several different amino acids. This economizing reduces the need for separate transport proteins for each different amino acid or sugar. A third major characteristic of transport systems is that their synthesis is often *highly regulated* by the cell. That is, the specific complement of transporters present in the cytoplasmic membrane of a cell is a function of both the nature and concentration of resources in its environment. Some nutrients are transported by one transporter when present at high concentration and by a separate, usually higher-affinity transporter, when present at very low concentration.

MINIQUIZ

- Why can a cell not depend on simple diffusion as a means of acquiring its nutrients?
- Why is physical damage to the cytoplasmic membrane potentially lethal for the cell?

2.9 Nutrient Transport

To fuel metabolism and support growth, cells need to import nutrients and export wastes on a continuous basis. To fulfill these

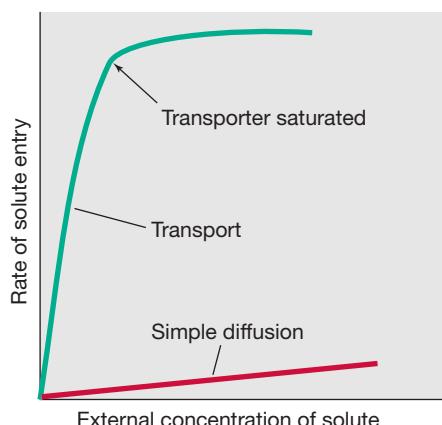

Figure 2.19 Transport versus diffusion. In transport, the uptake rate shows saturation at relatively low external concentrations.

requirements, several transport mechanisms exist in prokaryotes, each with its own unique features.

Transport Events and Transporters

At least three transport mechanisms have been well characterized in prokaryotes. **Simple transport** consists only of a membrane-spanning transport protein, **group translocation** employs a series of proteins in the transport event, and **ABC transport systems** consist of three components: a substrate-binding protein, a membrane-integrated transporter, and an ATP-hydrolyzing protein (Figure 2.20). All of these systems drive the actual transport event using the energy of the proton motive force or ATP or some other energy-rich organic compound.

Membrane transporters are typically composed of 12 polypeptides that weave back and forth through the membrane to form a

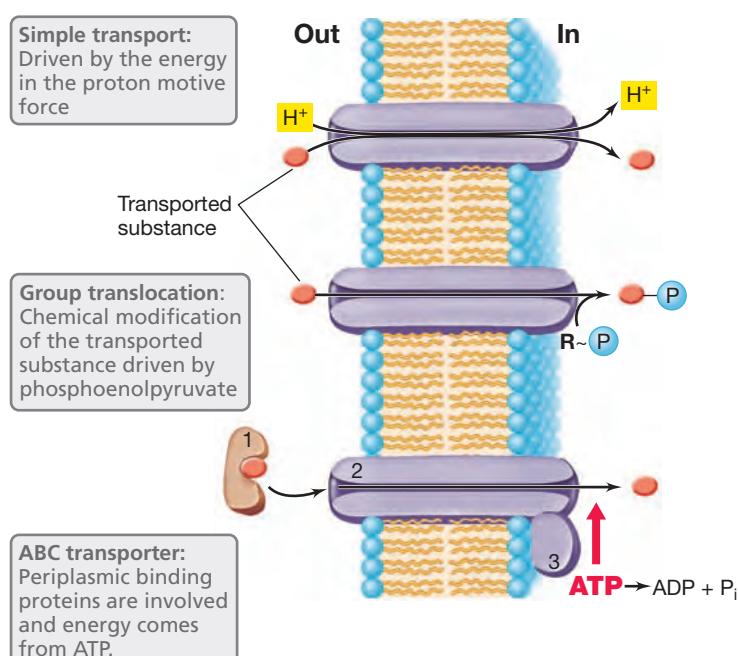

Figure 2.20 The three classes of transport systems. Note how simple transporters and the ABC system transport substances without chemically modifying them, whereas group translocation results in chemical modification (in this case phosphorylation) of the transported substance. The three proteins of the ABC system are labeled 1, 2, and 3.

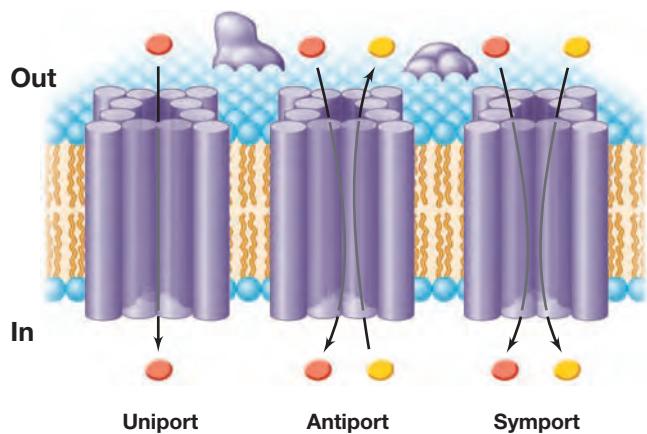

Figure 2.21 Structure of membrane-spanning transporters and types of transport events. Membrane-spanning transporters are made of 12 α -helices (each shown as a cylinder) that aggregate to form a channel through the membrane. Shown are examples of three different transport events: uniport, antiport, and symport. Red discs represent the transported molecule; yellow discs represent the cotransported molecule.

channel; it is through this channel that the solute is actually carried into the cell. Transport requires that a conformational change occur in the transport protein following binding of its solute. Like a gate swinging open, the conformational change then brings the solute into the cell.

Regardless of transport mechanism, actual transport events are of three types—*uniport*, *symport*, and *antiport*—and each event is catalyzed by a protein called a *porter* (Figure 2.21). Uniporters are proteins that carry a substance unidirectionally across the membrane, either in or out. Symporters are cotransporters; they transport a molecule along with a second substance, typically a proton. Antiporters are proteins that transport one substance into the cell while simultaneously transporting a second substance out of the cell.

Simple Transporters and Group Translocation

The bacterium *Escherichia coli* metabolizes the disaccharide sugar lactose, and lactose is transported into cells of *E. coli* by the activity of a simple transporter called *lac permease*, a type of symporter. As each lactose molecule is transported into the cell, the energy in the proton motive force is diminished slightly by the cotransport of one proton into the cytoplasm (Figure 2.21). The membrane is reenergized through energy-conserving reactions that we will describe in Chapter 3. The net result of *lac permease* activity is the energy-driven accumulation of lactose in the cytoplasm against the concentration gradient. Once in the cytoplasm, lactose is broken down and used for ATP synthesis and to make new carbon skeletons.

Group translocation differs from simple transport in two ways: (1) the transported substance is chemically modified during the transport process, and (2) an energy-rich organic compound rather than the proton motive force drives the transport event. One of the best-studied group translocation systems transports the sugars glucose, mannose, and fructose in *E. coli*. These compounds are phosphorylated during transport by the *phosphotransferase system*. The phosphotransferase system consists of a family of proteins that work in concert; five proteins are necessary to transport any given sugar. Before the sugar is transported, the proteins in the phosphotransferase system are themselves alternately phosphorylated and dephosphorylated in a cascading fashion until the actual transporter, Enzyme II_c, phosphorylates the sugar during the transport event (Figure 2.22). A protein called HPr, the enzyme that phosphorylates HPr (Enzyme I), and Enzyme II_a are all cytoplasmic proteins. By contrast, Enzyme II_b lies on the inner surface of the membrane and Enzyme II_c is an integral membrane protein.

HPr and Enzyme I are nonspecific components of the phosphotransferase system and participate in the uptake of several different sugars. Several different versions of Enzyme II exist, one for

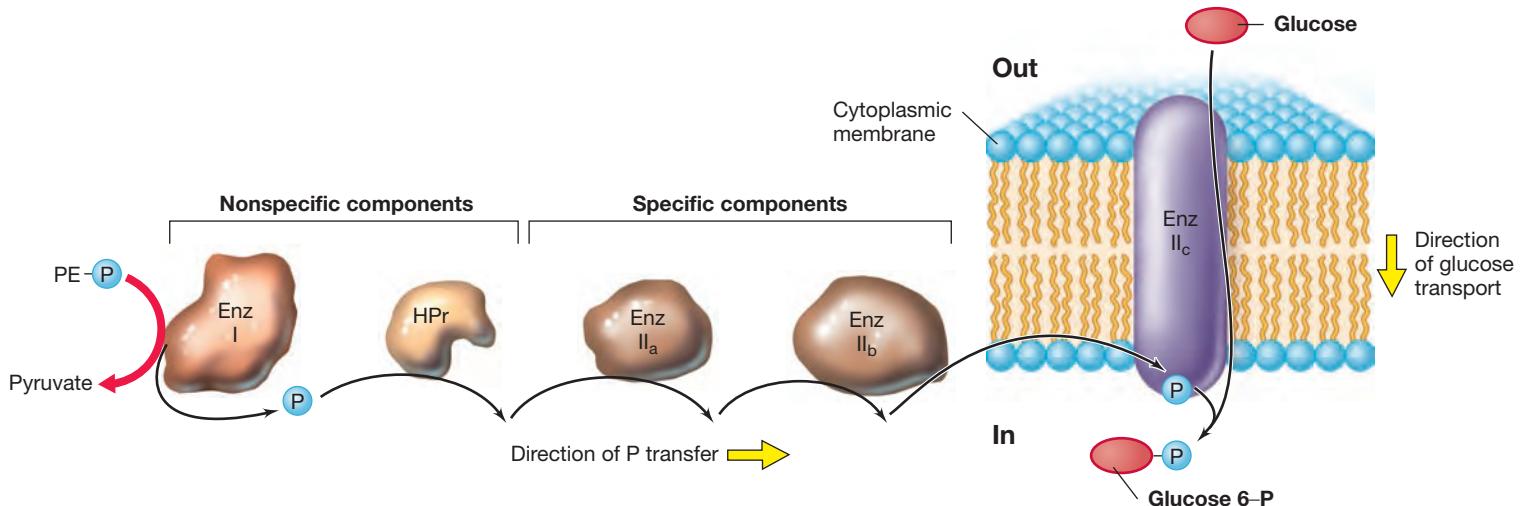

Figure 2.22 Mechanism of the phosphotransferase system of *Escherichia coli*. For glucose uptake, the system consists of five proteins: Enzyme (Enz) I, Enzymes II_a, II_b, and II_c, and HPr. A phosphate cascade occurs from phosphoenolpyruvate (PE-P) to Enzyme II_c and the latter actually transports and phosphorylates the sugar. Proteins HPr and Enz I are nonspecific and transport any sugar. The Enz II components are specific for each particular sugar.

each different sugar transported (Figure 2.22). Energy to drive the phosphotransferase system comes from phosphoenolpyruvate, an energy-rich intermediate in glycolysis (➡ Section 3.8).

Periplasmic Binding Proteins and the ABC System

We will learn shortly that gram-negative bacteria contain a region called the *periplasm* that lies between the cytoplasmic membrane and a second membrane layer called the *outer membrane*, part of the gram-negative cell wall (Section 2.11). The periplasm contains many different proteins, several of which function in transport and are called *periplasmic binding proteins*. Transport systems that employ periplasmic binding proteins along with a membrane transporter and ATP-hydrolyzing proteins are called ABC transport systems, the “ABC” standing for *ATP-binding cassette*, a structural feature of proteins that bind ATP (Figure 2.23). More than 200 different ABC transport systems have been identified in prokaryotes. ABC transporters exist for the uptake of organic compounds such as sugars and amino acids, inorganic nutrients such as sulfate and phosphate, and certain metals.

A characteristic property of periplasmic binding proteins is their high substrate affinity. These proteins can bind their substrate(s) even when the substrate is present at extremely low concentration; for example, less than 1 micromolar (10^{-6} M). Once its substrate is bound, the periplasmic binding protein interacts with its respective membrane transporter to transport the substrate into the cell driven by the energy in ATP (Figure 2.23).

Even though gram-positive bacteria lack a periplasm, they also have ABC transport systems. In gram-positive bacteria, however, substrate-binding proteins (the functional equivalent of periplasmic binding proteins) are anchored to the external surface of the cytoplasmic membrane. Once they bind their substrate, these proteins interact with a membrane transporter to catalyze the ATP-driven uptake of the substrate.

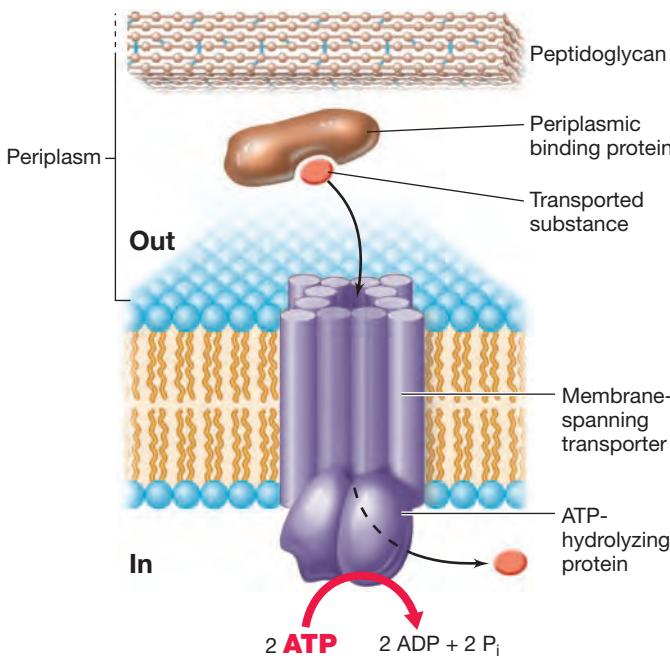

Figure 2.23 Mechanism of an ABC transporter. The periplasmic binding protein has high affinity for substrate, the membrane-spanning proteins form the transport channel, and the cytoplasmic ATP-hydrolyzing proteins supply the energy for the transport event.

MINIQUIZ

- Compare and contrast simple transporters, the phosphotransferase system, and ABC transporters in terms of (1) energy source, (2) chemical alterations of the solute during transport, and (3) number of proteins required.
- Which major characteristic of periplasmic-binding proteins makes them ideally suited for organisms living in very nutrient-poor environments?

IV • Cell Walls of *Bacteria* and *Archaea*

The cytoplasm of prokaryotic cells maintains a high concentration of dissolved solutes, and this creates a significant osmotic pressure—about 2 atm (203 kPa)—in a typical cell. This is about the same as the pressure in an automobile tire. To withstand these pressures and prevent bursting (cell lysis), most cells of *Bacteria* and *Archaea* contain a wall. Besides protecting against osmotic lysis, cell walls also confer shape and rigidity on the cell. Knowledge of cell wall structure and function is important not only for understanding how prokaryotic cells work, but also because certain antibiotics target cell wall synthesis, leaving the cell susceptible to lysis. Since human cells lack cell walls, these antibiotics are of obvious benefit for treating bacterial infections.

2.10 Peptidoglycan

As we saw earlier, species of *Bacteria* can be divided into two major groups, called *gram-positive* and *gram-negative*. The distinction

between gram-positive and gram-negative bacteria is based on the Gram stain reaction (Section 2.2), and differences in cell wall structure are at the heart of the Gram stain reaction. The surface of gram-positive and gram-negative cells as viewed in the electron microscope differs markedly, as shown in Figure 2.24. The gram-negative cell wall, or *cell envelope* as it is often called, consists of at least two layers, whereas the gram-positive cell wall is typically much thicker and consists primarily of a single type of molecule.

We focus here on the polysaccharide component of the cell walls of *Bacteria*, both gram-positive and gram-negative. In the next section, we describe the special wall components present in gram-negative *Bacteria*. In Section 2.12, we describe the cell walls of *Archaea*.

Chemistry of Peptidoglycan

The walls of *Bacteria* have a rigid layer that is primarily responsible for the strength of the wall. This rigid layer, called

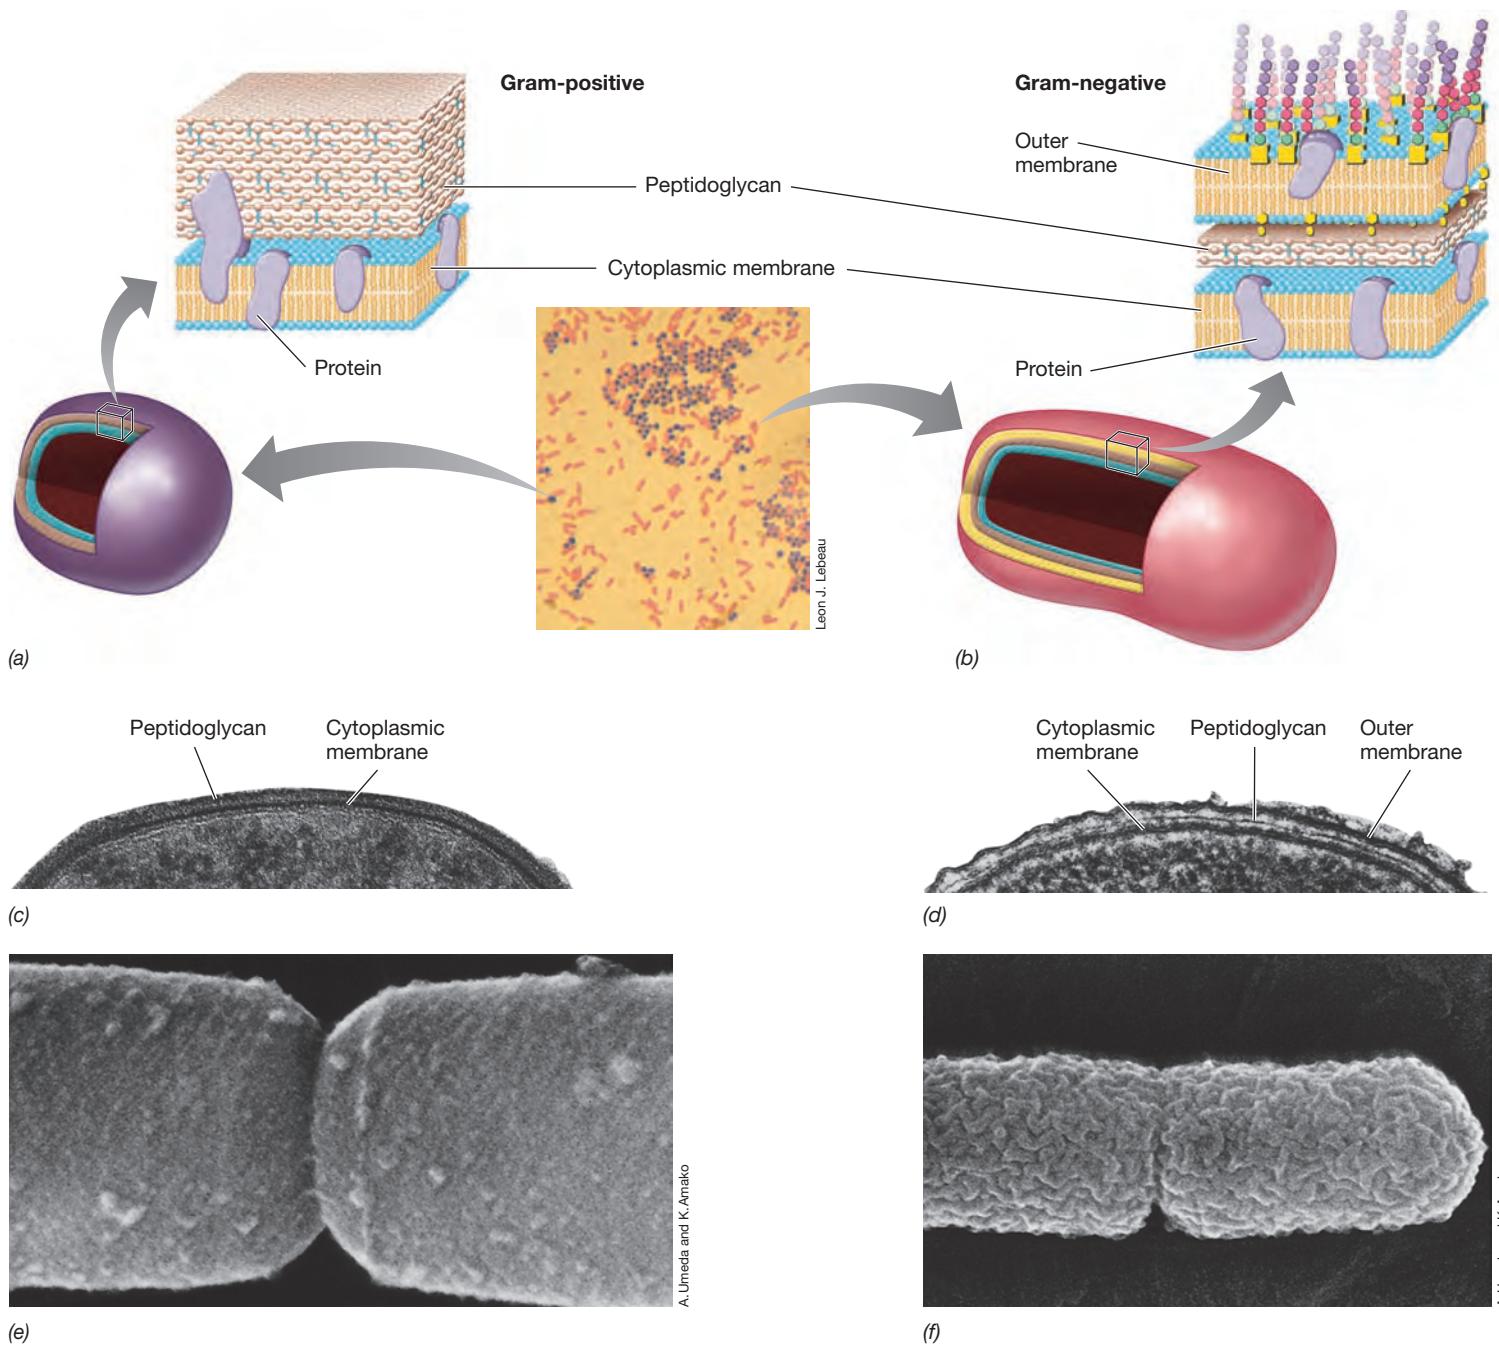

Figure 2.24 Cell walls of *Bacteria*. (a, b) Schematic diagrams of gram-positive and gram-negative cell walls. The Gram stain photo in the center shows cells of *Staphylococcus aureus* (purple, gram-positive) and *Escherichia coli* (pink, gram-negative). (c, d) Transmission electron micrographs (TEMs) showing the cell wall of a gram-positive bacterium and a gram-negative bacterium. (e, f) Scanning electron micrographs of gram-positive and gram-negative bacteria, respectively. Note differences in surface texture. Each cell in the TEMs is about 1 μm wide.

peptidoglycan, is a polysaccharide composed of two sugar derivatives—*N*-acetylglucosamine and *N*-acetylmuramic acid—and a few amino acids, including L-alanine, D-alanine, D-glutamic acid, and either L-lysine or a structurally similar molecule, diaminopimelic acid (DAP). These constituents are connected to form a repeating structure called the *glycan tetrapeptide* (Figure 2.25).

Long chains of peptidoglycan are biosynthesized adjacent to one another to form a sheet surrounding the cell. The individual chains are connected by cross-links of amino acids. The glycosidic bonds connecting the sugars in the glycan strands are covalent bonds, but these provide rigidity in only one direction. Only after cross-linking is peptidoglycan strong in both the X and Y directions (Figure 2.26). Cross-linking occurs to different degrees

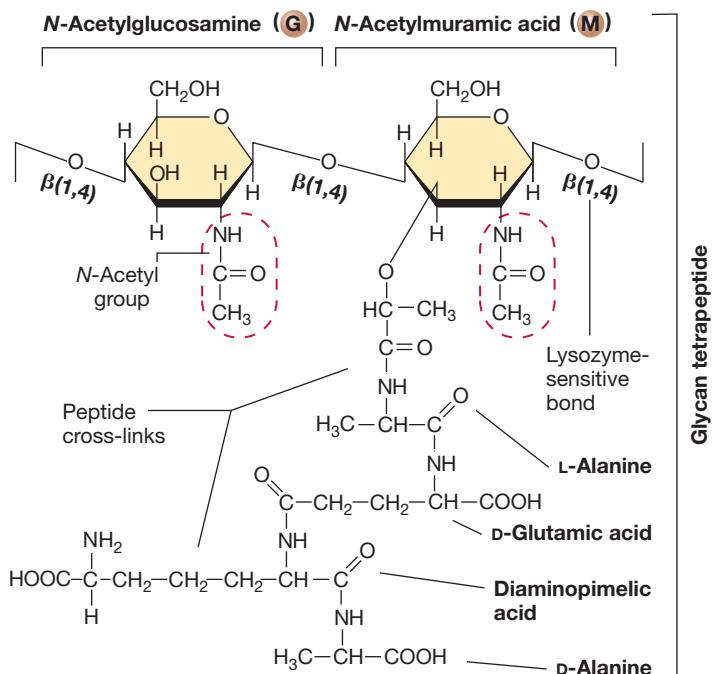

Figure 2.25 Structure of the repeating unit in peptidoglycan, the glycan tetrapeptide. The structure given is that found in *Escherichia coli* and most other gram-negative *Bacteria*. In some *Bacteria*, other amino acids are present as discussed in the text.

in different species of *Bacteria*, and the more extensive the cross-linking, the greater the rigidity.

In gram-negative bacteria, the peptidoglycan cross-link is formed by a peptide bond from the amino group of DAP of one glycan chain to the carboxyl group of the terminal d-alanine on the adjacent glycan chain (Figure 2.26). In gram-positive bacteria, the cross-link often occurs through a short peptide interbridge, the kinds and numbers of amino acids in the interbridge varying from species to species. In the gram-positive bacterium *Staphylococcus aureus*, whose cell wall chemistry is well understood, the interbridge consists of five glycine residues (Figure 2.26b). The overall structure of peptidoglycan is shown in Figure 2.26c.

Peptidoglycan can be destroyed by certain agents. One such agent is the enzyme *lysozyme*, a protein that cleaves the β -1,4-glycosidic bonds between *N*-acetylglucosamine and *N*-acetylmuramic acid in peptidoglycan (Figure 2.25), thereby weakening the wall. When this occurs, water can enter the cell and cause cell lysis. Lysozyme is present in animal secretions including tears, saliva, and other body fluids, and functions as a major line of defense against bacterial infection. When we consider peptidoglycan biosynthesis in Chapter 5 we will see that the antibiotic penicillin also targets peptidoglycan, but in a different way from that of lysozyme. Whereas lysozyme destroys preexisting peptidoglycan, penicillin instead prevents its biosynthesis, leading to a weakened molecule and osmotic lysis.

Peptidoglycan is found only in *Bacteria*; *N*-acetylmuramic acid and the amino acid analog DAP have never been found in the cell walls of *Archaea* or *Eukarya*. However, not all *Bacteria* examined have DAP in their peptidoglycan; some have lysine

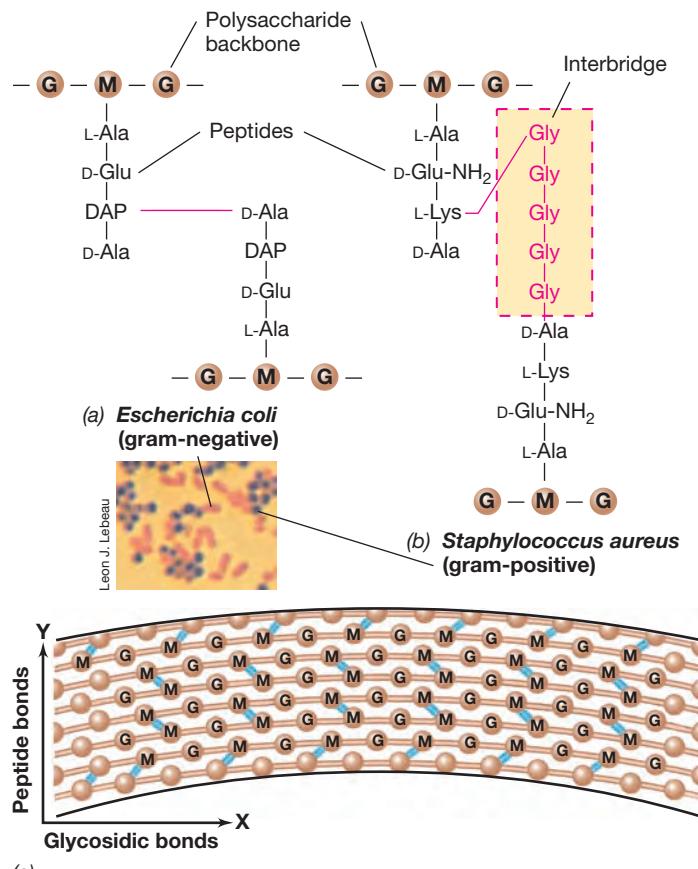

Figure 2.26 Peptidoglycan in *Escherichia coli* and *Staphylococcus aureus*.

(a) No interbridge is present in *E. coli* peptidoglycan nor that of other gram-negative *Bacteria*. (b) The glycine interbridge in *S. aureus* (gram-positive). (c) Overall structure of peptidoglycan. G, *N*-acetylglucosamine; M, *N*-acetylmuramic acid. Note how glycosidic bonds confer strength on peptidoglycan in the X direction whereas peptide bonds confer strength in the Y direction.

instead. An unusual feature of peptidoglycan is the presence of two amino acids of the D stereoisomer, d-alanine and d-glutamic acid. Proteins, by contrast, are always constructed of L-amino acids. More than 100 chemically distinct peptidoglycans have been described that vary in their peptide cross-links and/or interbridge. By contrast, the glycan portion of all peptidoglycans is constant; only *N*-acetylglucosamine and *N*-acetylmuramic acid are present and are connected in β -1,4 linkage (Figures 2.25 and 2.26).

The Gram-Positive Cell Wall

As much as 90% of the gram-positive cell wall is composed of peptidoglycan. And, although some bacteria have only a single layer of peptidoglycan, many gram-positive bacteria have several sheets of peptidoglycan stacked one upon another (Figure 2.26a). It is thought that peptidoglycan is synthesized by the cell in "cables" about 50 nm wide, with each cable containing several cross-linked glycan strands (Figure 2.27a). As the peptidoglycan is synthesized, the cables become cross-linked to form an even stronger cell wall structure.

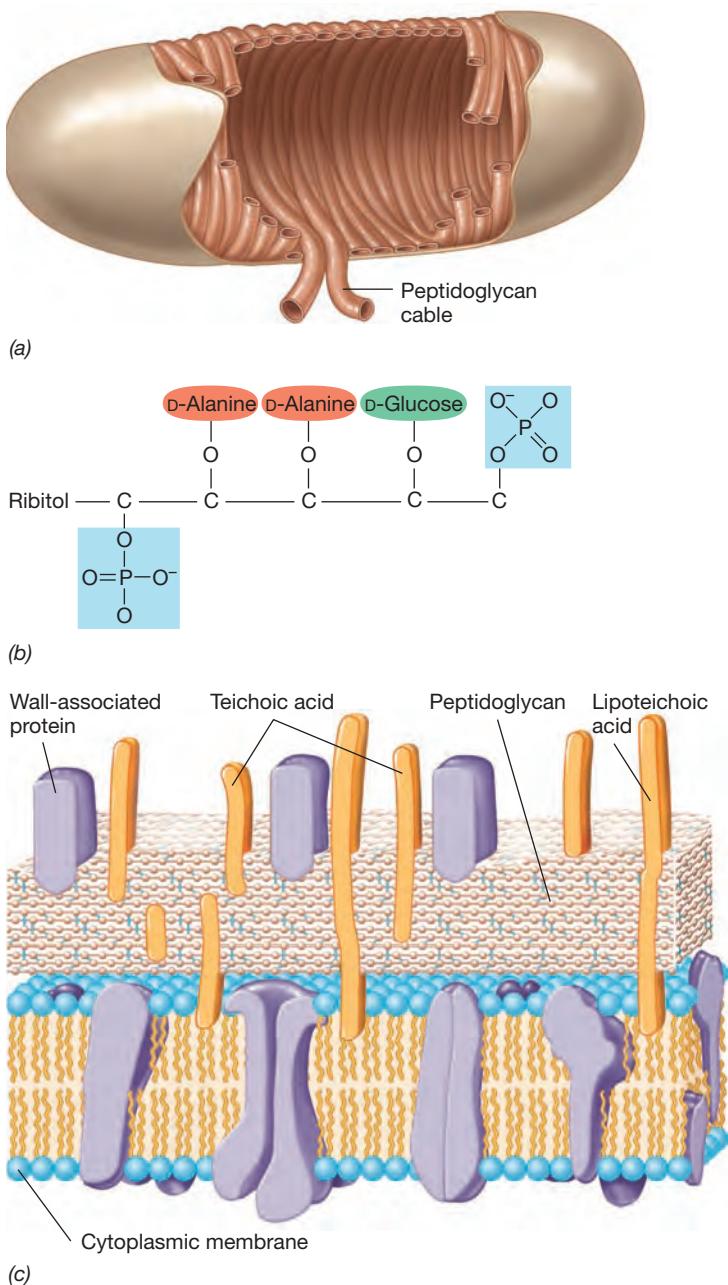

Figure 2.27 Structure of the gram-positive bacterial cell wall. (a) Schematic of a gram-positive rod showing the internal architecture of the peptidoglycan “cables.” (b) Structure of a ribitol teichoic acid. The teichoic acid is a polymer of the repeating ribitol unit shown here. (c) Summary diagram of the gram-positive bacterial cell wall.

Many gram-positive bacteria have acidic molecules called **teichoic acids** embedded in their cell wall. The term “teichoic acids” includes all cell wall, cytoplasmic membrane, and capsular polymers composed of glycerol phosphate or ribitol phosphate. These polyalcohols are connected by phosphate esters and typically contain sugars or D-alanine (Figure 2.27b). Teichoic acids are covalently bonded to muramic acid in the wall peptidoglycan. Because the phosphates are negatively charged, teichoic acids are in part responsible for the overall negative electrical charge of the cell surface. Teichoic acids also function to bind Ca^{2+} and

Mg^{2+} for eventual transport into the cell. Certain teichoic acids are covalently bound to membrane lipids, and these are called *lipoteichoic acids*. Figure 2.27 summarizes the structure of the cell wall of gram-positive *Bacteria* and shows how teichoic acids and lipoteichoic acids are arranged in the overall wall structure.

Although most prokaryotes cannot survive in nature without their cell walls, some do. These include the mycoplasmas, pathogenic bacteria related to gram-positive bacteria that cause several infectious diseases of humans and other animals, and *Thermoplasma* and its relatives, species of *Archaea* that naturally lack cell walls. These organisms are able to survive without cell walls because they either contain unusually tough cytoplasmic membranes or because they live in osmotically protected habitats such as the animal body. Most mycoplasmas have sterols in their cytoplasmic membranes, and these molecules function to add strength and rigidity to the membrane as they do in the cytoplasmic membranes of eukaryotic cells. *Thermoplasma* membranes contain molecules called *lipoglycans* that serve a similar strengthening function.

MINIQUIZ

- Why do bacterial cells need cell walls? Do all bacteria have cell walls?
- Why is peptidoglycan such a strong molecule?
- What does the enzyme lysozyme do?

2.11 LPS: The Outer Membrane

In gram-negative bacteria, only a small amount of the total cell wall consists of peptidoglycan, as most of the wall is composed of the **outer membrane**. This layer is effectively a second lipid bilayer, but it is not constructed solely of phospholipid and protein, as is the cytoplasmic membrane (Figure 2.15). Instead, the outer membrane also contains polysaccharide, and the lipid and polysaccharide are linked to form a complex. Because of this, the outer membrane is often called the **lipopolysaccharide** layer, or simply **LPS** for short.

Chemistry and Activity of LPS

The structure of LPS from several bacteria is known. As seen in Figure 2.28, the polysaccharide portion of LPS consists of two components, the *core polysaccharide* and the *O-specific polysaccharide*. In *Salmonella* species, where LPS has been well studied, the core polysaccharide consists of ketodeoxyoctonate (KDO), various seven-carbon sugars (heptoses), glucose, galactose, and N-acetylglucosamine. Connected to the core is the O-specific polysaccharide, which typically contains galactose, glucose, rhamnose, and mannose, as well as one or more dideoxyhexoses, such as abequose, colitose, paratose, or tyvelose. These sugars are connected in four- or five-membered sequences, which often are branched. When the sequences repeat, the long O-specific polysaccharide is formed.

The relationship of the LPS layer to the overall gram-negative cell wall is shown in Figure 2.29. The lipid portion of the LPS, called *lipid A*, is not a typical glycerol lipid (see Figure 2.14a), but instead the fatty acids are connected through the amine groups from a disaccharide composed of glucosamine phosphate. The disaccharide is attached to the core polysaccharide through KDO

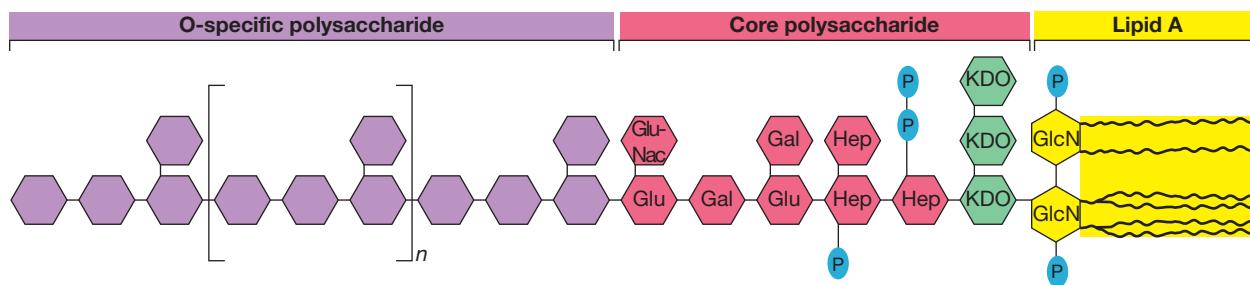

Figure 2.28 Structure of the lipopolysaccharide of gram-negative *Bacteria*. The chemistry of lipid A and the polysaccharide components varies among species of gram-negative *Bacteria*, but the major components (lipid A-KDO-core-O-specific) are typically the same. The O-specific polysaccharide is highly variable among species. KDO, ketodeoxyoctonate; Hep, heptose; Glu, glucose; Gal, galactose; GluNAc, N-acetylglucosamine; GlcN, glucosamine; P, phosphate. Glucosamine and the lipid A fatty acids are linked through the amine groups. The lipid A portion of LPS can be toxic to animals and comprises the endotoxin complex. Compare this figure with Figure 2.29 and follow the LPS components by their color-coding.

(Figure 2.28). Fatty acids commonly found in lipid A include caprylic (C_6), lauric (C_{12}), myristic (C_{14}), palmitic (C_{16}), and stearic (C_{18}) acids. LPS replaces much of the phospholipid in the outer half of the outer membrane and functions as an anchor tying the outer membrane to peptidoglycan. Thus, although the outer membrane is technically a lipid bilayer, its structure is distinct from that of the cytoplasmic membrane.

Besides its importance in rendering strength to the gram-negative cell, an important biological activity of LPS is its toxicity to animals. Common gram-negative pathogens for humans include species of *Salmonella*, *Shigella*, and *Escherichia*, among many others, and some of the gastrointestinal symptoms these pathogens elicit are due to toxic outer membrane components. Toxicity is associated with the LPS layer, in particular, lipid A. The term *endotoxin* refers to this toxic component of LPS. Some endotoxins cause violent symptoms in humans, including gas, diarrhea, and vomiting, and the endotoxins produced by *Salmonella* and enteropathogenic strains of *E. coli* transmitted in contaminated foods are classic examples of this (► Sections 23.10 and 31.10).

The Periplasm and Porins

Although permeable to small molecules, the outer membrane is impermeable to proteins and other very large molecules. In fact, one of the major functions of the outer membrane is to prevent proteins whose activities occur outside the cytoplasmic membrane from diffusing away from the cell. These proteins are present in a region called the **periplasm**. This space, located between the outer surface of the cytoplasmic membrane and the inner surface of the outer membrane, is about 15 nm wide (Figure 2.29). The periplasm is gel-like in consistency because of the high concentration of proteins there.

Depending on the organism, the periplasm can contain several different classes of proteins. These include hydrolytic enzymes, which function in the initial degradation of food molecules; binding proteins, which begin the process of transporting substrates (Section 2.9); and chemoreceptors, which are proteins that govern the chemotaxis response (Section 2.19). Most of these proteins reach the periplasm by way of a protein-exporting system present in the cytoplasmic membrane (► Section 4.14).

The outer membrane is relatively permeable to small molecules (even hydrophilic molecules) because of proteins called **porins**

that function as channels for the entrance and exit of solutes (Figure 2.29a, c). Several porins are known, including both specific and nonspecific classes. Nonspecific porins form water-filled channels through which any small substance can pass. By contrast, specific porins contain a binding site for only one or a small group of structurally related substances. Structurally, porins are transmembrane proteins made up of three identical subunits. Besides the channel present in each barrel of the porin, the barrels of the three porin proteins associate in such a way that a small hole about 1 nm in diameter is formed in the outer membrane through which very small molecules can travel (Figure 2.29c).

Relationship of Cell Wall Structure to the Gram Stain

The structural differences between the cell walls of gram-positive and gram-negative *Bacteria* are responsible for differences in the Gram stain reaction. Recall that in the Gram stain, an insoluble crystal violet–iodine complex forms inside the cell. This complex is extracted by alcohol from gram-negative but not from gram-positive bacteria (Section 2.2). As we have seen, gram-positive bacteria have very thick cell walls consisting primarily of peptidoglycan. During Gram staining, the gram-positive cell wall is dehydrated by the alcohol, causing the pores in the walls to close and preventing the insoluble crystal violet–iodine complex from escaping. By contrast, in gram-negative bacteria, alcohol readily penetrates the lipid-rich outer membrane and extracts the crystal violet–iodine complex from the cell. After alcohol treatment, gram-negative cells are nearly invisible unless they are counterstained with a second dye, a standard procedure in the Gram stain (Figure 2.4).

MINIQUIZ

- What chemical components are found in the outer membrane of gram-negative bacteria?
- What is the function of porins and where are they located in a gram-negative cell wall?
- What component of the gram-negative cell has endotoxin properties?
- Why does alcohol readily decolorize gram-negative but not gram-positive bacteria?

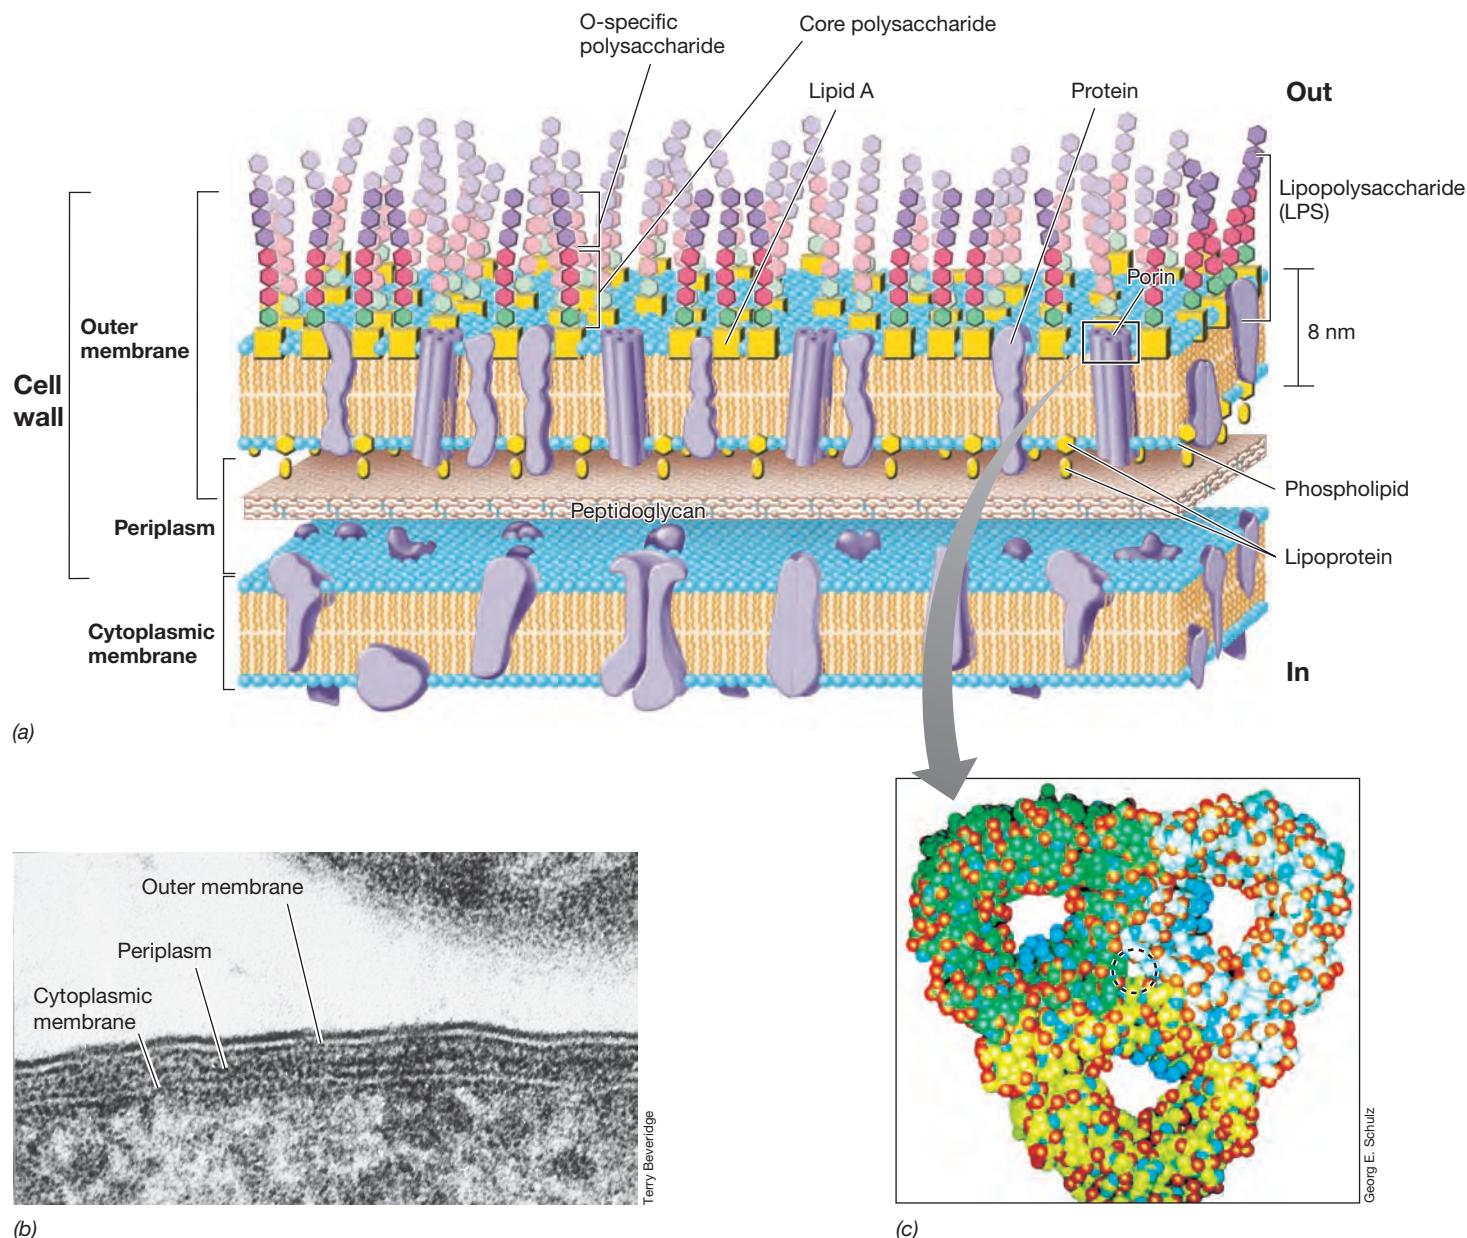

Figure 2.29 The gram-negative cell wall. (a) Arrangement of lipopolysaccharide, lipid A, phospholipid, porins, and lipoprotein in the outer membrane. See Figure 2.28 for details of the structure of LPS. (b) Transmission electron micrograph of a cell of *Escherichia coli* showing the cytoplasmic membrane and wall. (c) Molecular model of porin proteins. Note the four pores present, one within each of the proteins forming a porin molecule and a smaller central pore (circled) between the porin proteins. The view is perpendicular to the plane of the membrane.

2.12 Archaeal Cell Walls

Peptidoglycan, a key biomarker for *Bacteria*, is absent from the cell walls of *Archaea*. An outer membrane is typically lacking in *Archaea* as well. Instead, a variety of cell wall types are found in *Archaea*, including those containing polysaccharides, proteins, or glycoproteins.

Pseudomurein and Other Polysaccharide Walls

The cell walls of certain methanogenic *Archaea* contain a molecule that is remarkably similar to peptidoglycan, a polysaccharide called *pseudomurein* (the term “murein” is from the Latin

word for “wall” and was an old term for peptidoglycan) (Figure 2.30). The backbone of pseudomurein is formed from alternating repeats of *N*-acetylglucosamine (also present in peptidoglycan) and *N*-acetyltalosaminuronic acid; the latter replaces the *N*-acetylmuramic acid of peptidoglycan. Pseudomurein also differs from peptidoglycan in that the glycosidic bonds between the sugar derivatives are β -1,3 instead of β -1,4, and the amino acids are all of the L stereoisomer (Figure 2.30). It is thought that peptidoglycan and pseudomurein either arose by convergent evolution after *Bacteria* and *Archaea* had diverged or, more likely, by evolution from a common polysaccharide present in

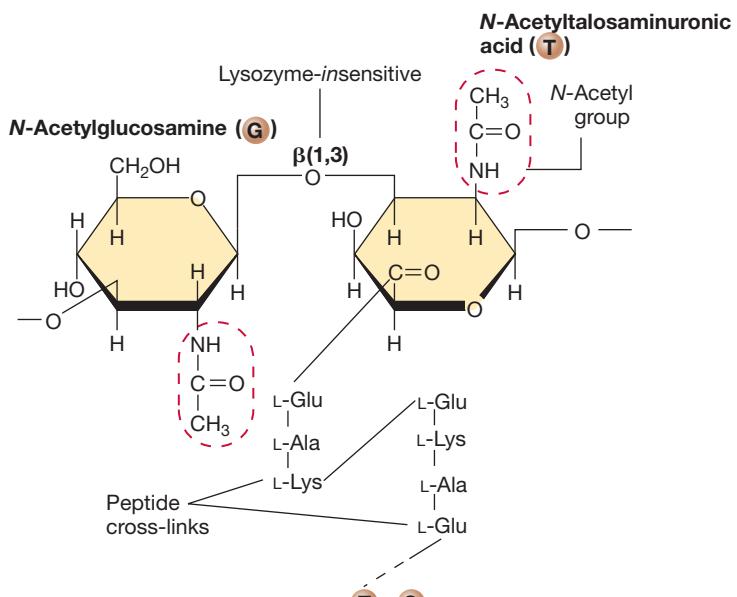

Figure 2.30 Pseudomurein. Structure of pseudomurein, the cell wall polymer of *Methanobacterium* species. Note the similarities and differences between pseudomurein and peptidoglycan (Figure 2.25).

the cell walls of the common ancestor of the domains *Bacteria* and *Archaea*.

Cell walls of some other *Archaea* lack pseudomurein and instead contain other polysaccharides. For example, *Methanoscincina* species have thick polysaccharide walls composed of polymers of glucose, glucuronic acid, galactosamine uronic acid, and acetate. Extremely halophilic (salt-loving) *Archaea* such as *Halococcus*, which are related to *Methanoscincina*, have similar cell walls that are also highly sulfated. The negative charges on the sulfate ion (SO_4^{2-}) bind Na^+ present in the habitats of *Halococcus*—salt evaporation ponds and saline seas and lakes—at high levels. The sulfate–sodium complex helps stabilize the *Halococcus* cell wall in such strongly ionic environments.

S-Layers

The most common type of cell wall in *Archaea* is the paracrystalline surface layer, or **S-layer** as it is called. S-layers consist of interlocking molecules of protein or glycoprotein (Figure 2.31). The paracrystalline structure of S-layers can form various symmetries, including hexagonal, tetragonal, or trimeric, depending upon the number and structure of the subunits of which it is composed. S-layers have been found in representatives of all major lineages of *Archaea* and also in several species of *Bacteria* (Figure 2.31).

The cell walls of some *Archaea*, for example the methanogen *Methanocoldococcus jannaschii*, consist only of an S-layer. Thus, S-layers are sufficiently strong to withstand osmotic pressures without any other wall components. However, in many organisms S-layers are present in addition to other cell wall components, usually polysaccharides. For example, in *Bacillus brevis*, a species of *Bacteria*, an S-layer is present along with peptidoglycan.

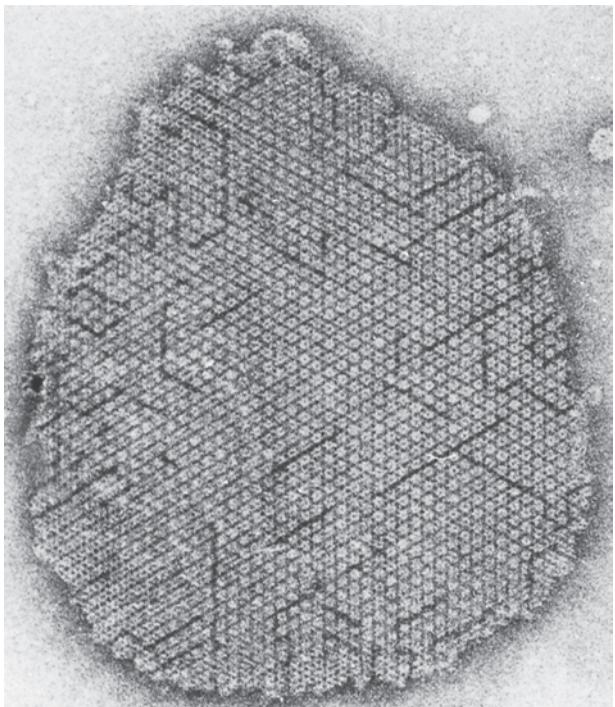

Figure 2.31 The S-layer. Transmission electron micrograph of a portion of an S-layer showing the paracrystalline structure. Shown is the S-layer from *Aquaspirillum* (a species of *Bacteria*), and this S-layer shows hexagonal symmetry common in S-layers of *Archaea*.

However, when an S-layer is present along with other wall components, the S-layer is always the *outermost* wall layer, the layer that is in direct contact with the environment.

Besides serving as protection from osmotic lysis, S-layers may have other functions. For example, as the interface between the cell and its environment, it is likely that the S-layer functions as a selective sieve, allowing the passage of low-molecular-weight solutes while excluding large molecules or structures (such as viruses). The S-layer may also function to retain proteins near the cell surface, much as the outer membrane (Section 2.11) does in gram-negative bacteria.

We thus see several cell wall structures in species of *Archaea*, varying from those that closely resemble peptidoglycan to those that totally lack polysaccharide. But with rare exception, all *Archaea* contain a cell wall of some sort, and as in *Bacteria*, the archaeal cell wall functions to prevent osmotic lysis and gives the cell its shape. Because they lack peptidoglycan, *Archaea* are naturally resistant to lysozyme (Figure 2.30) and the antibiotic penicillin, agents that either destroy peptidoglycan or interrupt its biosynthesis (Section 2.10).

MINIQUIZ

- How does pseudomurein resemble peptidoglycan? How do the two molecules differ?
 - What is the composition of an S-layer?
 - Why are Archaea insensitive to penicillin?

V • Other Cell Surface Structures and Inclusions

In addition to cell walls, cells of *Bacteria* and *Archaea* may have other layers or structures in contact with the environment and often contain one or more types of cellular inclusions. We examine some of these here.

2.13 Cell Surface Structures

Many prokaryotes secrete sticky or slimy materials on their cell surface that consist of either polysaccharide or protein. These are not considered part of the cell wall because they do not confer significant structural strength on the cell. The terms “capsule” and “slime layer” are used to describe these layers.

Capsules and Slime Layers

The terms capsule and slime layer are often used interchangeably, but the two terms do not refer to the same thing. Traditionally, if the layer is organized in a tight matrix that excludes small particles, such as India ink, it is called a **capsule**. Such a structure is readily visible by light microscopy if cells are treated with India ink and can also be seen in the electron microscope (Figure 2.32). By contrast, if the layer is more easily deformed, it will not exclude particles and is more difficult to see; this form is called a *slime layer*. Capsules typically adhere firmly to the cell wall, and some are even covalently linked to peptidoglycan. Slime layers, by contrast, are loosely attached and can be lost from the cell surface.

Outer surface layers have several functions. Surface polysaccharides assist in the attachment of microorganisms to solid surfaces. As we will see later, pathogenic microorganisms that enter the body by specific routes usually do so by first binding specifically to surface components of host tissues; this binding is often mediated by bacterial cell surface polysaccharides (➡ Section 23.1). When the opportunity arises, bacteria of all types typically bind to solid surfaces, often forming a thick layer of cells called a *biofilm*. Extracellular polysaccharides play a key role in the development and maintenance of biofilms as well.

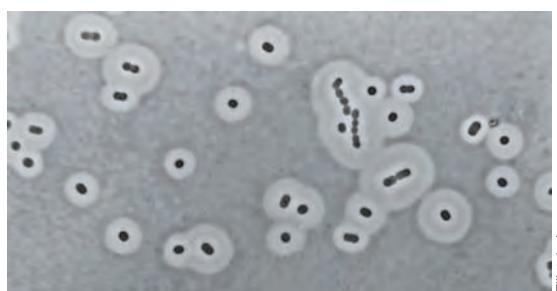

Besides attachment, outer surface layers can have other functions. These include acting as virulence factors in certain bacterial diseases and preventing the cell from suffering dehydration. For example, the causative agent of the diseases anthrax and bacterial pneumonia—*Bacillus anthracis* and *Streptococcus pneumoniae*, respectively—each contain a thick capsule of either protein (*B. anthracis*) or polysaccharide (*S. pneumoniae*). Encapsulated cells of these bacteria avoid destruction by the host immune system because the immune cells that would otherwise recognize these pathogens as foreign and destroy them are blocked from doing so because of the bacterial capsule. In addition to this role in disease, outer surface layers of virtually any type bind water and likely protect the cell from desiccation in periods of dryness.

Fimbriae and Pili

Fimbriae and pili are filamentous proteins that extend from the surface of a cell and can have many functions. Fimbriae (Figure 2.33) enable cells to stick to surfaces, including animal tissues in the case of pathogenic bacteria, or to form pellicles (thin sheets of

cells on a liquid surface) or biofilms on solid surfaces. Notorious human pathogens in which fimbriae assist in the disease process include *Salmonella* species (salmonellosis), *Neisseria gonorrhoeae* (gonorrhea), and *Bordetella pertussis* (whooping cough).

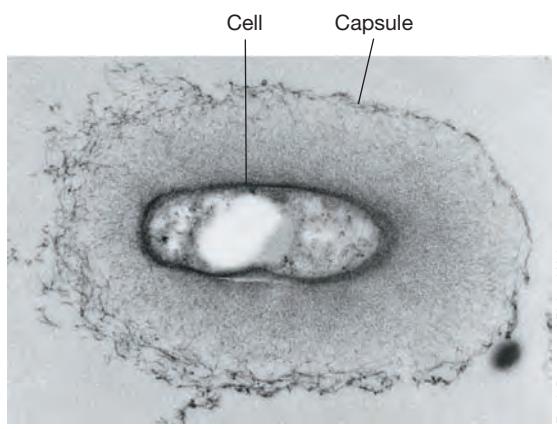

Pili are similar to fimbriae, but are typically longer and only one or a few pili are present on the surface of a cell. Because pili can be receptors for certain types of viruses, they can best be seen

(a)

(b)

(c)

Figure 2.32 Bacterial capsules. (a) Capsules of *Acinetobacter* species observed by phase-contrast microscopy after negative staining with India ink. India ink does not penetrate the capsule and so the capsule appears as a light area surrounding the cell, which appears black. (b) Transmission electron micrograph of a thin section of cells of *Rhodobacter capsulatus* with capsules (arrows) clearly evident; cells are about 0.9 μm wide. (c) Transmission electron micrograph of *Rhizobium trifoli* stained with ruthenium red to reveal the capsule. The cell is about 0.7 μm wide.

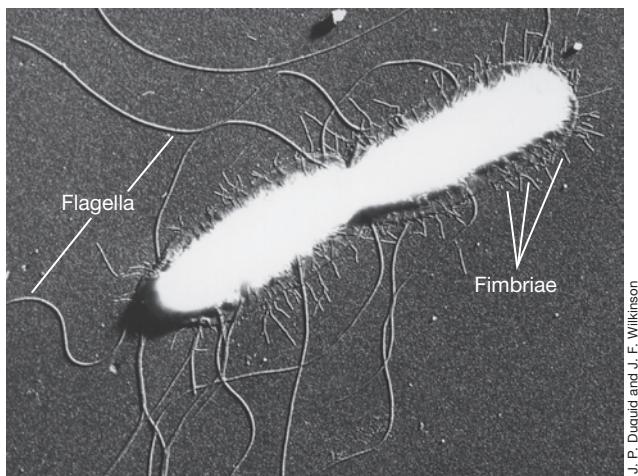

Figure 2.33 **Fimbriae.** Electron micrograph of a dividing cell of *Salmonella typhi*, showing flagella and fimbriae. A single cell is about 0.9 μm wide.

under the electron microscope when they become coated with virus particles (Figure 2.34). Many classes of pili are known, distinguished by their structure and function. Two very important functions of pili include facilitating genetic exchange between cells in a process called *conjugation* and enabling the adhesion of pathogens to specific host tissues that they subsequently invade. The latter function has been best studied in gram-negative pathogens such as *Neisseria*, species of which cause the diseases gonorrhea and meningitis, but pili are also present on certain gram-positive pathogens such as *Streptococcus pyogenes*, the bacterium that causes both strep throat and scarlet fever.

One important class of pili, called *type IV pili*, assist cells in adhesion but also allow for an unusual form of cell motility called *twitching motility*. Type IV pili are present only at the poles of those rod-shaped cells that contain them. Twitching motility is a type of gliding motility, movement along a solid surface (Section 2.18). In twitching motility, extension of pili followed by their retraction drags the cell along a solid surface, with energy supplied by ATP. Certain species of *Pseudomonas* and *Moraxella* are well known for their twitching motility.

Type IV pili have also been implicated as key colonization factors for certain human pathogens, including *Vibrio cholerae* (cholera) and *Neisseria gonorrhoeae* (gonorrhea). The twitching

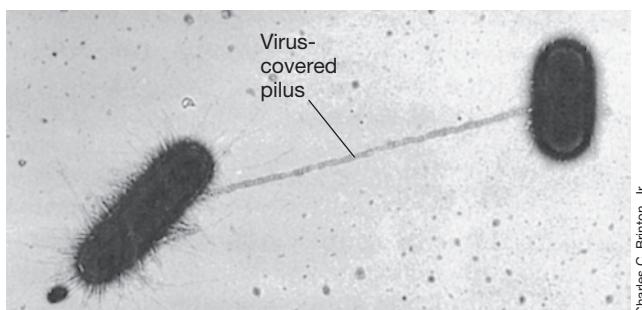

Figure 2.34 **Pili.** The pilus on an *Escherichia coli* cell that is undergoing conjugation (a form of genetic transfer) with a second cell is better resolved because viruses have adhered to it. The cells are about 0.8 μm wide.

motility of these pathogens presumably assists the organism to locate specific sites for attachment to initiate the disease process. Type IV pili are also thought to mediate genetic transfer by the process of transformation in some bacteria, which, along with conjugation and transduction, are the three known means of horizontal gene transfer in prokaryotes (Chapter 10).

MINIQUIZ

- Could a bacterial cell dispense with a cell wall if it had a capsule? Why or why not?
- How do fimbriae differ from pili, both structurally and functionally?

2.14 Cell Inclusions

Inclusions are often present in prokaryotic cells. Inclusions function as energy reserves and/or carbon reservoirs or have special functions. Inclusions can often be seen directly with the light microscope and are usually enclosed by single-layer (nonunit) membranes that partition the inclusion off in the cell. Storing carbon or other substances in an insoluble form is advantageous for cells because it reduces the osmotic stress that would occur should the same amount of the substance be dissolved in the cytoplasm.

Carbon Storage Polymers

One of the most common inclusion bodies in prokaryotic organisms is **poly-β-hydroxybutyric acid (PHB)**, a lipid that is formed from β-hydroxybutyric acid units. The monomers of PHB polymerize by ester linkage and then the polymer aggregates into granules; the latter can be seen by either light or electron microscopy (Figure 2.35).

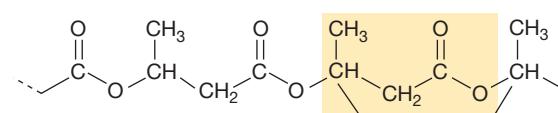

The monomer in the polymer is usually hydroxybutyrate (C_4) but can vary in length from as short as C_3 to as long as C_{18} . Thus, the more generic term **poly-β-hydroxyalkanoate (PHA)** is often used to describe this class of carbon- and energy-storage polymers. PHAs are synthesized by cells when there is an excess of carbon and are broken down as carbon or energy sources when conditions warrant. Many *Bacteria* and *Archaea* produce PHAs.

Another storage product is **glycogen**, which is a polymer of glucose and, like PHA, is a reservoir of both carbon and energy and is produced when carbon is in excess. Glycogen resembles starch, the major storage reserve of plants, but differs slightly from starch in the manner in which the glucose units are linked together.

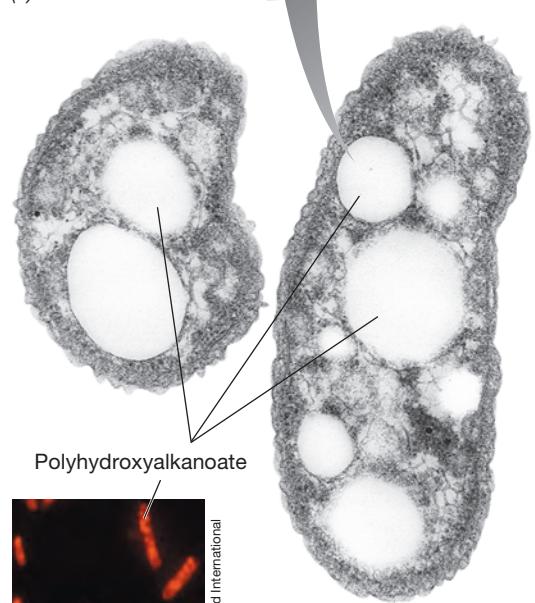

Polyphosphate, Sulfur, and Carbonate Minerals

Many microorganisms accumulate inorganic phosphate (PO_4^{3-}) in the form of granules of **polyphosphate** (Figure 2.36a). These granules can be degraded and used as sources of phosphate for nucleic acid and phospholipid biosyntheses and in some organisms can be used directly to make the energy-rich compound ATP. Phosphate is often a limiting nutrient in natural environments. Thus, if a cell happens upon an excess of phosphate, it is advantageous to be able to store it as polyphosphate for future use.

Many gram-negative prokaryotes can oxidize reduced sulfur compounds, such as hydrogen sulfide (H_2S); these organisms are the “sulfur bacteria,” discovered by the great microbiologist Sergei

(a)

(b)

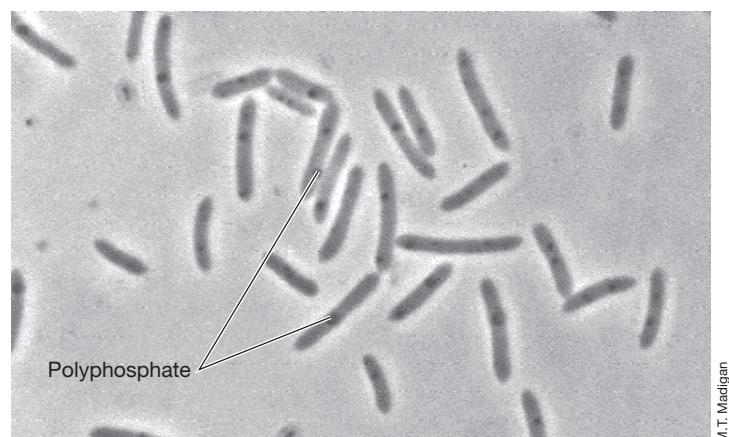

Figure 2.35 Poly- β -hydroxyalkanoates. (a) Chemical structure of poly- β -hydroxybutyrate, a common PHA. A monomeric unit is shown in color. Other PHAs are made by substituting longer-chain hydrocarbons for the $-\text{CH}_3$ group on the β -carbon. (b) Electron micrograph of a thin section of cells of a bacterium containing granules of PHB. Color photo: Nile red-stained cells of a PHA-containing bacterium.

Winogradsky (Section 1.9). The oxidation of sulfide is linked to the need for electrons to drive either reactions of energy metabolism (chemolithotrophy) or CO_2 fixation (autotrophy). In either case, *elemental sulfur* (S^0) from the oxidation of sulfide may accumulate in the cell in microscopically visible granules (Figure 2.36b). This sulfur remains as long as the source of reduced sulfur from which it was derived is still present. However, as the reduced sulfur source becomes limiting, the sulfur in the granules is oxidized to sulfate (SO_4^{2-}), and the granules slowly disappear as this reaction proceeds. Interestingly, although sulfur globules appear to reside in the cytoplasm, they are actually present in the periplasm (Section 2.11). In these cells the periplasm expands outward to accommodate the growing globules as H_2S is oxidized to S^0 and then contracts inward as S^0 is oxidized to SO_4^{2-} .

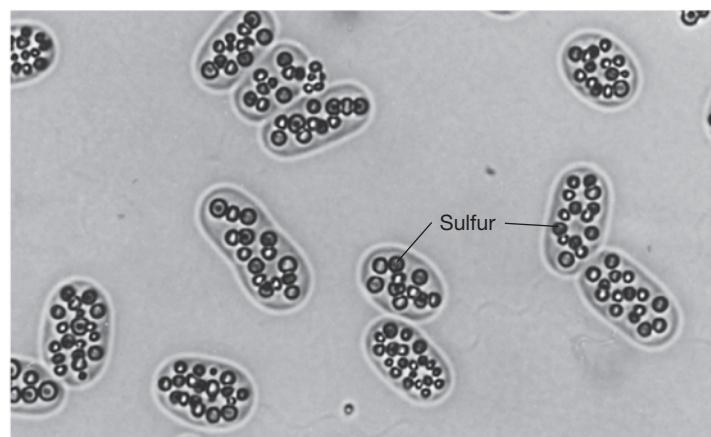

Filamentous cyanobacteria (see Figure 2.55) have long been known to form carbonate minerals on the external surface of their cells. However, some cyanobacteria also form carbonate minerals *inside* the cell, as cell inclusions. For example, the unicellular cyanobacterium *Gleomargarita* forms intracellular granules of benstonite, a carbonate mineral that contains barium, strontium, and magnesium (Figure 2.37). The microbiological process of forming minerals is called *biomineralization*. It is unclear exactly why this particular mineral is formed by this cyanobacterium, although it may serve the cell as ballast to maintain cells in their habitat, deep in an alkaline lake in Mexico. The biomineralization of several different minerals is catalyzed by various prokaryotes (Section 13.21), but only in the case of *Gleomargarita* and magnetosomes (to be discussed next) do we see the process yield intracellular inclusions.

Magnetic Storage Inclusions: Magnetosomes

Some bacteria can orient themselves within a magnetic field because they contain **magnetosomes**. These structures are intracellular particles of the iron oxide mineral magnetite— Fe_3O_4

(a)

(b)

Figure 2.36 Polyphosphate and sulfur storage products. (a) Phase-contrast photomicrograph of cells of *Helio bacterium modesticaldum* showing polyphosphate as dark granules; a cell is about 1 μm wide. (b) Bright-field photomicrograph of cells of the purple sulfur bacterium *Isochromatium budei*. The intracellular inclusions are sulfur globules formed from the oxidation of hydrogen sulfide (H_2S). A cell is about 4 μm wide.

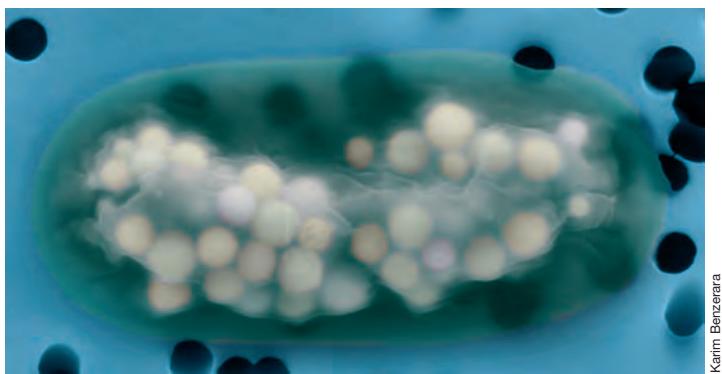

Figure 2.37 **Biomineralization by a cyanobacterium.** Electron micrograph of a cell of the cyanobacterium *Gleomargarita* containing granules of the mineral benstonite $[(\text{Ba}, \text{Sr}, \text{Ca})_6\text{Mg}(\text{CO}_3)_{13}]$. A cell is about 2 μm wide.

(**Figure 2.38**). In some magnetotactic bacteria the sulfur-containing mineral greigite (Fe_3S_4) is formed. Both magnetite and greigite are magnetic minerals. Magnetosomes impart a magnetic dipole on a cell, allowing it to orient itself in a magnetic field. Bacteria that produce magnetosomes exhibit *magnetotaxis*, the process of migrating along Earth's magnetic field lines. Magnetosomes have been found in several aquatic organisms that grow best at low O_2 concentrations. It has thus been hypothesized that one function

of magnetosomes may be to guide these primarily aquatic cells downward (the direction of Earth's magnetic field) toward the sediments where O_2 levels are lower. One greigite-producer is a sulfate-reducing bacterium, and these organisms are obligate anaerobes. Remaining in anoxic zones would be especially important for such magnetotactic species.

An individual magnetosome is enclosed by a thin membrane composed of phospholipid, protein, and glycoprotein (Figure 2.38b, c). Although this membrane is not a true unit (bilayer) membrane as is the cytoplasmic membrane, magnetosome membrane proteins are functional, as they catalyze Fe^{3+} precipitation during magnetosome synthesis. A similar nonunit membrane surrounds granules of PHAs and sulfur globules, as well. The morphology of magnetosomes appears to be species-specific, varying in shape from square to rectangular to spike-shaped. No magnetosome-containing *Archaea* have yet been discovered.

MINIQUIZ

- Under what growth conditions would you expect PHAs or glycogen to be produced?
- Why would it be impossible for gram-positive bacteria to store sulfur as gram-negative sulfur-oxidizing chemolithotrophs can?
- How are magnetosomes and the *Gleomargarita* inclusions similar and how do they differ?

2.15 Gas Vesicles

Some prokaryotes are *planktonic*, meaning that they live within the water column of lakes and the oceans. Many planktonic organisms can float because they contain **gas vesicles**, structures that confer buoyancy that allow the cells to position themselves in a water column in a particular location.

The most dramatic examples of gas-vesiculate bacteria are cyanobacteria that form massive accumulations called *blooms* in lakes or other bodies of water (**Figure 2.39**). Cyanobacteria are oxygenic phototrophic bacteria (☞ Sections 1.3, 13.4, and 14.3). Gas-vesiculate cells rise to the surface of the lake and are blown by winds into dense masses. Several other primarily aquatic

A cell is 2.2 μm wide. (b) Magnetosomes isolated from the magnetotactic bacterium *Magnetospirillum magnetotacticum*; each particle is about 50 nm wide. (c) Transmission electron micrograph of magnetosomes from a magnetic coccus. The arrow points to the membrane that surrounds each magnetosome. A single magnetosome is about 90 nm wide.

Figure 2.39 **Buoyant cyanobacteria.** Flotation of gas-vesiculate cyanobacteria that formed a bloom in a freshwater lake, Lake Mendota, Madison, Wisconsin (USA).

prokaryotes have gas vesicles, and the property is found in both *Bacteria* and *Archaea* but not microbial eukaryotes.

Gas Vesicle Structure

Gas vesicles are conical-shaped structures made of protein; they are hollow yet rigid and of variable length and diameter (Figure 2.40). Gas vesicles in different species vary in length from about 300 to more than 1000 nm and in width from 45 to 120 nm, but the vesicles of a given species are of constant size. Gas vesicles may number from a few to hundreds per cell and are impermeable to water and solutes but permeable to gases. The presence of gas vesicles in cells can be detected either by light microscopy, where clusters of vesicles, called *gas vacuoles*, appear as irregular bright inclusions (Figure 2.40a), or by transmission electron microscopy of cell thin sections (Figure 2.40b).

Gas vesicles are composed of two different proteins. The major protein, called *GvpA*, forms the watertight vesicle shell itself and is a small, hydrophobic, and very rigid protein, copies of which align to form the parallel “ribs” of the vesicle. The rigidity is essential for the structure to resist the pressures exerted on it from outside. The minor protein, called *GvpC*, functions to strengthen the shell of the gas vesicle by cross-linking and binding the ribs at an angle to group several *GvpA* molecules together (Figure 2.41).

The composition and pressure of the gas inside a gas vesicle is that in which the organism is suspended. Because an inflated gas vesicle has a density only one-tenth that of the cell proper, inflated

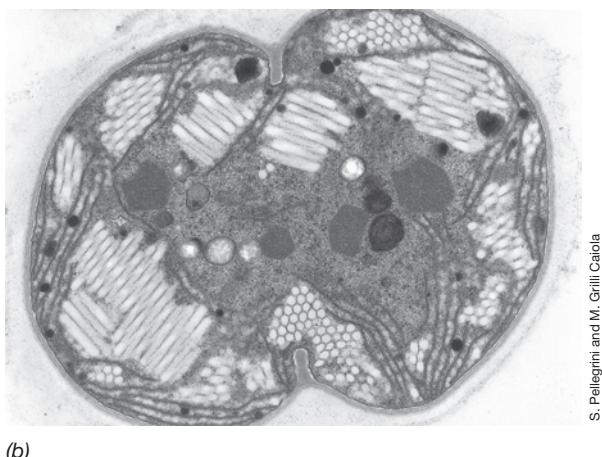

Figure 2.40 Gas vesicles of the cyanobacteria *Anabaena* and *Microcystis*. (a) Phase-contrast photomicrograph of *Anabaena*. Clusters of gas vesicles form phase-bright gas vacuoles (arrows). (b) Transmission electron micrograph of *Microcystis*. Gas vesicles are arranged in bundles, here seen in both longitudinal and cross section. Both cells are about 5 μm wide.

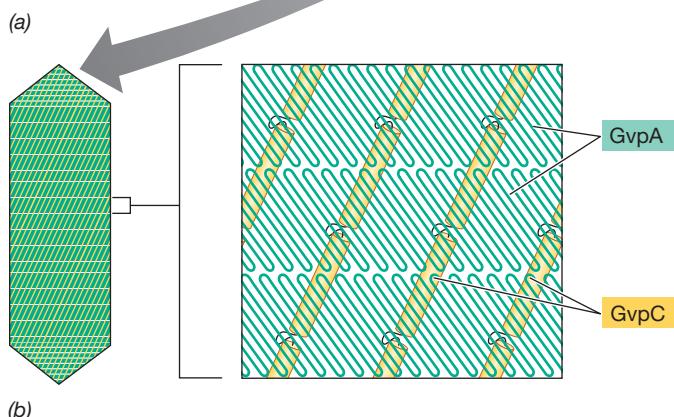

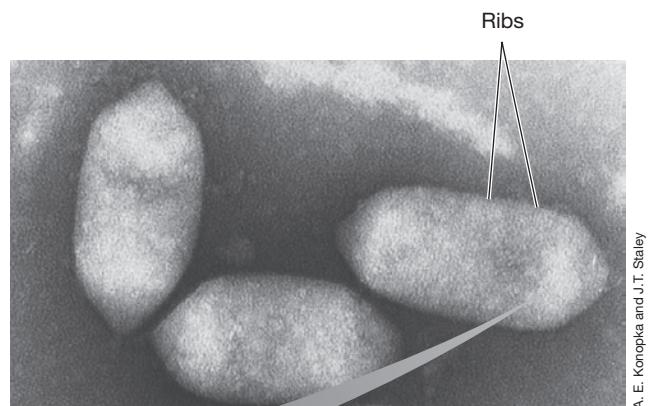

Figure 2.41 Gas vesicle architecture. Transmission electron micrograph of gas vesicles purified from the bacterium *Ancylobacter aquaticus* and examined in negatively stained preparations. A single vesicle is about 100 nm in diameter. (b) Model of how gas vesicle proteins *GvpA* and *GvpC* interact to form a watertight but gas-permeable structure. *GvpA*, a rigid β -sheet, makes up the rib, and *GvpC*, an α -helix structure, is the cross-link.

gas vesicles decrease a cell’s overall density and thereby increase its buoyancy; then, when vesicles are collapsed, buoyancy is lost. Phototrophic prokaryotes in particular can benefit from gas vesicles because they allow cells to adjust their vertical position in a water column to sink or rise to regions where conditions (for example, light intensity) are optimal for photosynthesis.

MINIQUIZ

- What gas is present in a gas vesicle? Why might a cell benefit from controlling its buoyancy?
- How are the two proteins that make up the gas vesicle, *GvpA* and *GvpC*, arranged to form such a water-impermeable structure?

2.16 Endospores

Certain species of *Bacteria* produce structures called **endospores** (Figure 2.42) during a process called *sporulation*. Endospores (the prefix *endo* means “within”) are highly differentiated cells that are extremely resistant to heat, harsh chemicals, and radiation. Endospores function as survival structures and enable the organism to endure unfavorable growth conditions, including but not limited to extremes of temperature, drying, or nutrient depletion. Endospores can thus be thought of as the dormant stage of

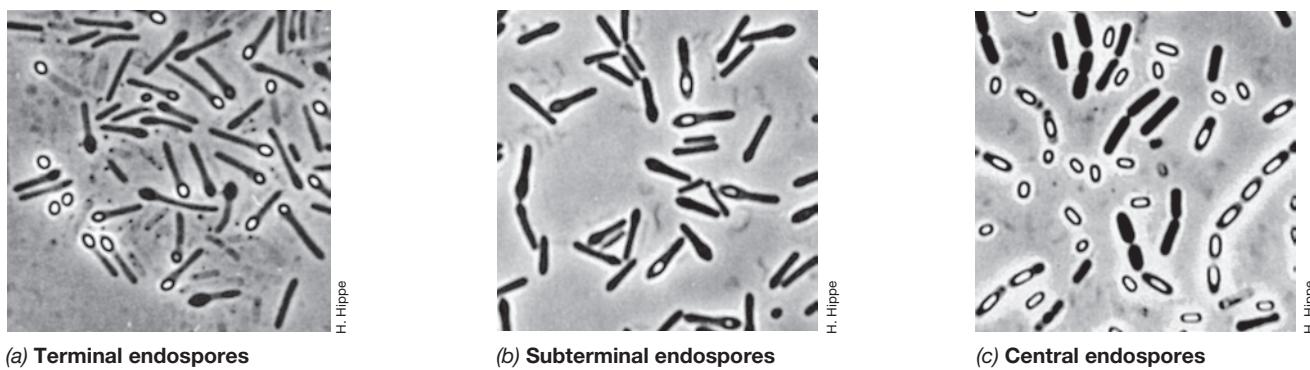

Figure 2.42 The bacterial endospore. Phase-contrast photomicrographs illustrating endospore morphologies and intracellular locations in different species of endospore-forming bacteria. Endospores appear bright by phase-contrast microscopy.

a bacterial life cycle: vegetative cell → endospore → vegetative cell. Endospores are also easily dispersed by wind, water, or through the animal gut. Endospore-forming bacteria are commonly found in soil, and species of *Bacillus* are the best-studied representatives.

Endospore Formation and Germination

During endospore formation, a vegetative cell is converted into a nongrowing, heat-resistant, and light-refractive structure (Figure 2.43). Cells do not sporulate when they are actively growing but only when growth ceases owing to the exhaustion of an essential nutrient. Thus, cells of *Bacillus*, a typical endospore-forming bacterium, cease vegetative growth and begin sporulation when, for example, a key nutrient such as carbon or nitrogen becomes limiting.

An endospore can remain dormant for years but can convert back to a vegetative cell rapidly. This process involves three steps: *activation*, *germination*, and *outgrowth* (Figure 2.44). Activation occurs when endospores are heated for several minutes at an

elevated but sublethal temperature. Activated endospores are then conditioned to germinate when supplied with certain nutrients, such as certain amino acids. Germination, typically a rapid process (on the order of minutes), involves loss of refractivity of the endospore, increased ability to be stained by dyes, and loss of resistance to heat and chemicals. The final stage, outgrowth, involves visible swelling due to water uptake and synthesis of RNA, proteins, and DNA. The vegetative cell emerges from the broken endospore and begins to grow, remaining in vegetative growth until environmental signals once again trigger sporulation.

Endospore Structure

Endospores are visible by light microscopy as strongly refractive structures (Figure 2.42). Endospores are impermeable to most dyes, so occasionally they are seen as unstained regions within cells that have been stained with basic dyes such as methylene blue. To stain endospores, special stains and procedures must be used. In the classical endospore-staining protocol, the stain malachite green is used and is infused into the spore with steam.

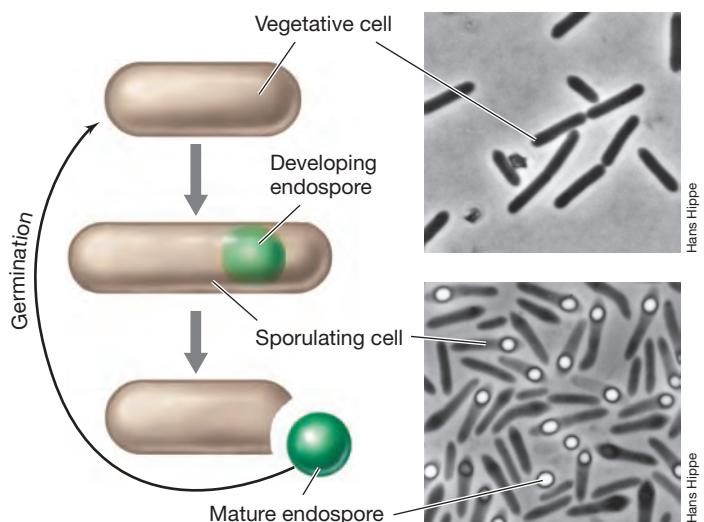

Figure 2.43 The life cycle of an endospore-forming bacterium. The phase-contrast photomicrographs are of cells of *Clostridium pascui*. A cell is about 0.8 μm wide.

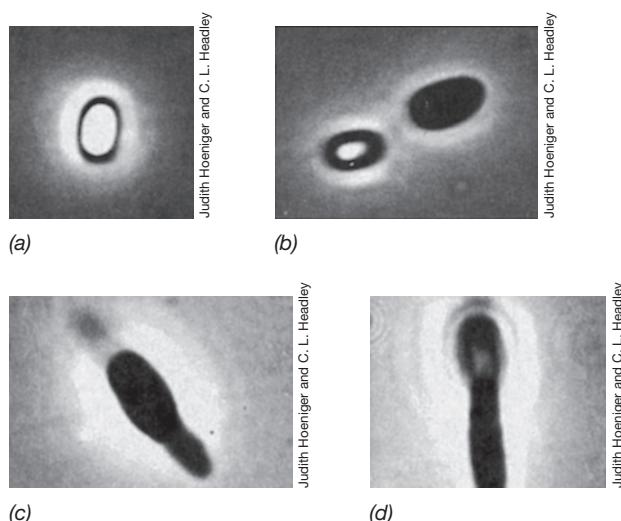

Figure 2.44 Endospore germination in *Bacillus*. Conversion of an endospore into a vegetative cell. The series of phase-contrast photomicrographs shows the sequence of events starting from (a) a highly refractive free endospore. (b) Activation: Refractivity is being lost. (c, d) Outgrowth: The new vegetative cell is emerging.

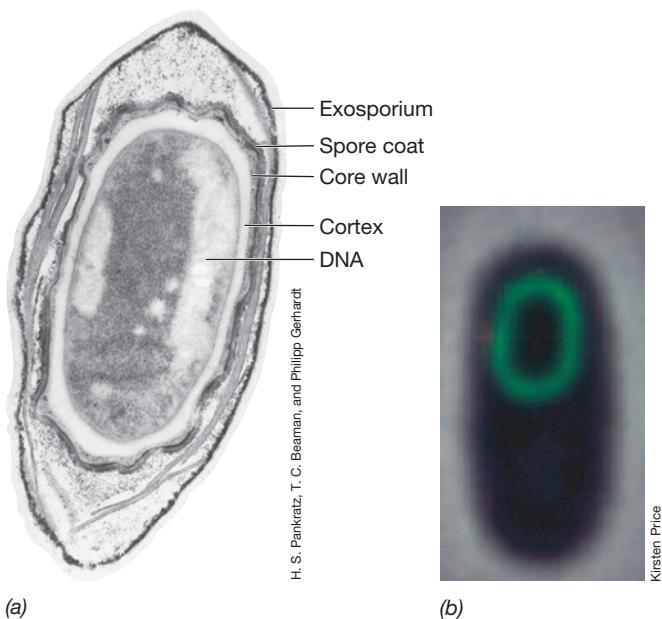

Figure 2.45 Structure of the bacterial endospore. (a) Transmission electron micrograph of a thin section through an endospore of *Bacillus megaterium*. (b) Fluorescent photomicrograph of a cell of *Bacillus subtilis* undergoing sporulation. The green color is a dye that specifically stains a sporulation protein in the spore coat.

The structure of the endospore as seen with the electron microscope differs distinctly from that of the vegetative cell (Figure 2.45). The endospore contains many layers absent from the vegetative cell. The outermost layer is the *exosporium*, a thin protein covering. Moving inward there are several *spore coats*, composed of layers of spore-specific proteins (Figure 2.45b). Below the spore coat is the *cortex*, which consists of loosely cross-linked peptidoglycan, and inside the cortex is the *core*, which contains the core wall, cytoplasmic membrane, cytoplasm, nucleoid, ribosomes, and other cellular essentials. Thus, the endospore differs structurally from the vegetative cell primarily in the kinds of structures found outside the core wall.

One chemical found in endospores but not vegetative cells is **dipicolinic acid** (Figure 2.46), which accumulates in the core. Endospores also contain large amounts of calcium (Ca^{2+}), most of which is complexed with dipicolinic acid (Figure 2.46b). The calcium–dipicolinic acid complex represents about 10% of the dry weight of the endospore and functions to bind free water

within the endospore, thus helping to dehydrate it. In addition, the complex inserts between bases in DNA, which helps stabilize DNA against heat denaturation.

The core of the endospore differs significantly from the cytoplasm of the vegetative cell that produced it. The core of an endospore contains less than one quarter of the water found in the vegetative cell, and thus the consistency of the core cytoplasm is that of a gel. Dehydration of the core greatly increases the heat resistance of macromolecules within the spore. Some bacterial endospores survive heating to temperatures as high as 150°C, although 121°C, the standard for microbiological sterilization (121°C is autoclave temperature, [Section 5.17](#)), kills the endospores of most species. Dehydration has also been shown to confer resistance in the endospore to toxic chemicals, such as hydrogen peroxide (H_2O_2), and causes enzymes in the core to become inactive. In addition to the low water content of the endospore, the pH of the core is about one unit lower than that of the vegetative cell cytoplasm.

The endospore core contains high levels of *small acid-soluble spore proteins* (SASPs). These proteins are only made during the sporulation process and have at least two functions. SASPs bind tightly to DNA in the core and protect it from potential damage from ultraviolet radiation, desiccation, and dry heat. Ultraviolet resistance is conferred when SASPs change the molecular structure of DNA from the normal “B” form to the more compact “A” form. A-form DNA better resists pyrimidine dimer formation by UV radiation, which can cause mutations ([Section 10.4](#)), and resists the denaturing effects of dry heat. In addition, SASPs function as a carbon and energy source for the outgrowth of a new vegetative cell from the endospore during germination.

The Sporulation Cycle

Sporulation is an example of cellular differentiation ([Figure 1.3](#)), and many genetically directed changes in the cell occur during the conversion from vegetative growth to sporulation. The structural changes occurring in sporulating cells of *Bacillus* are shown in Figure 2.47. Sporulation can be divided into several stages. In *Bacillus subtilis*, which has been studied in detail, sporulation takes about 8 hours and begins with asymmetric cell division (Figure 2.47). Genetic studies of mutants of *Bacillus*, each blocked at one of the stages of sporulation, indicate that more than 200 spore-specific genes exist.

Sporulation requires differential protein synthesis. This is accomplished by the activation of several families of endospore-specific genes and the turning off of many vegetative cell functions. The proteins encoded by sporulation-specific genes catalyze the series of events leading from the moist, metabolizing, vegetative cell to the relatively dry, metabolically inert, but extremely resistant endospore (Table 2.3). In Section 7.11 we examine some of the molecular events that take place during the sporulation process.

Diversity and Phylogenetic Aspects of Endospore Formation

Nearly 20 genera of *Bacteria* form endospores, although the process has only been studied in detail in a few species of *Bacillus* and *Clostridium*. Nevertheless, most of the secrets behind endospore biology, such as the formation of calcium–dipicolinate complexes

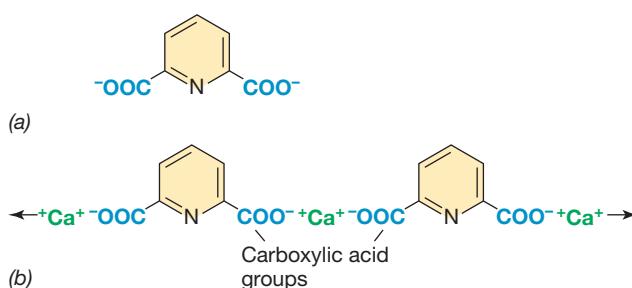

Figure 2.46 Dipicolinic acid (DPA). (a) Structure of DPA. (b) How Ca^{2+} cross-links DPA molecules to form a complex.

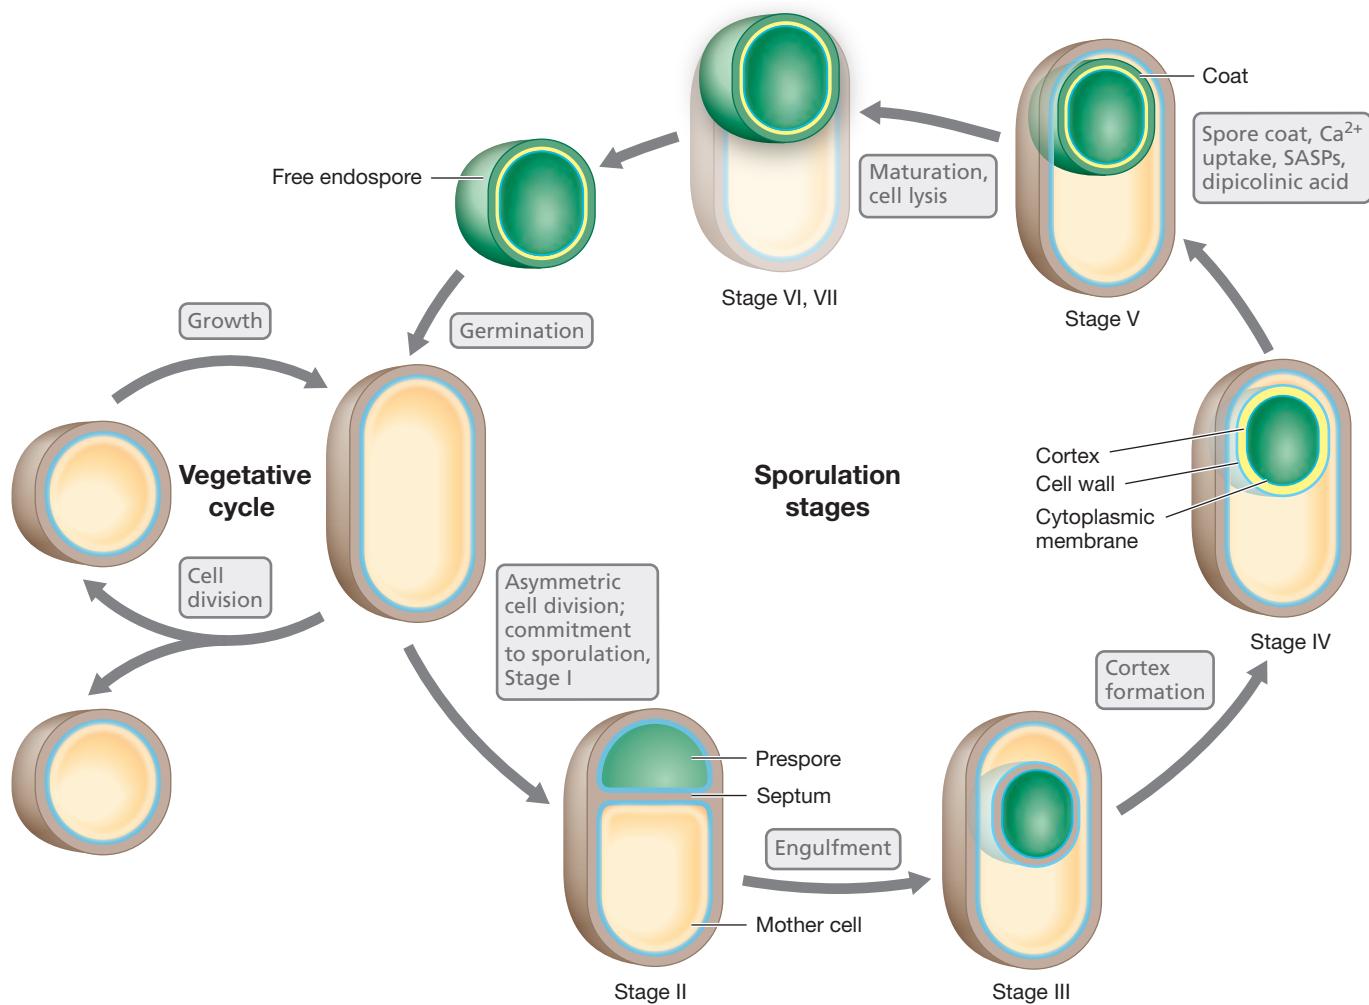

Figure 2.47 Stages in endospore formation. The stages are defined from genetic and microscopic analyses of sporulation in *Bacillus subtilis*, the model organism for studies of sporulation.

Table 2.3 Differences between endospores and vegetative cells

Characteristic	Vegetative cell	Endospore
Microscopic appearance	Nonrefractile	Refractile
Calcium content	Low	High
Dipicolinic acid	Absent	Present
Enzymatic activity	High	Low
Respiration rate	High	Low or absent
Macromolecular synthesis	Present	Absent
Heat resistance	Low	High
Radiation resistance	Low	High
Resistance to chemicals	Low	High
Lysozyme	Sensitive	Resistant
Water content	High, 80–90%	Low, 10–25% in core
Small acid-soluble spore proteins	Absent	Present

and the production of endospore-specific SASPs, seem universal. From a phylogenetic perspective, the capacity to produce endospores is found only in a particular sublineage of the gram-positive bacteria. Despite this, the physiologies of endospore-forming bacteria are highly diverse and include anaerobes, aerobes, phototrophs, and chemolithotrophs. In light of this physiological diversity, the actual triggers for endospore formation may vary with different species and could include signals other than simple nutrient starvation, the major trigger for endospore formation in *Bacillus*. No Archaea have been shown to form endospores, suggesting that the capacity to produce endospores evolved sometime after the prokaryotic lineages diverged about 3.5 billion years ago (➡ Figure 1.4b).

MINIQUIZ

- What is dipicolinic acid and where is it found?
- What are SASPs and what is their function?
- What is formed when an endospore germinates?

VI • Microbial Locomotion

We finish our survey of prokaryotic structure and function by examining cell locomotion. Many microbial cells can move under their own power. Motility allows cells to reach different parts of their environment, and in nature, movement may present new opportunities and resources for a cell and spell the difference between life and death.

We examine here the two major types of prokaryotic cell movement, *swimming* and *gliding*. We then consider how motile cells are able to move in a directed fashion toward or away from particular stimuli (phenomena called *taxis*) and present examples of these simple behavioral responses.

2.17 Flagella and Swimming Motility

Many prokaryotes are motile by swimming due to a structure called the **flagellum** (plural, flagella) (Figure 2.48). The flagellum functions to push or pull the cell through a liquid medium.

Flagella of Bacteria

Bacterial flagella are long, thin appendages free at one end and attached to the cell at the other end. Bacterial flagella are so thin (15–20 nm, depending on the species) that a single flagellum cannot be seen by light microscopy unless it is stained to increase its diameter (Figure 2.48). However, flagella are easily seen with the electron microscope (Figure 2.49).

Flagella can attach to cells in different locations. In **polar flagellation**, the flagella are attached at one or both ends of a cell. Occasionally a group of flagella (called a *tuft*) may arise at one end of the cell, a type of polar flagellation called *lophotrichous* (Figure 2.48c). Tufts of flagella can often be seen in unstained cells by dark-field or phase-contrast microscopy (Figure 2.50). When a tuft of flagella emerges from both poles of the cell, flagellation is called *amphitrichous*. In **peritrichous flagellation** (Figures 2.48a and 2.49b), flagella are inserted at many locations around the cell surface. The type of flagellation—polar or peritrichous—is a characteristic used in the classification of bacteria.

Flagellar Structure

Flagella are not straight but helical. When flattened, flagella show a constant distance between adjacent curves, called the *wavelength*, and this wavelength is characteristic for the flagella of any

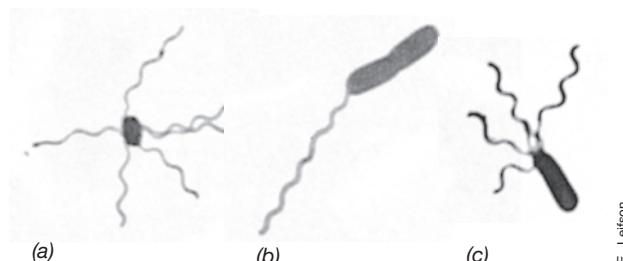

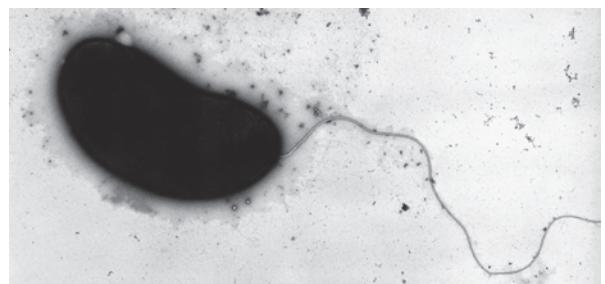

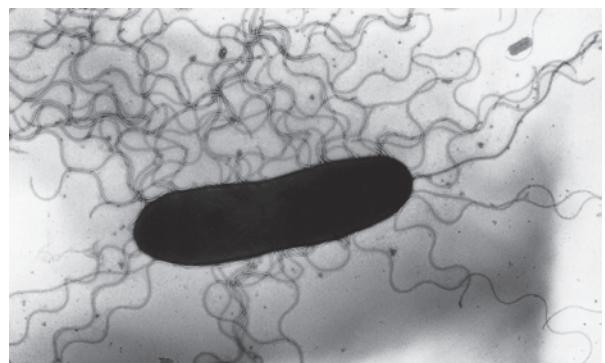

Figure 2.48 Bacterial flagella. Classic light photomicrographs taken by Einar Leifson of bacteria containing different arrangements of flagella. Cells are stained with the Leifson flagella stain. (a) Peritrichous. (b) Polar. (c) Lophotrichous.

Both micrographs are of cells of the phototrophic bacterium *Rhodospirillum centenum*, which are about 1.5 μm wide. Cells of *R. centenum* are normally polarly flagellated but under certain growth conditions form peritrichous flagella. See Figure 2.59b for a photo of colonies of *R. centenum* cells that move toward an increasing gradient of light (phototaxis).

given species. The filament of a bacterial flagellum is composed of many copies of a protein called *flagellin*. The shape and wavelength of the flagellum are in part determined by the structure of the flagellin protein and also to some extent by the direction of rotation of the filament. The amino acid sequence of flagellin is highly conserved in species of *Bacteria*, suggesting that flagellar motility evolved early and has deep roots within this domain.

A flagellum consists of several components and rotates, much like a propeller on a boat motor. The base of the flagellum is structurally different from the filament. There is a wider region at the base of the filament called the *hook*. The hook consists of a single type of protein and connects the filament to the flagellum motor in the base (Figure 2.51).

The flagellum motor is anchored in the cytoplasmic membrane and cell wall. The motor consists of a central rod that passes through a series of rings. In gram-negative bacteria, an outer ring, called the *L ring*, is anchored in the lipopolysaccharide layer. A second ring, called the *P ring*, is anchored in the peptidoglycan layer of the cell wall. A third set of rings, called the *MS* and *C rings*, are located within the cytoplasmic membrane and the cytoplasm, respectively (Figure 2.51a). In gram-positive bacteria, which lack an outer membrane, only the inner pair of rings

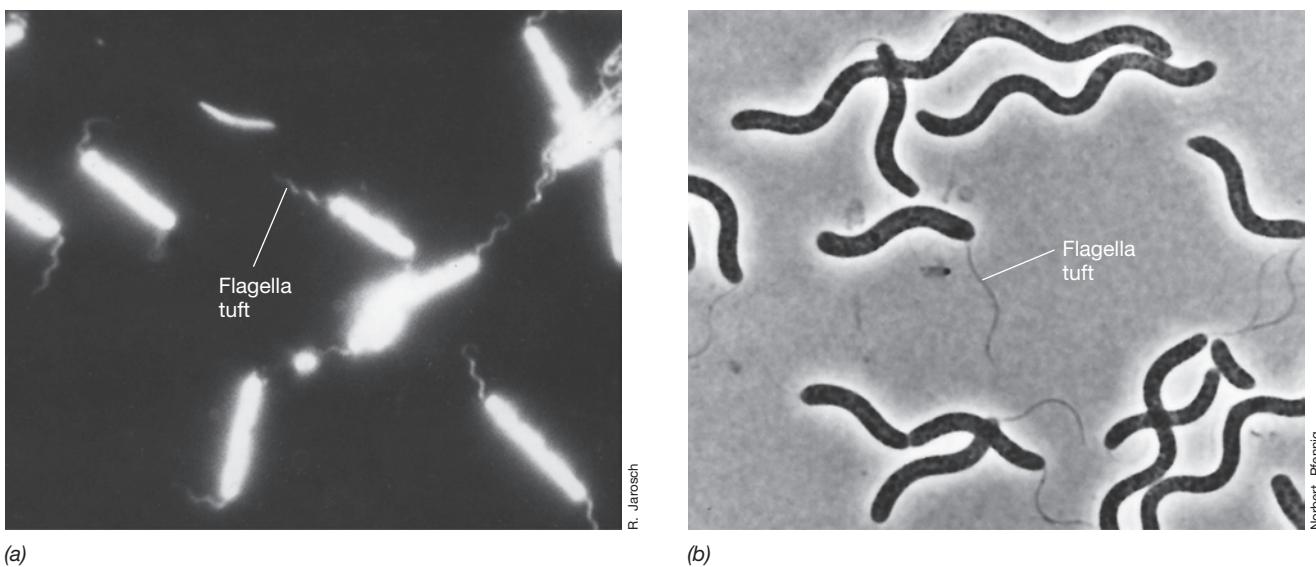

Figure 2.50 Bacterial flagella observed in living cells. (a) Dark-field photomicrograph of a group of large rod-shaped bacteria with flagellar tufts at each pole (amphitrichous flagellation). A single cell is about 2 μm wide. (b) Phase-contrast photomicrograph of cells of the large phototrophic purple bacterium *Rhodospirillum photometricum* with a tuft of lophotrichous flagella that emanate from one of the poles. A single cell measures about $3 \times 30 \mu\text{m}$.

is present. Surrounding the inner ring and anchored in the cytoplasmic membrane are a series of proteins called *Mot proteins*. A final set of proteins, called *Fli proteins* (Figure 2.51a), function as the motor switch, reversing the direction of rotation of the flagella in response to intracellular signals.

Flagellar Movement

The flagellum is a tiny rotary motor. How does this motor work? Rotary motors contain two main components: the *rotor* and the *stator*. In the flagellar motor, the rotor consists of the central rod and the L, P, C, and MS rings. Collectively, these structures make up the **basal body**. The stator consists of the Mot proteins that surround the basal body and function to generate torque.

Rotation of the flagellum is imparted by the basal body. The energy required for rotation of the flagellum comes from the proton motive force (Section 2.8). Proton movement across the cytoplasmic membrane through the Mot complex drives rotation of the flagellum, and about 1000 protons are translocated per rotation of the flagellum; a model for how this works is shown in Figure 2.51b. In this proton turbine model, protons flowing through channels in the Mot proteins exert electrostatic forces on helically arranged charges on the rotor proteins. Attractions between positive and negative charges would then cause the basal body to rotate as protons flow through the Mot proteins.

Archaeal Flagella

As for *Bacteria*, flagellar motility is widespread among species of *Archaea*; major genera of methanogens, extreme halophiles, thermoacidophiles, and hyperthermophiles (Figure 1.6b) are all capable of swimming motility. Archaeal flagella are roughly half the diameter of bacterial flagella, measuring only 10–13 nm in width (Figure 2.52), but impart movement to the cell by rotating, as do flagella in *Bacteria*. However, unlike *Bacteria*, in which a single

type of protein makes up the flagellar filament, several different flagellin proteins are known from *Archaea*, and their amino acid sequences and genes that encode them bear little relationship to those of bacterial flagellin.

Studies of swimming cells of the extreme halophile *Halobacterium* show that they swim at speeds only about one-tenth that of cells of *Escherichia coli*. Whether this holds for all *Archaea* is unknown, but the significantly smaller diameter of the archaeal flagellum compared with the bacterial flagellum would naturally reduce the torque and power of the flagellar motor such that slower swimming speeds are not surprising. Moreover, from biochemical experiments with *Halobacterium* it appears that archaeal flagella are powered directly by ATP rather than by the proton motive force, the source of energy for the flagella of *Bacteria* (Figure 2.51b). If this holds for the flagella of all motile *Archaea*, it would mean that the flagellar motors of *Archaea* and *Bacteria* employ fundamentally different energy-coupling mechanisms. Combined with the clear differences in flagellar protein structure between *Archaea* and *Bacteria*, this suggests that, as for endospores, flagellar motility evolved separately as prokaryotes diverged over 3.5 billion years ago (Figure 1.4b).

Flagellar Synthesis

Several genes encode the motility proteins of *Bacteria*. In *Escherichia coli* and *Salmonella enterica* serovar Typhimurium, for which motility studies have been extensive, over 50 genes are linked to motility. These genes encode the structural proteins of the flagellum and motor apparatus, of course, but also proteins that export the structural proteins through the cytoplasmic membrane to the outside of the cell, and proteins that regulate the many biochemical events surrounding the synthesis of new flagella.

A flagellar filament grows not from its base, as does an animal hair, but from its tip. The MS ring is synthesized first and inserted

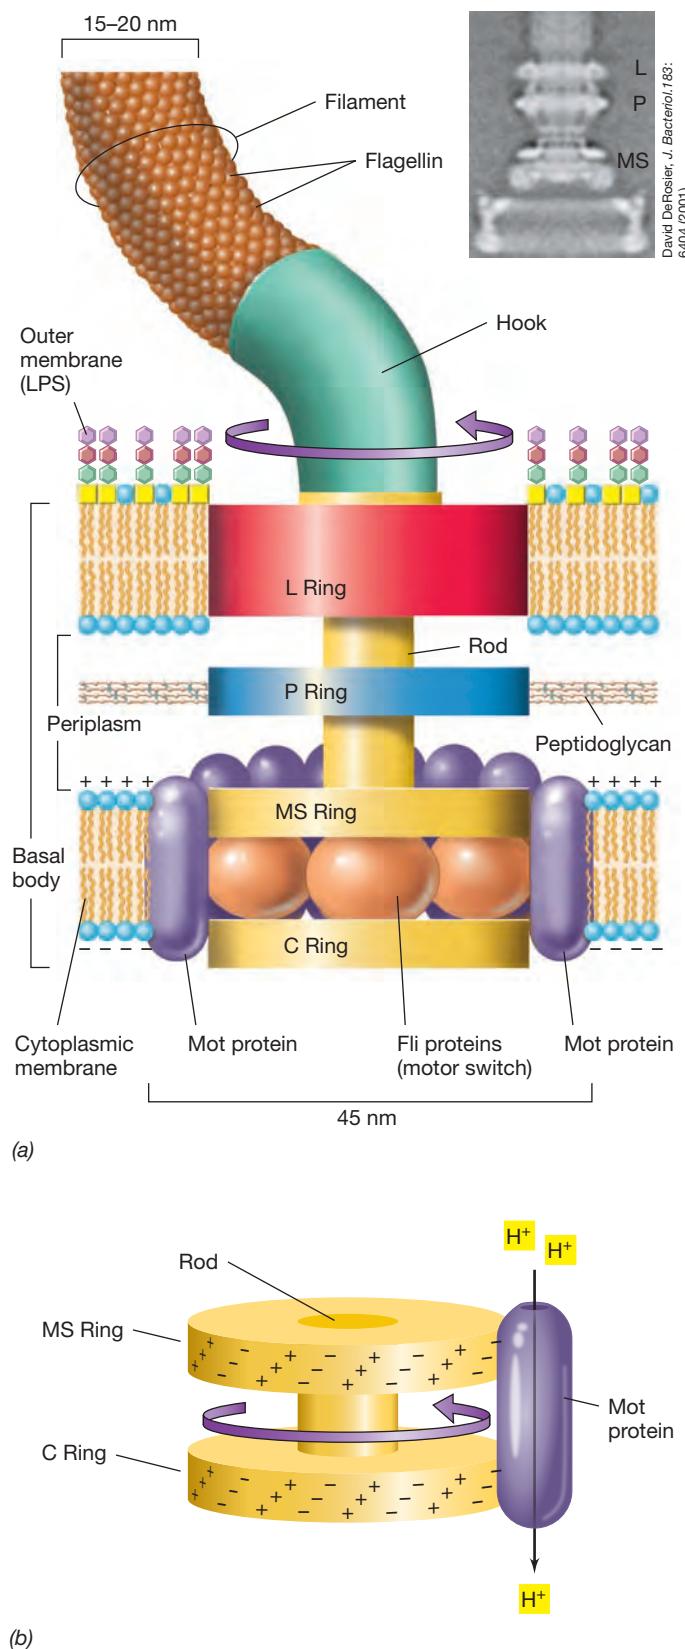

Figure 2.51 Structure and function of the flagellum in gram-negative Bacteria.

Bacteria. (a) Structure. The L ring is embedded in the LPS and the P ring in peptidoglycan. The MS ring is embedded in the cytoplasmic membrane and the C ring in the cytoplasm. A narrow channel exists in the rod and filament through which flagellin molecules diffuse to reach the site of flagellar synthesis. The Mot proteins function as the flagellar motor, whereas the Fli proteins function as the motor switch. The flagellar motor rotates the filament to propel the cell through the medium. Inset: transmission electron micrograph of a flagellar basal body from *Salmonella enterica* with the various rings labeled. (b) Function. A “proton turbine” model has been proposed to explain rotation of the flagellum. Protons, flowing through the Mot proteins, exert forces on charges present on the C and MS rings, thereby spinning the rotor.

into the cytoplasmic membrane. Then other anchoring proteins are synthesized along with the hook before the filament forms (Figure 2.53). Flagellin molecules synthesized in the cytoplasm pass up through a 3-nm channel inside the filament and add on at the terminus to form the mature flagellum. A protein “cap” is present at the end of the growing flagellum. Cap proteins assist flagellin molecules that have diffused through the filament channel to assemble in the proper fashion at the flagellum terminus (Figure 2.53). Approximately 20,000 flagellin protein molecules are needed to make one filament. The flagellum grows more or less continuously until it reaches its final length. Broken flagella still rotate and can be repaired with new flagellin units passed through the filament channel to replace the lost ones.

Cell Speed and Motion

In *Bacteria*, flagella do not rotate at a constant speed but instead increase or decrease their rotational speed in relation to the strength of the proton motive force. Flagella can rotate at up to 300 revolutions per second and propel cells through a liquid at up to 60 cell lengths/sec. By contrast, the fastest known animal, the cheetah, moves at a maximum rate of about 25 body lengths/sec. Thus, when size is accounted for, a bacterial cell swimming at 60 cell lengths/sec is actually moving over twice as fast as the fastest animal!

The swimming motions of polarly and lophotrichously flagellated organisms differ from those of peritrichously flagellated organisms, and these can be distinguished microscopically (Figure 2.54). Peritrichously flagellated organisms typically move in a straight line in a slow, deliberate fashion. Polarly flagellated organisms, on

Figure 2.52 Archaeal flagella. Transmission electron micrograph of flagella isolated from cells of the methanogen *Methanococcus maripaludis*. A single flagellum is about 12 nm wide.

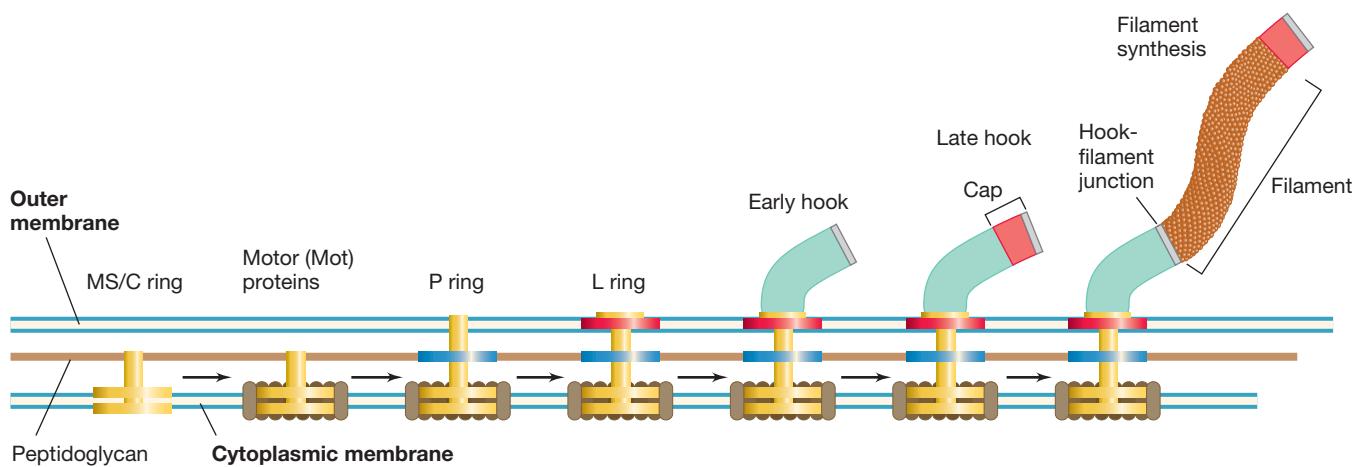

Figure 2.53 Flagella biosynthesis. Synthesis begins with assembly of MS and C rings in the cytoplasmic membrane, followed by the other rings, the hook, and the cap. Flagellin protein flows through the hook to form the filament and is guided into position by cap proteins.

the other hand, move more rapidly, spinning around and seemingly dashing from place to place. The different behavior of flagella on polar and peritrichous organisms, including differences in reversibility of the flagellum, is illustrated in Figure 2.54.

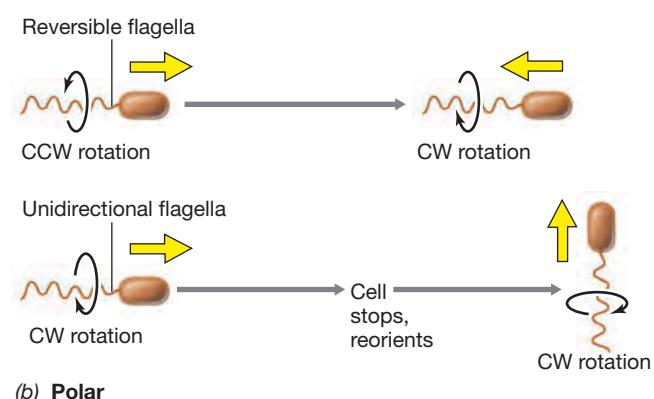

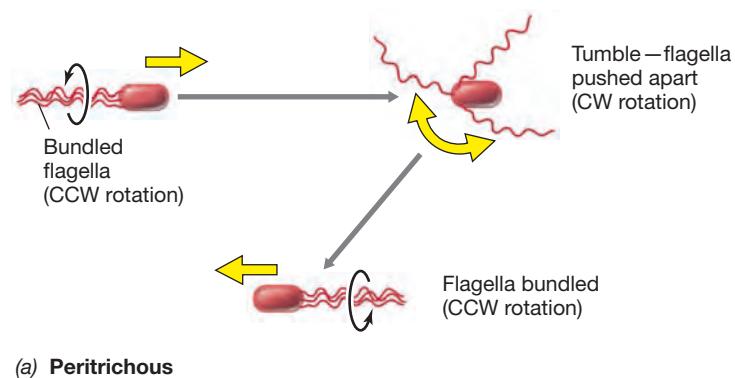

Figure 2.54 Movement in peritrichously and polarly flagellated prokaryotes. (a) Peritrichous: Forward motion is imparted by all flagella rotating counterclockwise (CCW) in a bundle. Clockwise (CW) rotation causes the cell to tumble, and then a return to counterclockwise rotation leads the cell off in a new direction. (b) Polar: Cells change direction by reversing flagellar rotation (thus pulling instead of pushing the cell) or, with unidirectional flagella, by stopping periodically to reorient, and then moving forward by clockwise rotation of its flagella. The yellow arrows show the direction the cell is traveling.

Swimming speed is a genetically governed property because different motile species, even different species that are the same cell size, can swim at different maximum speeds. When assessing the capacity of a laboratory culture of a bacterium for swimming motility and swimming speed, observations should be made on young cultures. In old cultures, otherwise motile cells often stop swimming and the culture may appear to be nonmotile.

MINIQUIZ

- Cells of *Salmonella* are peritrichously flagellated, those of *Pseudomonas* polarly flagellated, and those of *Spirillum* lophotrichously flagellated. Using a sketch, show how each organism would appear in a flagella stain.
- Compare the flagella of *Bacteria* and *Archaea* in terms of their structure and function.

2.18 Gliding Motility

Some prokaryotes are motile but lack flagella. Most of these non-swimming yet still motile bacteria move by *gliding*. Unlike flagellar motility, in which cells stop and then start off in a different direction, gliding motility is a slower and smoother form of movement and typically occurs along the long axis of the cell.

Diversity of Gliding Motility

Gliding motility is widely distributed among *Bacteria* but has been well studied in only a few groups. The gliding movement itself—up to 10 m/sec in some gliding bacteria—is considerably slower than propulsion by flagella but still offers the cell a means of moving about its habitat.

Gliding prokaryotes are filamentous or rod-shaped cells, and the gliding process requires that the cells be in contact with a solid surface (Figure 2.55). The morphology of colonies of a typical gliding bacterium are distinctive, because cells glide out and move away from the center of the colony (Figure 2.55c). Perhaps the best-known gliding bacteria are the filamentous cyanobacteria (Figure 2.55a, b), certain gram-negative *Bacteria* such as

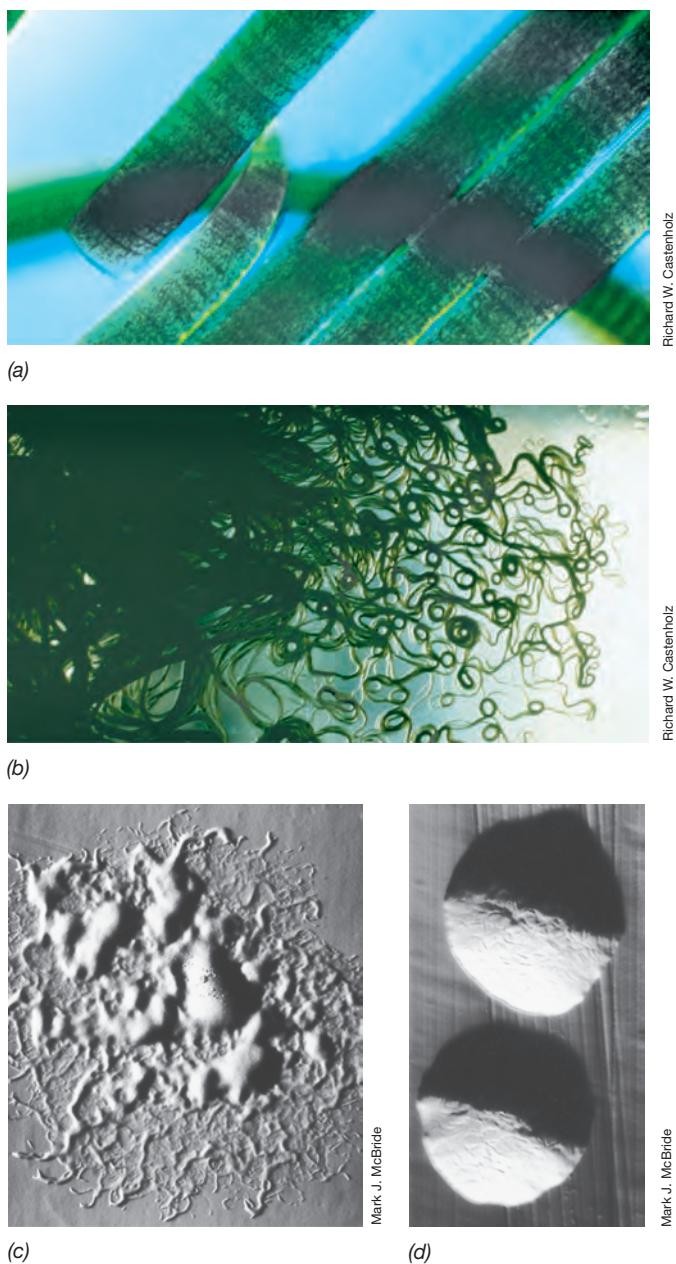

Figure 2.55 Gliding bacteria. (a, b) The large filamentous cyanobacterium *Oscillatoria* has cells about 35 μm wide. (b) *Oscillatoria* filaments gliding on an agar surface. (c) Masses of the bacterium *Flavobacterium johnsoniae* gliding away from the center of the colony (the colony is about 2.7 mm wide). (d) Nongliding mutant strain of *F. johnsoniae* showing typical colony morphology of nongliding bacteria (the colonies are 0.7–1 mm in diameter). See also Figure 2.56.

Myxococcus and other myxobacteria, and species of *Cytophaga* and *Flavobacterium* (Figure 2.55c, d). No gliding Archaea are known.

Mechanisms of Gliding Motility

More than one mechanism is responsible for gliding motility. Cyanobacteria glide by secreting a polysaccharide slime from pores onto the outer surface of the cell. The slime contacts both the cell surface and the solid surface against which the cell moves. As the excreted slime adheres to the surface, the cell is pulled

along. The nonphototrophic gliding bacterium *Cytophaga* also moves at the expense of slime excretion, rotating along its long axis as it does.

Cells capable of “twitching motility” also display a form of gliding motility using a mechanism by which repeated extension and retraction of type IV pili (Section 2.13) drag the cell along a surface. The gliding myxobacterium *Myxococcus xanthus* has two forms of gliding motility. One form is driven by type IV pili, whereas the other is distinct from either the type IV pili or the slime extrusion methods. In this form of *M. xanthus* motility, a protein adhesion complex is formed at one pole of the rod-shaped cell and remains at a fixed position on the surface as the cell glides forward. This means that the adhesion complex moves in the direction opposite that of the cell, presumably fueled by some sort of cytoplasmic motility engine.

Neither slime extrusion nor twitching is the mechanism of gliding in other gliding bacteria. In the genus *Flavobacterium* (Figure 2.55c), for example, no slime is excreted and cells lack type IV pili. Instead of using one of these gliding mechanisms, the movement of proteins on the *Flavobacterium* cell surface supports gliding motility in this organism. Specific motility proteins anchored in the cytoplasmic and outer membranes are thought to propel cells of *Flavobacterium* forward by a ratcheting mechanism (Figure 2.56). Movement of gliding-specific proteins in the cytoplasmic membrane is driven by energy from the proton motive force, and this motion is then transmitted to complementary glide proteins in the outer membrane. Movement of the outer membrane proteins against the solid surface then pulls the cell forward (Figure 2.56).

Like other forms of motility, gliding motility has ecological relevance. Gliding allows a cell to exploit new resources and to interact with other cells. For example, myxobacteria, such as *Myxococcus xanthus*, have a very social and cooperative lifestyle, and gliding motility may play an important role in the intimate cell-to-cell interactions necessary to complete their life cycle (Section 14.19).

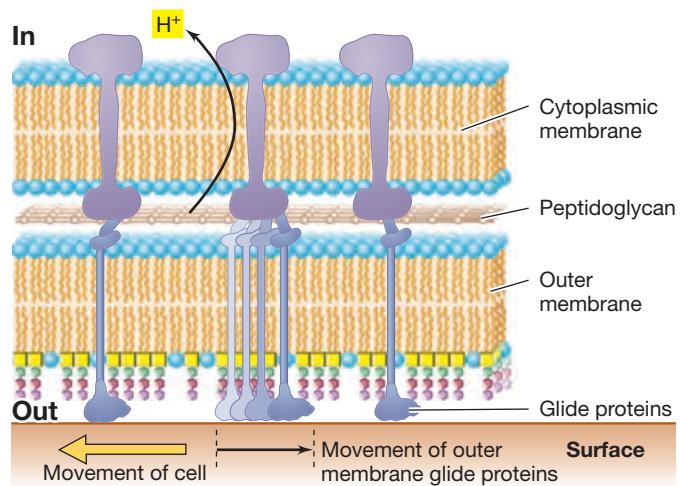

Figure 2.56 Gliding motility in *Flavobacterium johnsoniae*. Tracks (yellow) exist in the peptidoglycan that connect cytoplasmic proteins to outer membrane glide proteins and propel the glide proteins along the solid surface. Note that the glide proteins and the cell proper move in opposite directions.

MINIQUIZ

- How does gliding motility differ from swimming motility in both mechanism and requirements?
- Contrast the mechanism of gliding motility in a filamentous cyanobacterium and in *Flavobacterium*.

2.19 Chemotaxis and Other Taxes

Prokaryotes often encounter gradients of physical or chemical agents in nature and have evolved means to respond to these gradients by moving either toward or away from the agent. Such a directed movement is called a *taxis* (plural, *taxes*). **Chemotaxis**, a response to chemicals, and **phototaxis**, a response to light, are two well-studied taxes. Here we discuss these taxes in a general way. In Section 7.8 we examine the molecular mechanism of chemotaxis and its regulation in *Escherichia coli* as a model for all taxes in *Bacteria*.

Chemotaxis has been well studied in swimming bacteria, and much is known at the genetic level concerning how information on the chemical state of the environment is communicated to the flagellum. Our discussion here will thus deal solely with swimming bacteria. However, some gliding bacteria (Section 2.18) are also chemotactic, and there are phototactic movements in filamentous cyanobacteria (Figure 2.55a, b). In addition, many species of *Archaea* are also chemotactic and many of the same types of proteins that control chemotaxis in *Bacteria* are present in motile *Archaea* as well.

Chemotaxis in Peritrichously Flagellated Bacteria

Much research on chemotaxis has been done with the peritrichously flagellated bacterium *E. coli*. To understand how chemotaxis affects the behavior of *E. coli*, consider the situation in which a cell encounters a gradient of some chemical in its environment

(Figure 2.57). In the absence of the gradient, cells move in a random fashion that includes *runs*, in which the cell is swimming forward in a smooth fashion, and *tumbles*, when the cell stops and jiggles about. During forward movement in a run, the flagellar motor rotates counterclockwise. When flagella rotate clockwise, the bundle of flagella pushes apart, forward motion ceases, and the cells tumble (Figure 2.57).

Following a tumble, the direction of the next run is random. Thus, by means of runs and tumbles, the cell moves about its environment in a random fashion but does not really go anywhere. However, if a gradient of a chemical attractant is present, these random movements become biased. If the organism senses that it is moving toward higher concentrations of the attractant, runs become longer and tumbles are less frequent. The result of this behavioral response is that the organism moves up the concentration gradient of the attractant (Figure 2.57b). If the organism senses a repellent, the same general mechanism applies, although in this case it is the *decrease* in concentration of the repellent (rather than the *increase* in concentration of an attractant) that promotes runs.

How are chemical gradients sensed? Prokaryotic cells are too small to sense a gradient of a chemical along the length of a single cell. Instead, while moving, cells monitor their environment by sampling chemicals periodically and comparing the concentration with that sensed a few moments before. Bacterial cells thus respond to *temporal* rather than *spatial* differences in the concentration of a chemical as they swim. Sensory information is fed through an elaborate cascade of proteins that eventually affect the direction of rotation of the flagellar motor. The attractants and repellents are sensed by a series of membrane proteins called *chemoreceptors*. These proteins bind the chemicals and begin the process of sensory transduction to the flagellum (Section 7.8). Chemotaxis can thus be considered a type of sensory response system, analogous to sensory responses in the nervous system of animals.

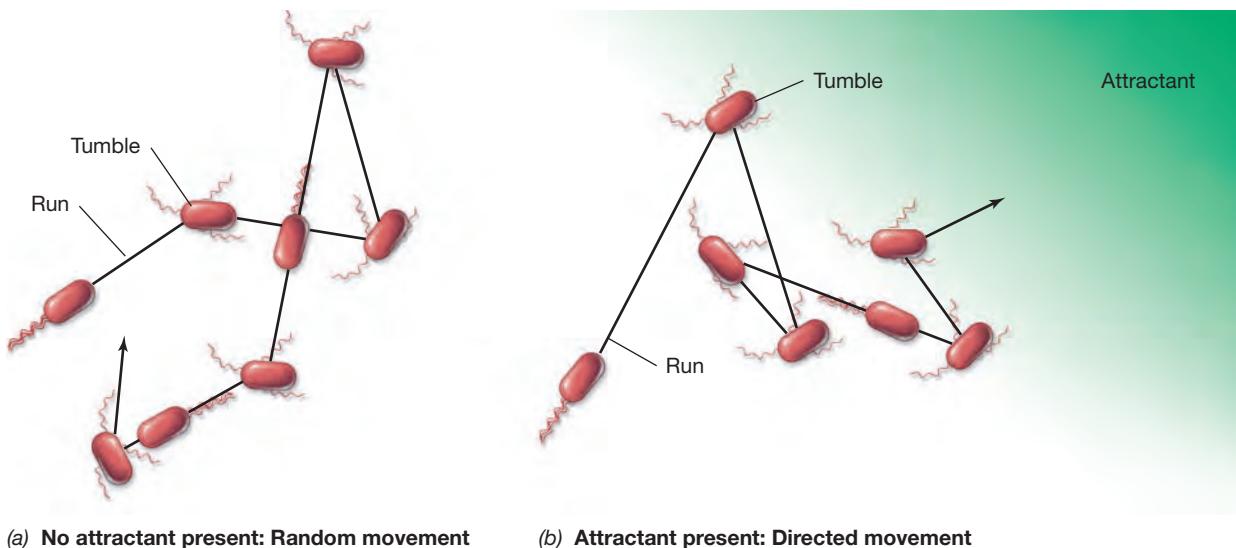

Figure 2.57 Chemotaxis in a peritrichously flagellated bacterium such as *Escherichia coli*. (a) In the absence of a chemical attractant, the cell swims randomly in runs, changing direction during tumbles. (b) In the presence of an attractant, runs become biased, and the cell moves up the gradient of the attractant. The attractant gradient is depicted in green, with the highest concentration where the color is most intense.

Chemotaxis in Polarly Flagellated Bacteria

Chemotaxis in polarly flagellated cells is similar to that in peritrichously flagellated cells such as *E. coli*, but there are some differences. Many polarly flagellated bacteria, such as *Pseudomonas* species, can reverse the direction of rotation of their flagella and in so doing immediately reverse their direction of movement (Figure 2.54b). However, some polarly flagellated bacteria, such as the phototrophic purple bacterium *Rhodobacter sphaeroides*, have flagella that rotate only in a clockwise direction. How do such cells change direction, and are they chemotactic?

In cells of *R. sphaeroides*, which have only a single flagellum inserted subpolarly, rotation of the flagellum stops periodically. When it stops, the cell becomes reoriented in a random way (Figure 2.54b). As the flagellum begins to rotate again, the cell moves in a new direction. Nevertheless, cells of *R. sphaeroides* are strongly chemotactic to certain organic compounds and also show tactic responses to oxygen and light. *R. sphaeroides* cannot reverse its flagellar motor and tumble as *E. coli* can, but cells do maintain runs as long as they sense an increasing concentration of attractant. If the cells sense a decreasing concentration of attractant, movement ceases. By such starting and stopping, a cell eventually finds the path of increasing attractant and maintains a run until either its chemoreceptors are saturated or it begins to sense a decrease in the level of attractant.

Measuring Chemotaxis

Bacterial chemotaxis can be demonstrated by immersing a small glass capillary tube containing an attractant into a suspension of

motile bacteria that does not contain the attractant. From the tip of the capillary, a gradient forms into the surrounding medium, with the concentration of chemical gradually decreasing with distance from the tip (Figure 2.58). When an attractant is present, chemotactic bacteria will move toward it, forming a swarm around the open tip (Figure 2.58c) with many of the bacteria swimming into the capillary itself. Of course, because of random movements some chemotactic bacteria will swim into the capillary even if it contains a solution of the same composition as the medium (control solution, Figure 2.58b). However, when an attractant is present, the number of bacteria within the capillary will be many times higher than external cell numbers. If the capillary is removed after a time period and the cells within the capillary are counted and compared with that of the control, attractants can easily be identified (Figure 2.58e).

If the inserted capillary contains a repellent, just the opposite occurs; the cells sense an increasing gradient of repellent and the appropriate chemoreceptors affect flagellar rotation to gradually move the cells away from the repellent. In this case, the number of bacteria within the capillary will be fewer than in the control (Figure 2.58d). Using this capillary method, it is possible to screen chemicals to see if they are attractants or repellents for a given bacterium.

Chemotaxis can also be observed under a microscope. Using a video camera that captures the position of bacterial cells with time and shows the motility tracks of each cell, it is possible to see the chemotactic movements of cells (Figure 2.58f). This method has been adapted to studies of chemotaxis of bacteria in natural environments. In nature it is thought that the major chemotactic

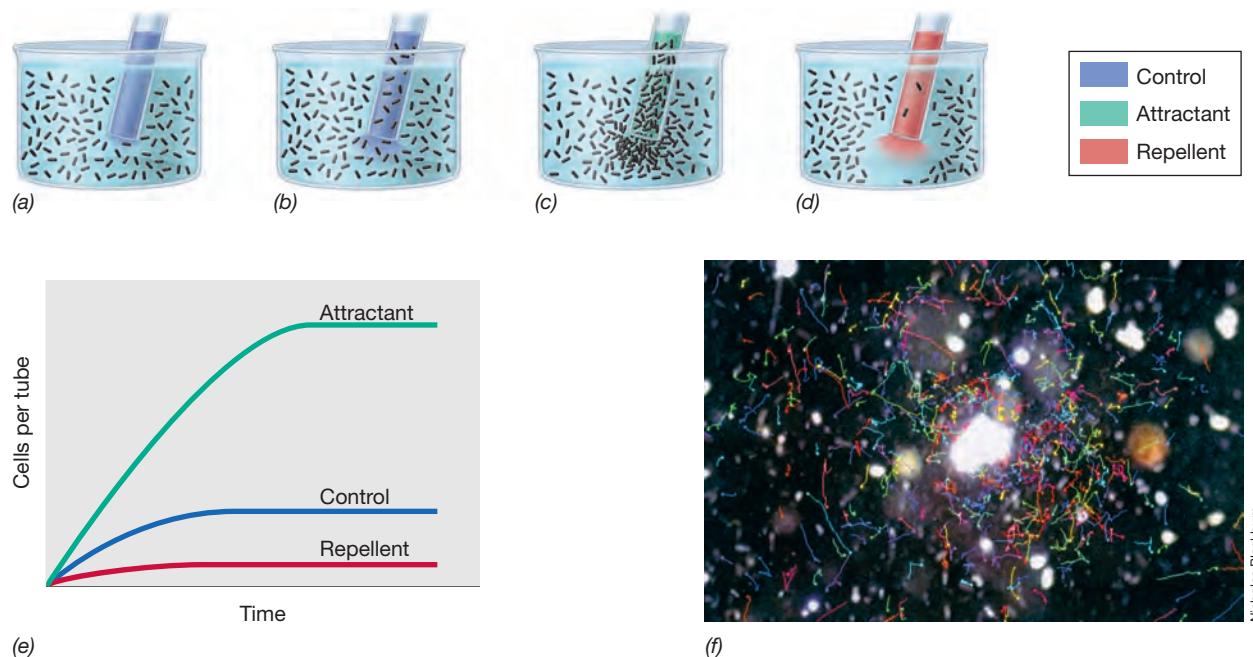

Figure 2.58 Measuring chemotaxis using a capillary tube assay. (a) Insertion of the capillary into a bacterial suspension. As the capillary is inserted, a gradient of the chemical begins to form. (b) Control capillary contains a salt solution that is neither an attractant nor a repellent. Cell concentration inside the capillary becomes the same as that outside. (c) Accumulation of bacteria in a capillary containing an attractant. (d) Repulsion of bacteria by a repellent. (e) Time course showing cell numbers in capillaries containing various chemicals. (f) Tracks of motile bacteria in seawater swarming around an algal cell (large white spot, center) photographed with a tracking video camera system attached to a microscope. The bacterial cells are showing positive aerotaxis by moving toward the oxygen-producing algal cell. The alga is about 60 μm in diameter.

agents for bacteria are nutrients excreted from larger microbial cells or from live or dead macroorganisms. Algae, for example, produce both organic compounds and oxygen (O_2 , from photosynthesis) that can trigger chemotactic movements of bacteria toward the algal cell (Figure 2.58f).

Phototaxis

Many phototrophic microorganisms can move toward light, a process called *phototaxis*. The advantage of phototaxis for a phototrophic organism is that it allows it to orient itself most efficiently to receive light for photosynthesis. This can be shown if a light spectrum is spread across a microscope slide on which there are motile phototrophic purple bacteria. On such a slide the bacteria accumulate at wavelengths at which their photosynthetic pigments absorb (Figure 2.59; Sections 13.1–13.4 cover photosynthesis). These pigments include, in particular, bacteriochlorophylls and carotenoids.

Two different light-mediated taxes are observed in phototrophic bacteria. One, called *scotophobotaxis*, can be observed

only microscopically and occurs when a phototrophic bacterium happens to swim outside the illuminated field of view of the microscope into darkness. Entering darkness negatively affects photosynthesis and thus the energy state of the cell and signals the cell to tumble, reverse direction, and once again swim in a run, thus reentering the light. Scotophobotaxis is presumably a mechanism by which phototrophic purple bacteria avoid entering darkened habitats when they are moving about in illuminated ones, and this likely improves their competitive success.

True phototaxis differs from scotophobotaxis; in phototaxis, cells move up a gradient of light from lower to higher intensities. Phototaxis is analogous to chemotaxis except that the attractant in this case is light instead of a chemical. In some species, such as the highly motile phototrophic purple bacterium *Rhodospirillum centenum* (Figure 2.49), entire colonies of cells show phototaxis and move in unison toward the light (Figure 2.59b).

Several components of the regulatory system that govern chemotaxis also control phototaxis. This connection has emerged from the study of mutants of phototrophic bacteria defective in phototaxis; such mutants show defective chemotaxis systems as well. A *photoreceptor*, a protein that functions similar to a chemo-receptor but senses a gradient of light instead of chemicals, is the initial sensor in the phototaxis response. The photoreceptor then interacts with the same cytoplasmic proteins that control flagellar rotation in chemotaxis, maintaining the cell in a run if it is swimming toward an increasing intensity of light. Thus, although the stimulus in chemotaxis and phototaxis is different—chemicals versus light—the response following reception of the stimulus is controlled by a common series of proteins. Section 7.8 discusses the activities of these proteins in more detail.

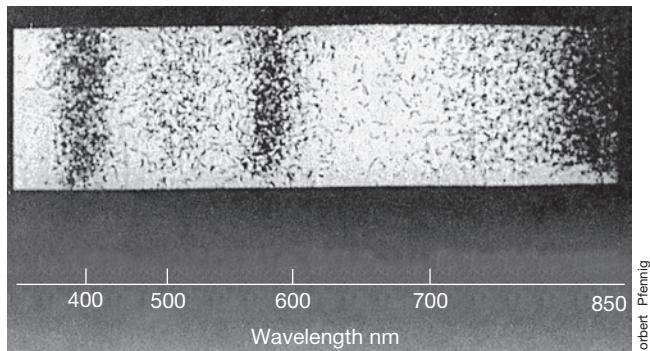

Other Taxes

Other bacterial taxes, such as movement toward or away from oxygen (*aerotaxis*, see Figure 2.58f) or toward or away from conditions of high ionic strength (*osmotaxis*), are known among various swimming prokaryotes. In some gliding cyanobacteria an unusual taxis, *hydrotaxis* (movement toward water), has also been observed. Hydrotaxis allows gliding cyanobacteria that inhabit dry environments, such as desert soils, to glide toward a gradient of increasing hydration.

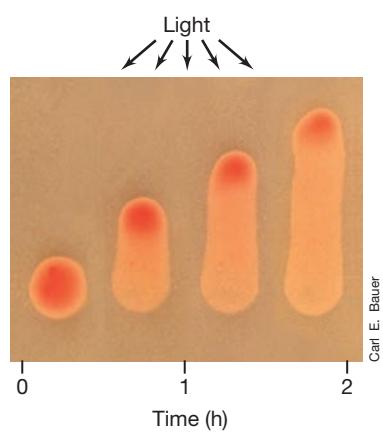

From the study of microbial taxes, it is obvious that motile prokaryotes are “tuned in” to the chemical and physical state of their habitats. And from a mechanistic standpoint, it is interesting that these cells process the results of their environmental samplings through a common system that ultimately controls flagellar activity. By being able to move toward or away from various stimuli, prokaryotic cells improve their chances of competing for resources and avoiding the harmful effects of substances that could damage or kill them.

MINIQUIZ

- Define the word chemotaxis. How does chemotaxis differ from aerotaxis?
- What causes a run versus a tumble?
- How can chemotaxis be measured quantitatively?
- How does scotophobotaxis differ from phototaxis?

(a)

(b)

Figure 2.59 Phototaxis of phototrophic bacteria. (a) Scotophobic accumulation of the phototrophic purple bacterium *Thiospirillum jenense* at wavelengths of light at which its pigments absorb. A light spectrum was displayed on a microscope slide containing a dense suspension of the bacteria; after a period of time, the bacteria had accumulated selectively and the photomicrograph was taken. The wavelengths at which the bacteria accumulated are those at which the photosynthetic pigment bacteriochlorophyll *a* absorbs (compare with Figure 13.3b). (b) Phototaxis of an entire colony of the purple phototrophic bacterium *Rhodospirillum centenum*. These strongly phototactic cells move in unison toward the light source at the top. See Figure 2.49 for electron micrographs of flagellated *R. centenum* cells.

VII • Eukaryotic Microbial Cells

Compared with prokaryotic cells, microbial eukaryotes typically have structurally more complex and much larger cells (Figure 1.2). We finish up our study of microbial cell structure and function with a consideration of structure/function issues in microbial eukaryotes, common models for the study of eukaryotic biology. Microbial eukaryotes include the fungi, the algae, and the protozoa and other protists. We cover the diversity of microbial eukaryotes in Chapter 17.

2.20 The Nucleus and Cell Division

Eukaryotic cells vary in the complement of organelles they contain, but a unit membrane–enclosed nucleus is universal and a hallmark of the eukaryotic cell. Mitochondria are nearly universal among eukaryotic cells, while pigmented chloroplasts are found only in phototrophic cells. Other structures include the Golgi complex, lysosomes, endoplasmic reticula, and microtubules and microfilaments (Figure 2.60). Some microbial eukaryotes have flagella or cilia—organelles of motility—while others do not. Microbial eukaryotes may also have extracellular components,

such as a cell wall in fungi and algae (most protozoans lack a cell wall).

Nucleus

The **nucleus** contains the chromosomes of the eukaryotic cell. DNA within the nucleus is wound around basic (positively charged) proteins called **histones**, which tightly pack the negatively charged DNA to form nucleosomes (Figure 2.61b) and from them, chromosomes. The nucleus is enclosed by a pair of membranes, each with its own function, separated by a space. The inner membrane is a simple sac while the outer membrane is in many places continuous with the endoplasmic reticulum. The inner and outer nuclear membranes specialize in interactions with the nucleoplasm and the cytoplasm, respectively. The nuclear membranes contain pores (Figures 2.60 and 2.61a), formed from holes where the inner and outer membranes are joined. The pores allow transport proteins to import and export other proteins and nucleic acids into and out of the nucleus, a process called *nuclear transport*.

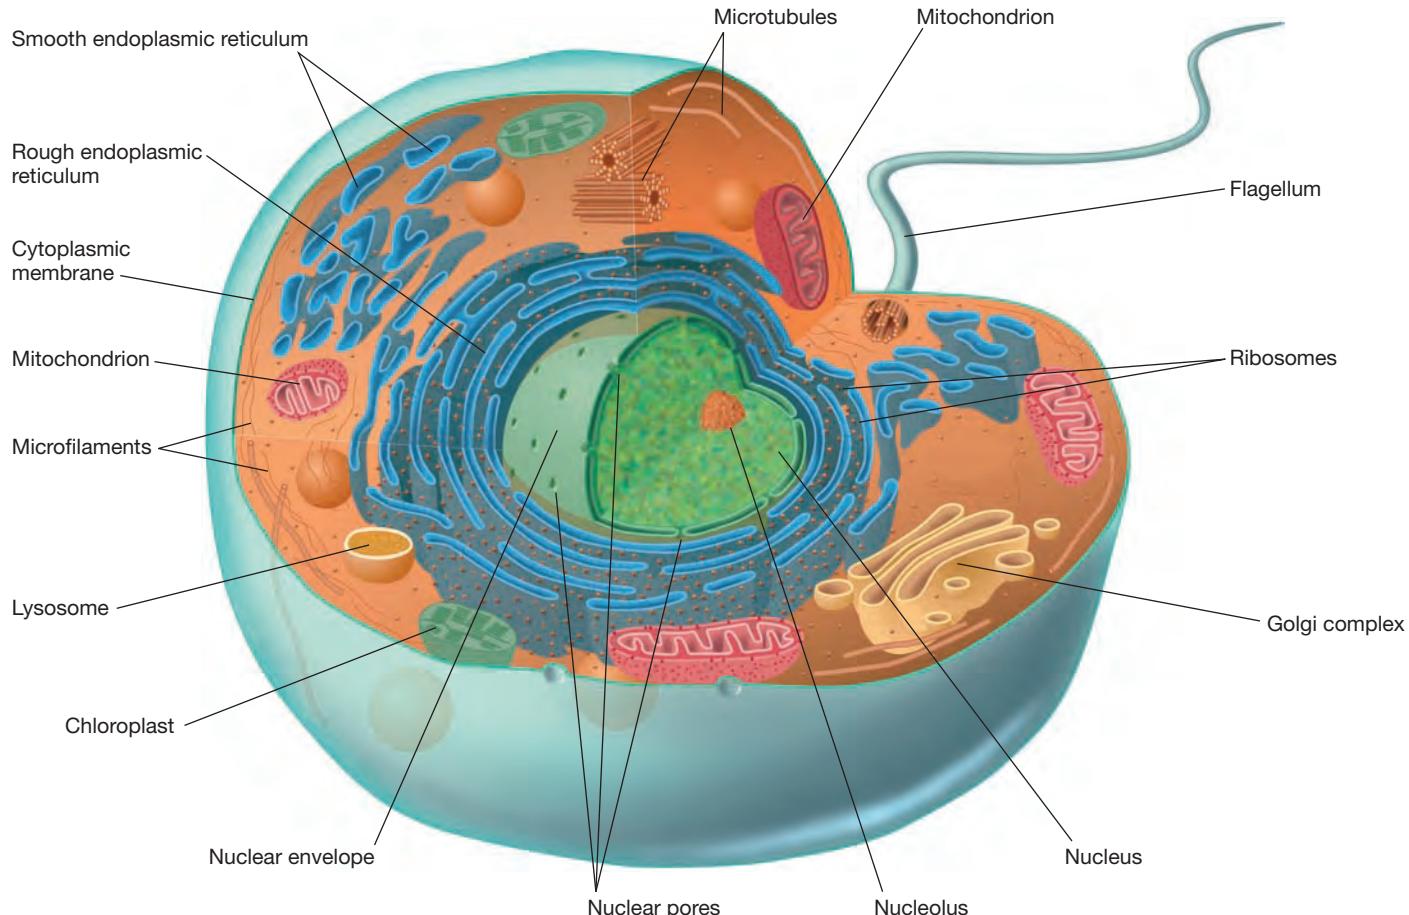

Figure 2.60 Cutaway schematic of a microbial eukaryote. Although all eukaryotic cells contain a nucleus, not all organelles and other structures shown are present in all microbial eukaryotes. Not shown is the cell wall, found in fungi, algae, plants, and a few protists.

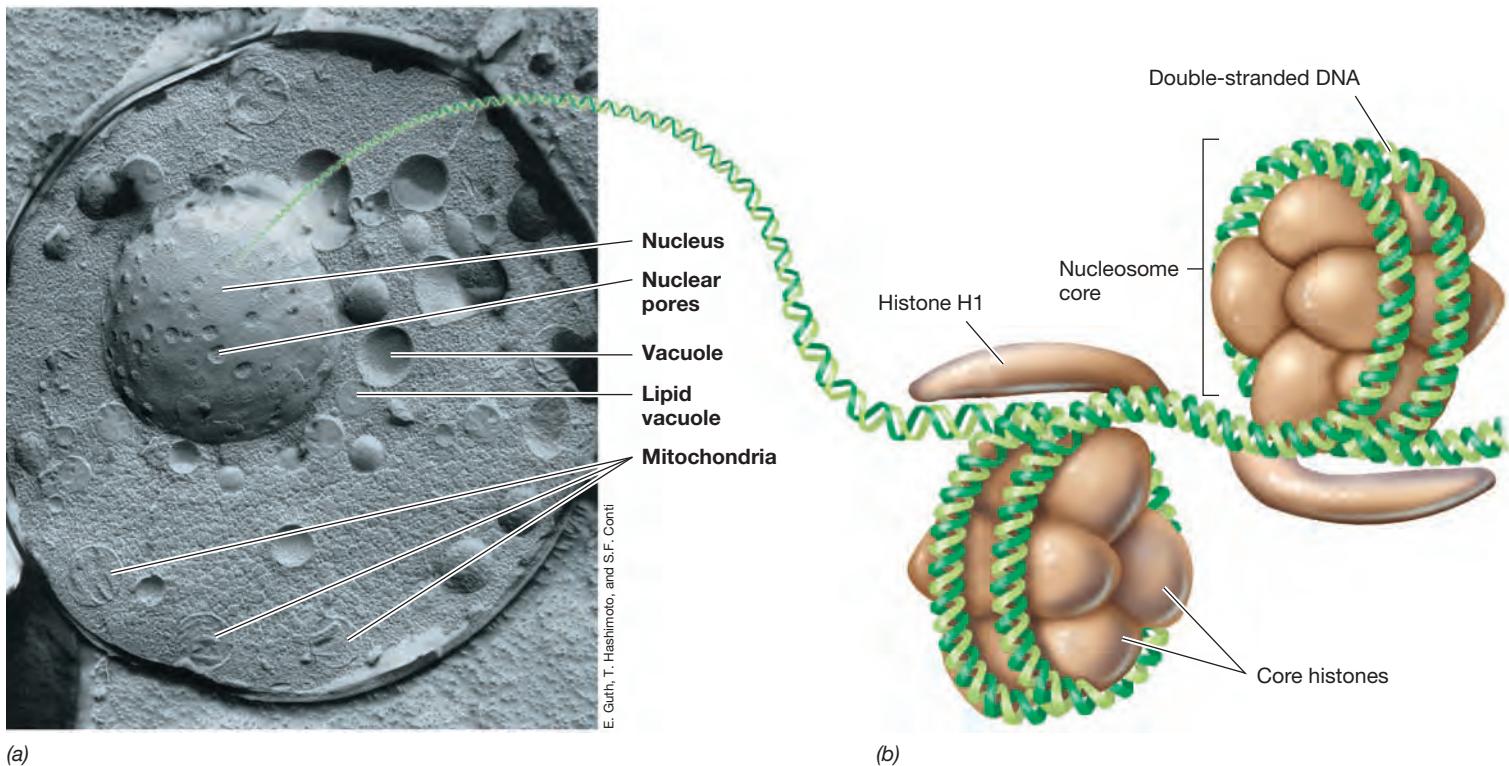

Figure 2.61 The nucleus and DNA packaging in eukaryotes. (a) Electron micrograph of a yeast cell prepared in such a way as to reveal a surface view of the nucleus. The cell is about 8 μm wide. (b) Packaging of DNA around histone proteins to form a nucleosome. Nucleosomes are arranged along the DNA strand like beads on a string and aggregate to form chromosomes during the process of mitosis (see Figure 2.62).

Within the nucleus is found the *nucleolus* (Figure 2.60), the site of ribosomal RNA (rRNA) synthesis. The nucleolus is rich in RNA, and ribosomal proteins synthesized in the cytoplasm are transported into the nucleolus and combine with rRNA to form the small and large subunits of eukaryotic ribosomes. These are then exported to the cytoplasm, where they associate to form the intact ribosome and function in protein synthesis.

Cell Division

Eukaryotic cells divide by a process in which the chromosomes are replicated, the nucleus disassembled, the chromosomes segregated into two sets, and a nucleus reassembled in each daughter cell. Many microbial eukaryotes can exist in either of two genetic states: *haploid* or *diploid*. Diploid cells have two copies of each

chromosome whereas haploid cells have only one. For example, the brewer's yeast *Saccharomyces cerevisiae* can exist in the haploid state (16 chromosomes) as well as in the diploid state (32 chromosomes). However, regardless of its genetic state, during cell division the chromosome number is first doubled and later halved to give each daughter cell its correct complement of chromosomes. This is the process of **mitosis**, unique to eukaryotic cells. During mitosis, the chromosomes condense, divide, and are separated into two sets, one for each daughter cell (Figure 2.62).

In contrast to mitosis, **meiosis** is the process of conversion from the diploid to the haploid stage. Meiosis consists of two cell divisions. In the first meiotic division, homologous chromosomes segregate into separate cells, changing the genetic state from diploid to haploid. The second meiotic division is essentially the

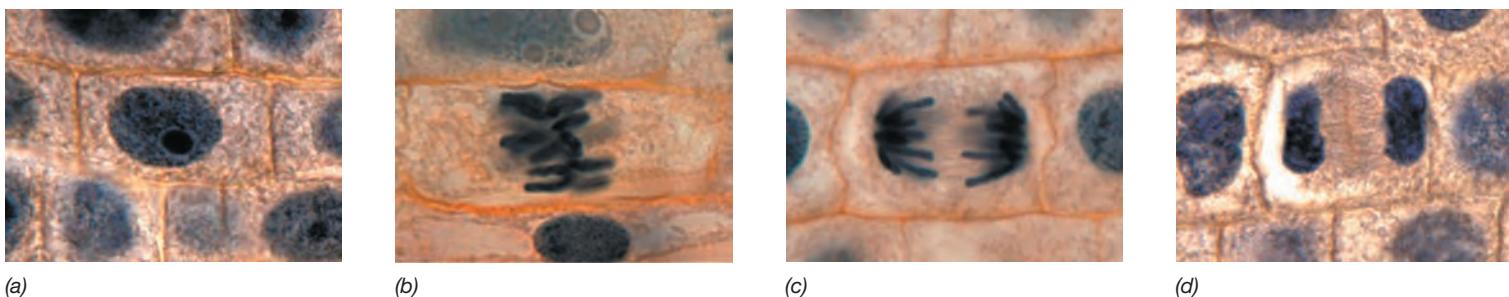

Figure 2.62 Light micrograph of plant cells undergoing mitosis. (a) Interphase, distinct chromosomes are not apparent. (b) Metaphase. Homologous chromosomes are lining up along the cell center. (c) Anaphase. Homologous chromosomes are pulling apart. (d) Telophase. Chromosomes have separated into the newly forming daughter cells.

same as mitosis, as the two haploid cells divide to form a total of four haploid cells called *gametes*. In higher organisms these are the eggs and sperm; in eukaryotic microorganisms, they are spores or related structures.

MINIQUIZ

- How is DNA arranged in eukaryotic chromosomes?
- What are histones and what do they do?
- What are the major differences between mitosis and meiosis?

2.21 Mitochondria, Hydrogenosomes, and Chloroplasts

Organelles that specialize in energy metabolism in eukaryotes include the mitochondrion or hydrogenosome, and in phototrophic eukaryotes, the chloroplast.

Mitochondria

In aerobic eukaryotic cells, respiration occurs in the mitochondrion. **Mitochondria** are of bacterial dimensions and can take on many shapes (Figure 2.63). The number of mitochondria per cell depends somewhat on the cell type and size. A yeast cell may have

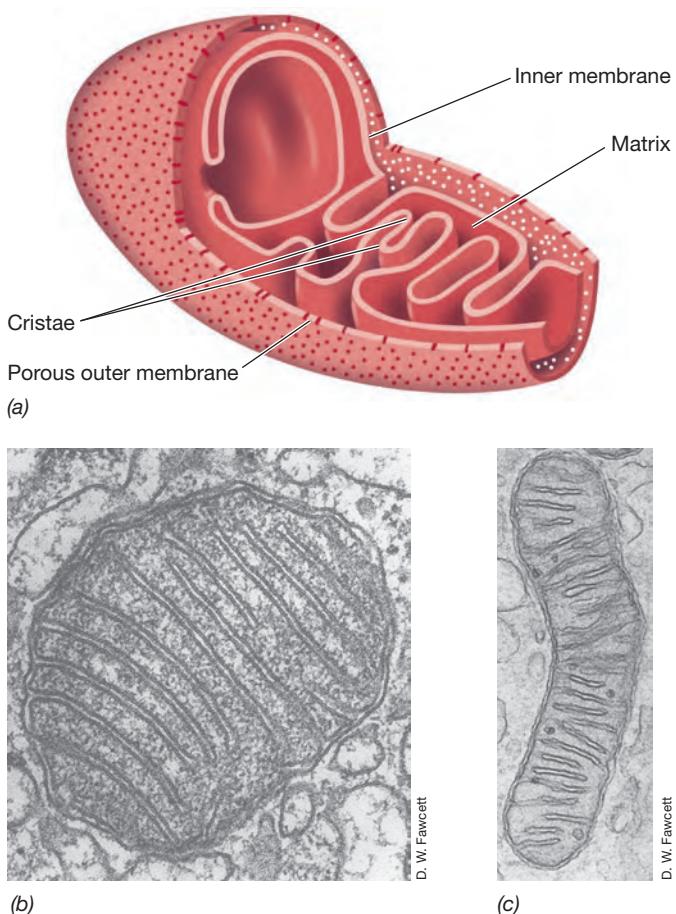

Figure 2.63 Structure of the mitochondrion. (a) Diagram showing the overall structure of the mitochondrion; note the inner and outer membranes. (b, c) Transmission electron micrographs of mitochondria from rat tissue showing the variability in morphology; note the cristae.

only a few mitochondria per cell (Figures 2.60 and 2.61a), while an animal cell may have a thousand. The mitochondrion is enclosed by a double membrane system. Like the nuclear membrane, the outermost mitochondrial membrane is relatively permeable and contains pores that allow the passage of small molecules. The inner membrane is less permeable and its structure more closely resembles that of the cytoplasmic membrane of *Bacteria*.

Mitochondria also contain folded internal membranes called **cristae**. These membranes, formed by invagination of the inner membrane, contain the enzymes needed for respiration and ATP production, the major function of the mitochondrion. Cristae also contain transport proteins that regulate the passage of key molecules such as ATP into and out of the *matrix*, the innermost compartment of the mitochondrion (Figure 2.63a). The matrix contains enzymes for the oxidation of organic compounds, in particular, enzymes of the citric acid cycle, the major pathway for the combustion of organic compounds to CO₂ (Section 3.12).

Hydrogenosomes

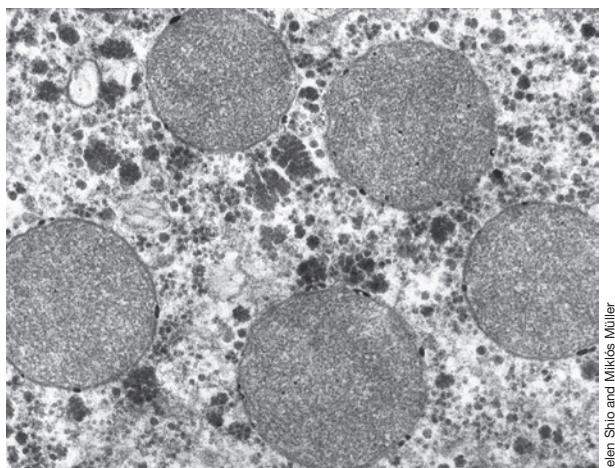

Some eukaryotic microorganisms are killed by O₂ and, like many prokaryotes, live an anaerobic lifestyle. Such cells lack mitochondria and some of them contain structures called **hydrogenosomes** (Figure 2.64). Although similar in size to mitochondria, hydrogenosomes lack citric acid cycle enzymes and also lack cristae. Microbial eukaryotes that contain hydrogenosomes carry out a strictly fermentative metabolism. Examples include the human parasite *Trichomonas* (Sections 17.3 and 32.4) and various protists that inhabit the rumen of ruminant animals (Sections 1.5 and 22.7) or anoxic muds and lake sediments.

The major biochemical reaction in the hydrogenosome is the oxidation of the compound pyruvate to H₂, CO₂, and acetate (Figure 2.64b). Some anaerobic eukaryotes have H₂-consuming methanogens in their cytoplasm. These *Archaea* consume the H₂ and CO₂ produced by the hydrogenosome and use it to form methane (CH₄). Because hydrogenosomes cannot respire, they cannot oxidize the acetate produced from pyruvate oxidation as mitochondria do. Acetate is therefore excreted from the hydrogenosome into the cytoplasm of the host cell (Figure 2.64b).

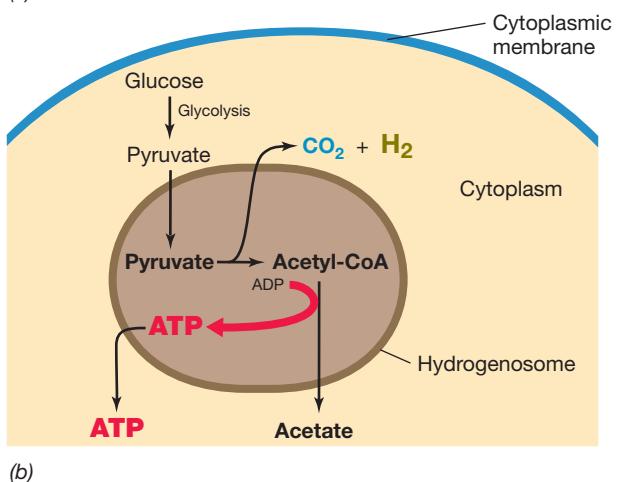

Chloroplasts

Chloroplasts are the chlorophyll-containing organelles of phototrophic microbial eukaryotes and function to carry out photosynthesis. Chloroplasts are relatively large and readily visible with the light microscope (Figure 2.65), and their number per cell varies among species.

Like mitochondria, chloroplasts have a permeable outer membrane and a much less-permeable inner membrane. The inner membrane surrounds the **stroma**, analogous to the matrix of the mitochondrion (Figure 2.65c). The stroma contains the enzyme *ribulose bisphosphate carboxylase* (RubisCO), the key enzyme of the **Calvin cycle**, the series of biosynthetic reactions by which most phototrophs convert CO₂ to organic compounds (Section 13.5). The permeability of the outer chloroplast membrane allows glucose and ATP produced during photosynthesis to diffuse into the cell cytoplasm where they can be used in biosynthesis.

(a)

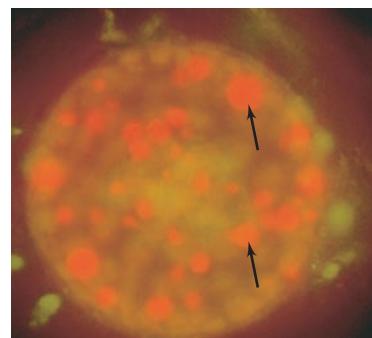

(b)

Figure 2.64 The hydrogenosome. (a) Electron micrograph of a thin section through a cell of the anaerobic protist *Trichomonas vaginalis* showing five hydrogenosomes in cross section. Compare their internal structure with that of mitochondria in Figure 2.63. (b) Biochemistry of the hydrogenosome. Pyruvate is taken up by the hydrogenosome, and H_2 , CO_2 , acetate, and ATP are produced.

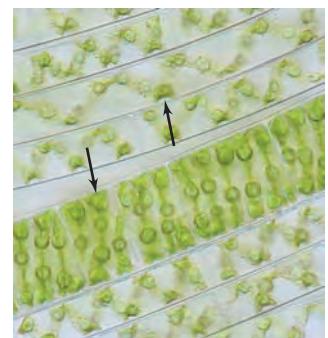

Chlorophyll and all other components needed for the light reactions of photosynthesis in chloroplasts are located in a series of flattened membrane discs called **thylakoids** (Figure 2.65c). Like the cytoplasmic membrane, the thylakoid membrane is highly impermeable and its major function is to form the light-driven proton motive force (Figure 2.18c) that results in ATP synthesis.

Organelles and Endosymbiosis

On the basis of their relative autonomy, size, and morphological resemblance to bacteria, it was hypothesized over 100 years ago that mitochondria and chloroplasts were descendants of respiratory and photosynthetic bacterial cells, respectively. By associating with nonphototrophic eukaryal hosts, the latter gained a new form of energy metabolism while the symbiotic bacterial cells received a stable and supportive growth environment inside the host. Gradually, over time these originally free-living symbionts became an intimate part of the eukaryotic cell. This idea of symbiotic bacteria as the ancestors of the mitochondrion, hydrogenosome, and chloroplast is called the **endosymbiotic hypothesis**.

(a)

(b)

(c)

Figure 2.65 Chloroplasts of a diatom and a green alga cell. (a) Fluorescence photomicrograph of a diatom shows chlorophyll fluorescence (compare with Figure 2.6); arrows, chloroplasts. The cell is about 40 μm wide. (b) Phase-contrast photomicrograph of the filamentous green alga *Spirogyra* showing the characteristic spiral-shaped chloroplasts (arrows) of this phototroph. A cell is about 20 μm wide. (c) Transmission electron micrograph showing a chloroplast of a diatom; note the thylakoids.

(“endo” means “inside”) of eukaryotic cell origin (► Sections 12.3 and 17.1) and is now well accepted in biology.

Several lines of evidence support the endosymbiotic hypothesis. These include in particular the fact that mitochondria, hydrogenosomes, and chloroplasts contain their own genomes and ribosomes. The genomes are arranged in a circular fashion as for bacterial chromosomes, and the sequence of genes that encode ribosomal RNA (► Figure 1.6a) from organelles clearly points to their bacterial origin. Thus, the eukaryotic cell is a genetic chimera containing genes from two domains of life: host cell (*Eukarya*) genes and endosymbiont (*Bacteria*) genes.

MINIQUIZ

- What key reactions occur in the mitochondrion and chloroplast, and what key product is made there?
- Compare and contrast pyruvate metabolism in the mitochondrion and the hydrogenosome.
- What is the endosymbiotic hypothesis and what evidence is there to support it?

2.22 Other Major Eukaryotic Cell Structures

Besides the nucleus and the mitochondrion (or hydrogenosome), and chloroplasts in photosynthetic cells, other cytoplasmic structures may be present in microbial eukaryotes. These include the

endoplasmic reticulum, the Golgi complex, lysosomes, a variety of tubular structures, and structures that impart motility. However, unlike mitochondria and chloroplasts, these structures lack DNA and are not of endosymbiotic origin. Cell walls are also present in certain microbial eukaryotes and function as they do in prokaryotic cells to provide shape and protect the cell from osmotic lysis. The exact structure of the cell wall varies with the organism, but various polysaccharides and proteins are commonly observed.

Endoplasmic Reticulum, the Golgi Complex, and Lysosomes

The endoplasmic reticulum (ER) is a network of membranes continuous with the nuclear membrane. Two types of endoplasmic reticulum exist: *rough*, which contains attached ribosomes, and *smooth*, which does not (Figure 2.60). Smooth ER participates in the synthesis of lipids and in some aspects of carbohydrate metabolism. Rough ER, through the activity of its ribosomes, is a major producer of glycoproteins and also produces new membrane material that is transported throughout the cell to enlarge the various membrane systems before cell division.

The Golgi complex is a stack of membranes (Figure 2.66) that arise from preexisting Golgi bodies and function in concert with the ER. In the Golgi, products of the ER are chemically modified and sorted into those destined for secretion versus those that will function in other membranous structures in the cell. Many of the modifications are glycosylations (addition of sugar residues) that convert the proteins into various glycoproteins that can then be targeted to specific locations in the cell.

Lysosomes (Figure 2.60) are membrane-enclosed compartments that contain digestive enzymes that hydrolyze proteins, fats, and polysaccharides. The lysosome fuses with food that enters the cell in vacuoles and then releases its digestive enzymes, which break down the foods for biosynthesis and energy generation. Lysosomes also function in hydrolyzing damaged cellular components and recycling these materials for new biosyntheses.

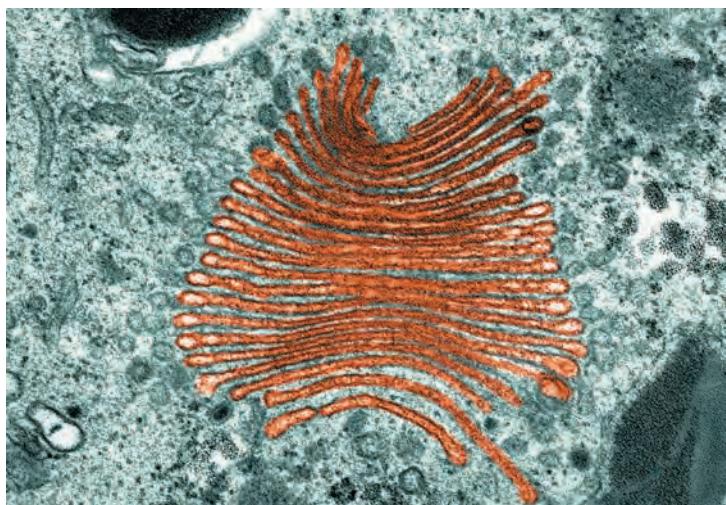

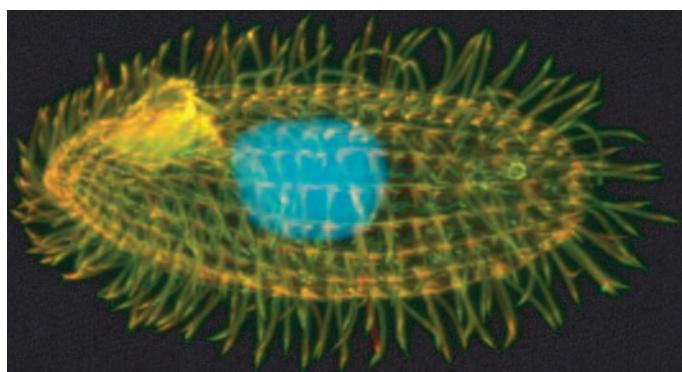

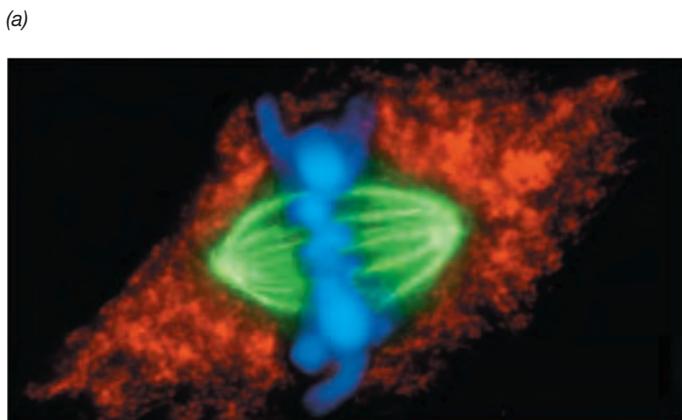

Figure 2.66 The Golgi complex. Transmission electron micrograph of a portion of an eukaryotic cell showing the Golgi complex (colored in gold). Note the multiple folded membranes of the Golgi complex (membrane stacks are 0.5–1.0 μm in diameter).

Rupal Thazhath and Jacek Gaertig

(b)

Onah Medala and Wolfgang Baumeister

Figure 2.67 Tubulin and microfilaments. (a) Fluorescence photomicrograph of a cell of *Tetrahymena* labeled with antitubulin antibodies (red/green) and with DAPI, which stains DNA (blue, nucleus). A cell is about 10 μm wide. (b) An animal cell showing the role of tubulin (green) in separating chromosomes during metaphase of mitosis. (c) Electron microscopic image of the cellular slime mold *Dictyostelium discoideum* showing the network of actin microfilaments that along with microtubules functions as the cell cytoskeleton. Microfilaments are about 7 nm in diameter. Homologs of tubulin and microfilaments are present in *Bacteria* in the form of the proteins FtsZ and MreB, respectively (see Section 5.3).

The lysosome thus allows the cell's lytic activities to be partitioned away from the cytoplasm proper. Following hydrolysis of macromolecules in the lysosome, the resulting nutrients pass from the lysosome into the cytoplasm for use by cytoplasmic enzymes.

Microtubules, Microfilaments, and Intermediate Filaments

Just as buildings are supported by structural reinforcement, the large size of eukaryotic cells and their ability to move requires structural reinforcement. This internal support network consists of *microtubules*, *microfilaments*, and *intermediate filaments*; together, these structures form the cell **cytoskeleton** (Figure 2.60).

Microtubules are tubes about 25 nm in diameter containing a hollow core and are composed of the proteins α -*tubulin* and β -*tubulin*. Microtubules have many functions including maintaining cell shape and cell motility by cilia and flagella (Figure 2.67a), moving chromosomes during mitosis (Figure 2.67b), and in movement of organelles within the cell. **Microfilaments** (Figure 2.67c) are smaller, about 7 nm in diameter, and are polymers of two intertwined strands of the protein actin. Microfilaments function in maintaining or changing cell shape, in cell motility by cells that move by amoeboid movement, and during cell division. **Intermediate filaments** are fibrous keratin proteins that form into fibers 8–12 nm in diameter and function in maintaining cell shape and positioning organelles in the cell.

Flagella and Cilia

Flagella and cilia are present on many eukaryotic microorganisms and function as organelles of motility, allowing cells to move by swimming. Motility has survival value, as the ability to move allows motile organisms to move about their habitat and exploit new resources. *Cilia* are essentially short flagella that beat in synchrony to propel the cell—usually quite rapidly—through the medium. *Flagella*, by contrast, are long appendages present singly or in groups that propel the cell along—typically more slowly than by cilia—through a whiplike motion (Figure 2.68a). The flagella of

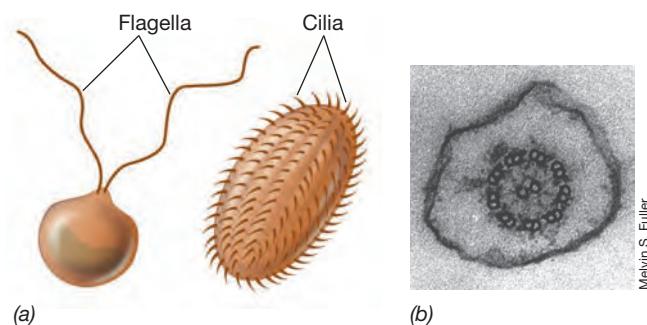

Figure 2.68 Motility organelles in eukaryotic cells: Flagella and cilia.

- (a) Flagella can be present as single or multiple filaments. Cilia are structurally very similar to flagella but much shorter. Eukaryotic flagella move in a whiplike motion.
- (b) Cross section through a flagellum of the fungus *Blastocladiella* showing the outer sheath, the outer nine pairs of microtubules, and the central pair of microtubules.

eukaryotic cells are structurally quite distinct from bacterial flagella and do not rotate as do bacterial flagella (Section 2.17).

In cross section, cilia and flagella appear similar. Each contains a bundle of nine pairs of microtubules surrounding a central pair of microtubules (Figure 2.68b). A protein called *dynein* is attached to the microtubules and uses ATP to drive motility. Movement of flagella and cilia is similar. In both cases, movement is the result of the coordinated sliding of microtubules against one another in a direction toward or away from the base of the cell. This movement confers the whiplike motion on the flagellum or cilium that results in cell propulsion.

MINIQUIZ

- Why are the activities in the lysosome best partitioned away from the cytoplasm proper?
- How is the cell's cytoskeleton held together?
- From a functional standpoint, how does the flagellum of eukaryotic and prokaryotic cells differ?

BIG IDEAS

2.1 • Microscopes are essential for studying microorganisms. Bright-field microscopy, the most common form of microscopy, employs a microscope with a series of lenses to magnify and resolve the image.

2.2 • An inherent limitation of bright-field microscopy is the lack of contrast between cells and their surroundings. This problem can be overcome by the use of stains or by alternative forms of light microscopy, such as phase contrast or dark field.

2.3 • Differential interference contrast (DIC) microscopy and confocal scanning laser microscopy allow enhanced

three-dimensional imaging or imaging through thick specimens.

2.4 • Electron microscopes have far greater resolving power than do light microscopes, the limits of resolution being about 0.2 nm. The two major forms of electron microscopy are transmission, used primarily to observe internal cell structure, and scanning, used to examine the surface of specimens.

2.5 • Prokaryotic cells can have many different shapes; rods, cocci, and spirilla are common cell morphologies. Morphology is a poor predictor of other cell properties and is a genetically

directed characteristic that has evolved to best serve the ecology of the cell.

2.6 • Prokaryotes are typically smaller than eukaryotes, although some very large prokaryotes are known. The typical small size of prokaryotic cells affects their physiology, growth rate, ecology, and evolution. The lower limit for the diameter of a coccus-shaped cell is about 0.15 m.

2.7 • The cytoplasmic membrane is a highly selective permeability barrier constructed of lipids and proteins that form a bilayer, hydrophobic inside and hydrophilic outside. In contrast to *Bacteria* and *Eukarya*, where fatty acids are ester-linked to glycerol, *Archaea* contain ether-linked lipids and some form monolayer instead of bilayer membranes.

2.8 • The major functions of the cytoplasmic membrane are permeability, transport, and energy conservation. To accumulate nutrients against the concentration gradient, transport systems are used that are characterized by their specificity and saturation effect.

2.9 • At least three types of nutrient transporters are known: simple, group translocation, and ABC systems. Transport requires energy from either an energy-rich compound such as ATP or from the proton motive force in order to accumulate solutes against the concentration gradient.

2.10 • Peptidoglycan is a polysaccharide found only in *Bacteria* that consists of an alternating repeat of *N*-acetylglucosamine and *N*-acetylmuramic acid, the latter cross-linked by tetrapeptides in adjacent strands. The enzyme lysozyme and the antibiotic penicillin both target peptidoglycan, leading to cell lysis.

2.11 • Gram-negative *Bacteria* have an outer membrane consisting of LPS, protein, and lipoprotein. Porins allow for permeability across the outer membrane. The gap between the outer and cytoplasmic membranes is called the periplasm and contains proteins involved in transport, sensing chemicals, and other important cell functions.

2.12 • Cell walls of *Archaea* are of several types, including pseudomurein, various polysaccharides, and S-layers, which are composed of protein or glycoprotein. As for *Bacteria*, the walls of *Archaea* protect the cell from osmotic lysis.

2.13 • Many prokaryotic cells contain capsules, slime layers, pili, or fimbriae. These structures have several functions, including attachment, genetic exchange, and twitching motility.

2.14 • Prokaryotic cells can contain inclusions of sulfur, polyphosphate, or carbon polymers, or minerals that form magnetic particles (magnetosomes). These substances function as storage materials or in magnetotaxis.

2.15 • Gas vesicles are gas-filled structures that confer buoyancy on cells. Gas vesicles are composed of two different proteins arranged to form a gas-permeable but watertight structure.

2.16 • The endospore is a highly resistant and differentiated bacterial cell produced by certain gram-positive *Bacteria*. Endospores are dehydrated and contain calcium dipicolinate and small acid-soluble proteins, absent from vegetative cells. Endospores can remain dormant indefinitely but can germinate quickly when conditions warrant.

2.17 • Swimming motility is due to flagella. The flagellum is composed of several proteins and is anchored in the cell wall and cytoplasmic membrane. In *Bacteria*, the flagellum filament is made of the protein flagellin and rotates at the expense of the proton motive force. The flagella of *Archaea* and *Bacteria* differ in structure and how energy is coupled to rotation.

2.18 • Bacteria that move by gliding do not employ rotating flagella but instead creep along a solid surface by employing one of several different mechanisms including polysaccharide excretion, twitching, or rotating glide proteins.

2.19 • Motile bacteria respond to chemical and physical gradients in their environment by controlling the lengths of runs and frequency of tumbles. Tumbles are controlled by the direction of rotation of the flagellum, which in turn is controlled by a network of sensory and response proteins.

2.20 • Microbial eukaryotes contain various organelles including the nucleus, which is universal; mitochondria or hydrogenosomes; and chloroplasts. The nucleus contains the cell's chromosomes in the form of linear DNA wrapped around histone proteins. Microbial eukaryotes divide following the process of mitosis and may undergo meiosis as well if a haploid/diploid life cycle occurs.

2.21 • The mitochondrion and hydrogenosome are energy-generating organelles of eukaryotic cells. Mitochondria carry out aerobic respiration, whereas hydrogenosomes ferment pyruvate to H₂, CO₂, and acetate. Chloroplasts are the site of photosynthetic energy production and CO₂ fixation in eukaryotic cells. These organelles were originally free-living *Bacteria* that established permanent residence inside cells of *Eukarya* (endosymbiosis).

2.22 • Endoplasmic reticula are membranous structures in eukaryotes that either contain attached ribosomes (rough ER) or do not (smooth ER). Flagella and cilia are means of motility while lysosomes specialize in breaking down large molecules. Microtubules, microfilaments, and intermediate filaments function as internal cell scaffolds.

KEY TERMS

ABC (ATP-binding cassette) transport system a membrane transport system consisting of three proteins, one of which hydrolyzes ATP; the system transports specific nutrients into the cell

Basal body the “motor” portion of the bacterial flagellum, embedded in the cytoplasmic membrane and wall

Calvin cycle the series of biosynthetic reactions by which most photosynthetic organisms convert CO₂ to organic compounds

Capsule a polysaccharide or protein outermost layer, usually rather slimy, present on some bacteria

Chemotaxis directed movement of an organism toward (positive chemotaxis) or away from (negative chemotaxis) a chemical gradient

Chloroplast the photosynthetic organelle of phototrophic eukaryotes

Cristae the internal membranes of a mitochondrion

Cytoplasmic membrane the permeability barrier of the cell, separating the cytoplasm from the environment

Cytoskeleton the cellular scaffolding typical of eukaryotic cells in which microtubules, microfilaments, and intermediate filaments define the cell’s shape

Dipicolinic acid a substance unique to endospores that confers heat resistance on these structures

Endospore a highly heat-resistant, thick-walled, differentiated structure produced by certain gram-positive *Bacteria*

Endosymbiotic hypothesis the idea that mitochondria and chloroplasts originated from *Bacteria*

Flagellum a long, thin cellular appendage that rotates (in prokaryotic cells) and is responsible for swimming motility

Gas vesicles gas-filled cytoplasmic structures bounded by protein and conferring buoyancy on cells

Gram-negative a bacterial cell with a cell wall containing small amounts of peptidoglycan, and an outer membrane containing lipopolysaccharide, lipoprotein, and other complex macromolecules

Gram-positive a bacterial cell whose cell wall consists chiefly of peptidoglycan; it lacks the outer membrane of gram-negative cells

Gram stain a differential staining procedure that stains cells either purple (gram-positive cells) or pink (gram-negative cells)

Group translocation an energy-dependent transport system in which the substance transported is chemically modified during the process of being transported by a series of proteins

Histones highly basic proteins that compact and wind DNA in the nucleus of eukaryotic cells

Hydrogenosome an organelle of endosymbiotic origin present in certain microbial eukaryotes that oxidizes pyruvate to H₂, CO₂, acetate, and couples this to ATP synthesis

Intermediate filament a filamentous polymer of fibrous keratin proteins, supercoiled into thicker fibers, that functions in maintaining cell shape and the positioning of certain organelles in the eukaryotic cell

Lipopolysaccharide (LPS) a combination of lipid with polysaccharide and protein that forms the major portion of the outer membrane in gram-negative *Bacteria*

Lysosome an organelle containing digestive enzymes for hydrolysis of proteins, fats, and polysaccharides

Magnetosome a particle of magnetite (Fe₃O₄) enclosed by a nonunit membrane in the cytoplasm of magnetotactic *Bacteria*

Meiosis the nuclear division that halves the diploid number of chromosomes to the haploid

Microfilament a filamentous polymer of the protein actin that helps maintain the shape of a eukaryotic cell

Microtubule a filamentous polymer of the proteins α-tubulin and β-tubulin that functions in eukaryotic cell shape and motility

Mitochondrion the respiratory organelle of eukaryotic organisms

Mitosis nuclear division in eukaryotic cells in which chromosomes are replicated and partitioned into two daughter cells during cell division

Morphology the *shape* of a cell—rod, coccus, spirillum, and so on

Nucleus the organelle that contains the eukaryotic cell’s chromosomes

Outer membrane a phospholipid- and polysaccharide-containing unit membrane that lies external to the peptidoglycan layer in cells of gram-negative *Bacteria*

Peptidoglycan a polysaccharide composed of alternating repeats of N-acetylglucosamine and N-acetylmuramic acid arranged in adjacent layers and cross-linked by short peptides

Periplasm a gel-like region between the outer surface of the cytoplasmic membrane and the inner surface of the lipopolysaccharide layer of gram-negative *Bacteria*

Peritrichous flagellation having flagella located in many places around the surface of the cell

Phototaxis movement of an organism toward light

Pili thin, filamentous structures that extend from the surface of a cell and, depending on type, facilitate cell attachment, genetic exchange, or twitching motility

Polar flagellation having flagella emanating from one or both poles of the cell

Poly-β-hydroxybutyric acid (PHB) a common storage material of prokaryotic cells consisting of a polymer of β-hydroxybutyrate or another β-alkanoic acid or mixtures of β-alkanoic acids

Resolution the ability to distinguish two objects as distinct and separate when viewed under the microscope

S-layer an outermost cell surface layer composed of protein or glycoprotein present on some *Bacteria* and *Archaea*

Simple transport system a transporter that consists of only a membrane-spanning protein and is typically driven by energy from the proton motive force

Stroma the lumen of the chloroplast, surrounded by the inner membrane

Teichoic acid a phosphorylated polyalcohol found in the cell wall of some gram-positive *Bacteria*

Thylakoid a membrane layer containing the photosynthetic pigments in chloroplasts

REVIEW QUESTIONS

- What is the difference between magnification and resolution? Can either increase without the other? (Section 2.1)
- What is the function of staining in light microscopy? What is the advantage of phase-contrast microscopy over bright-field microscopy? What is the advantage of DIC microscopy over bright-field microscopy? (Sections 2.2 and 2.3)
- What is the major advantage of electron microscopes over light microscopes? What type of electron microscope would be used to view the three-dimensional features of a cell? (Section 2.4)
- What are the major morphologies of prokaryotes? Draw cells for each morphology you list. (Section 2.5)
- How large can a prokaryote be? How small? Why is it that we likely know the lower limit more accurately than the upper limit? What are the dimensions of the rod-shaped bacterium *Escherichia coli*? (Section 2.6)
- Describe in a single sentence the structure of a unit membrane. (Section 2.7)
- Describe the major structural differences between membranes of *Bacteria* and *Archaea*. (Section 2.7)
- Explain in a single sentence why ionized molecules do not passively move through the cytoplasmic membrane. How do such molecules get through the cytoplasmic membrane? (Section 2.8)
- Cells of *Escherichia coli* take up lactose via lac permease, glucose via the phosphotransferase system, and maltose via an ABC-type transporter. For each of these sugars describe: (1) the components of the transport system and (2) the source of energy that drives the transport event. (Section 2.9)
- Why is the rigid layer of the bacterial cell wall called peptidoglycan? What are the structural reasons for the rigidity that is conferred on the cell wall by the peptidoglycan structure? (Section 2.10)
- List several functions of the outer membrane in gram-negative *Bacteria*. What is the chemical composition of the outer membrane? (Section 2.11)
- What cell wall polysaccharide common in *Bacteria* is absent from *Archaea*? What is unusual about S-layers compared to other cell walls of prokaryotes? What types of cell walls are found in *Archaea*? (Section 2.12)
- What function(s) do polysaccharide layers outside the cell wall have in prokaryotes? (Section 2.13)
- What types of cytoplasmic inclusions are formed by prokaryotes? How does an inclusion of poly-β-hydroxybutyric acid differ from a magnetosome in composition and metabolic role? (Section 2.14)
- What is the function of gas vesicles? How are these structures made such that they can remain gas tight? (Section 2.15)
- In a few sentences, indicate how the bacterial endospore differs from the vegetative cell in structure, chemical composition, and ability to resist extreme environmental conditions. (Section 2.16)
- Define the following terms: mature endospore, vegetative cell, and germination. (Section 2.16)
- Describe the structure and function of a bacterial flagellum. What is the energy source for the flagellum? How do the flagella of *Bacteria* differ from those of *Archaea* in both size and composition? (Section 2.17)
- Contrast the mechanism for motility in *Flavobacterium* from that in *Escherichia coli*. (Sections 2.17 and 2.18)
- In a few sentences, explain how a motile bacterium is able to sense the direction of an attractant and move toward it. (Section 2.19)
- In the experiment described in Figure 2.58, what is the control and why is it essential? (Section 2.19)
- List at least three features of eukaryotic cells that clearly differentiate them from prokaryotic cells. What are histones and what do they do? (Section 2.20)
- How are the mitochondrion and the hydrogenosome similar structurally? How do they differ? How do they differ metabolically? (Section 2.21)
- What major physiological processes occur in the chloroplast? (Section 2.21)
- What evidence exists that supports the idea that the major organelles of eukaryotes were once *Bacteria*? (Section 2.21)
- What are the functions of the following eukaryotic cell structures: endoplasmic reticulum, Golgi complex, and lysosomes? (Section 2.22)

APPLICATION QUESTIONS

- Calculate the size of the smallest resolvable object if 600-nm (red) light is used to observe a specimen with a 100× oil-immersion lens having a numerical aperture of 1.32. How could resolution be improved using this same lens?
- Calculate the surface-to-volume ratio of a spherical cell 15 μm in diameter and of a cell 2 μm in diameter. What are the consequences of these differences in surface-to-volume ratio for cell function?
- Assume you are given two cultures, one of a species of gram-negative *Bacteria* and one of a species of *Archaea*. Discuss at least four different ways you could tell which culture was which.
- Calculate the amount of time it would take a cell of *Escherichia coli* ($1 \times 2 \text{ } \mu\text{m}$) swimming at maximum speed (60 cell lengths per second) to travel all the way up a 3-cm-long capillary tube containing a chemical attractant.
- Assume you are given two cultures of rod-shaped bacteria, one gram-positive and the other gram-negative. How could you differentiate them using (a) light microscopy; (b) electron microscopy; (c) chemical analyses of cell walls; and (d) phylogenetic analyses?

3 • Microbial Metabolism

microbiologynow

A Metabolic Surprise

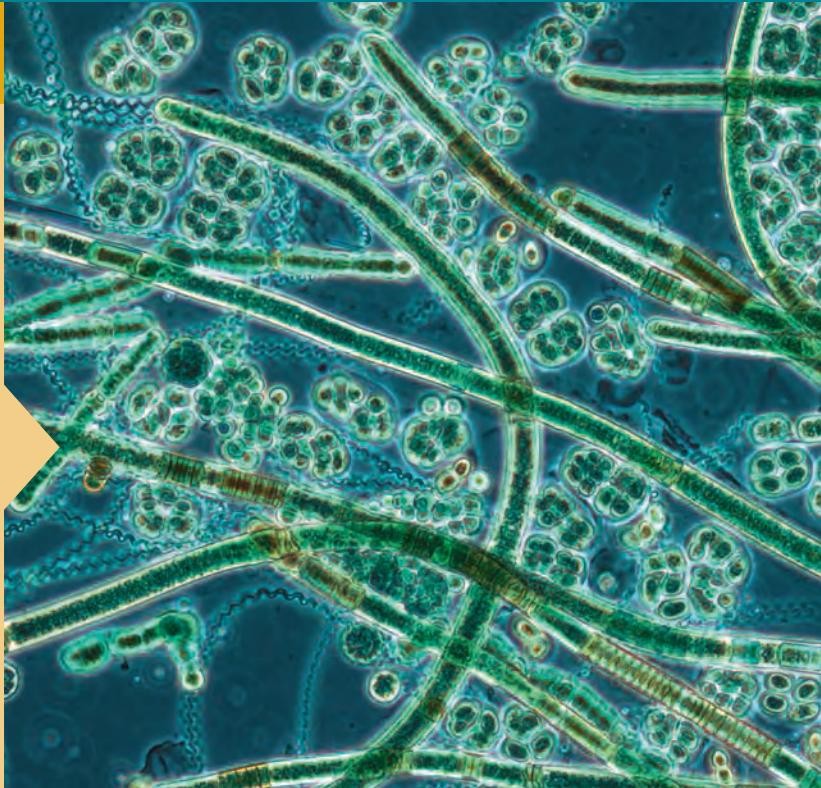

Students often get the impression that when it comes to metabolism, everything is known and nothing new will ever be discovered. This is especially so when they study classical metabolic pathways such as the citric acid cycle (Krebs cycle), an important series of reactions found in all cells and whose details will be covered in this chapter. It is just “another boring metabolic pathway” whose biochemistry was worked out years ago, right?

Wrong. For years, microbiologists have been baffled by the absence of two key enzymes of the citric acid cycle (CAC) in certain prokaryotes, in particular, the cyanobacteria. Cyanobacteria (photo) are oxygenic phototrophs whose photosynthetic activities oxygenated Earth billions of years ago and made the evolution of higher life forms possible. But the absence from cyanobacteria of the CAC enzymes α -ketoglutarate dehydrogenase and succinyl-CoA synthetase (enzymes that work in concert to convert α -ketoglutarate into succinate) has long pegged these organisms as “having an incomplete CAC.” Is this really true?

A group of microbiologists at Penn State University (USA) reinvestigated this puzzling situation and, using a combination of genomics and biochemistry, discovered a new CAC paradigm.¹ It turns out that cyanobacteria do run a complete CAC, but convert α -ketoglutarate to succinate using two novel enzymes previously unknown to biology. For some reason(s), evolution has selected these enzymes rather than the canonical ones to complete the CAC in cyanobacteria and a few other prokaryotes where genes encoding these enzymes have also been discovered.

Besides solving a major metabolic mystery, this research shows the power of combining genomic analyses with biochemistry and good scientific intuition. The study also reminds us of the importance of understanding classic metabolisms as a basis for discovering new metabolisms in the microbial world.

I • Laboratory Culture of Microorganisms

To cultivate microorganisms in the laboratory it is necessary to supply them with all of the nutrients they require. Nutrient requirements vary widely, and knowledge of the principles of microbial nutrition is necessary for the successful culture of microorganisms. We focus here on some general principles of microbial nutrition and then expand on this in Chapter 13 where the broad metabolic diversity of the microbial world will unfold.

3.1 Cell Chemistry and Nutrition

Different organisms need different complements of nutrients, and not all nutrients are required in the same amounts. Some nutrients, called *macronutrients*, are required in large amounts, while others, called *micronutrients*, are required in just trace amounts.

Chemical Makeup of a Cell

All microbial nutrients are compounds constructed from the chemical elements. However, just a handful of elements dominate

living systems and are essential: hydrogen (H), oxygen (O), carbon (C), nitrogen (N), phosphorus (P), sulfur (S), and selenium (Se). In addition to these, at least 50 other elements, although not required, are metabolized in some way by microorganisms (Figure 3.1).

Besides water, which makes up 70–80% of the wet weight of a microbial cell (a single cell of *Escherichia coli* weighs just 10^{-12} g), cells consist primarily of macromolecules—proteins, nucleic acids, lipids, and polysaccharides; the building blocks (monomers) of these macromolecules are the amino acids, nucleotides, fatty acids, and sugars, respectively. Proteins dominate the macromolecular composition of a cell, making up 55% of total cell dry weight. Moreover, the diversity of proteins exceeds that of all other macromolecules combined. Interestingly, as important as DNA is to a cell, it contributes a very small percentage of a cell's dry weight; RNA is far more abundant (Figure 3.1c).

The data shown in Figure 3.1 are from actual analyses of cells of *E. coli*; comparable data vary a bit from one microorganism to the next. But in any microbial cell, carbon and nitrogen are important

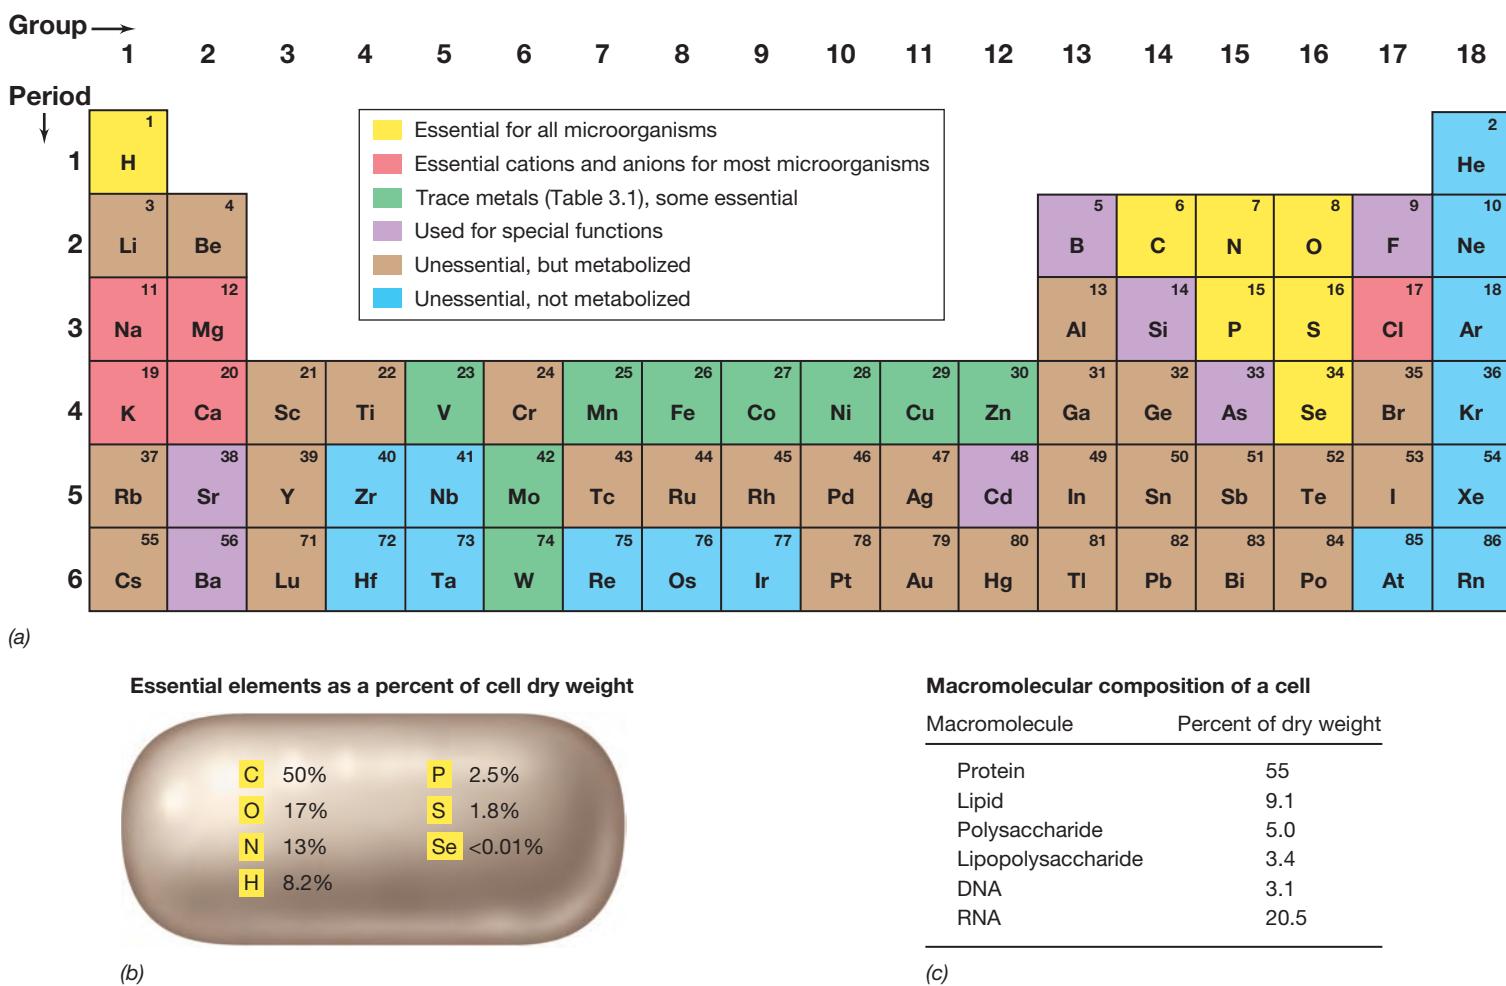

Figure 3.1 Elemental and macromolecular composition of a bacterial cell. (a) A microbial periodic table of the elements. With the exception of uranium, which can be metabolized by some prokaryotes, elements in period 7 or beyond in the complete periodic table of the elements are not known to be metabolized. (b) Contributions of the essential elements to cell dry weight. (c) Relative abundance of macromolecules in a bacterial cell. Data in (b) from *Aquat. Microb. Ecol.* 10: 15–27 (1996) and in (c) from *Escherichia coli* and *Salmonella typhimurium*: *Cellular and Molecular Biology*. ASM, Washington, DC (1996).

macronutrients, and thus we begin our study of microbial nutrition with these key elements.

Carbon, Nitrogen, and Other Macronutrients

All cells require carbon, and most prokaryotes require *organic* (carbon-containing) compounds as their source of carbon. About 50% of the dry weight of a bacterial cell is carbon (Figure 3.1b). Carbon is obtained from amino acids, fatty acids, organic acids, sugars, nitrogen bases, aromatic compounds, and countless other organic compounds. Some microorganisms are autotrophic and these organisms build their cellular structures from carbon dioxide (CO_2).

A bacterial cell is about 13% nitrogen, which is present in proteins, nucleic acids, and several other cell constituents. The bulk of nitrogen available in nature is as ammonia (NH_3), nitrate (NO_3^-), or nitrogen gas (N_2). Virtually all prokaryotes can use NH_3 as their nitrogen source, many can also use NO_3^- , and some can use organic nitrogen sources, such as amino acids. N_2 can only be used as an N source by nitrogen-fixing prokaryotes (Section 3.17).

In addition to C, N, and O and H (from H_2O), many other macronutrients are needed by cells but typically in smaller amounts (Figure 3.1b). Phosphorus is required for nucleic acids and phospholipids and is usually supplied to a cell as phosphate (PO_4^{2-}). Sulfur is present in the amino acids cysteine and methionine and also in several vitamins, including thiamine, biotin, and lipoic acid and is commonly supplied to cells as sulfate (SO_4^{2-}). Potassium (K) is required for the activity of several enzymes, whereas magnesium (Mg) is required to stabilize ribosomes, membranes, and

nucleic acids and is also required for the activity of many enzymes. Calcium (Ca) and sodium (Na) are essential nutrients for only a few organisms, sodium in particular for marine microorganisms.

Micronutrients: Trace Metals and Growth Factors

Microorganisms require several metals for growth, typically in very small amounts, and these are part of their *micronutrient* requirements (Figure 3.1a). Chief among the required metals is iron (Fe), which plays a major role in cellular respiration. Iron is a key component of cytochromes and of iron–sulfur proteins that function in electron transport reactions (Section 3.10). Besides iron, many other metals are required or otherwise metabolized by microorganisms (Figure 3.1a). Collectively these micronutrients are called *trace elements* or *trace metals*. Trace elements typically function as cofactors for enzymes. **Table 3.1** lists the major trace elements and examples of enzymes in which each plays a role.

Growth factors are organic micronutrients (Table 3.1). Common growth factors include the vitamins, but amino acids, purines, pyrimidines, or various other organic molecules may be growth factors for one or another microorganism. Vitamins are the most commonly required growth factors and a few common ones are included in Table 3.1. Most vitamins function as coenzymes, which are nonprotein components of enzymes (Section 3.5). Vitamin requirements vary among microorganisms, ranging from none to several. Lactic acid bacteria, which include the genera *Streptococcus*, *Lactobacillus*, and *Leuconostoc* (► Section 15.6), are notorious for their many vitamin requirements, which are even more extensive than those of humans (see Table 3.2).

Table 3.1 Micronutrients needed by microorganisms^a

I. Trace Elements		II. Growth Factors	
Element	Function	Growth factor	Function
Boron (B)	Autoinducer for quorum sensing in bacteria; also found in some polyketide antibiotics	PABA (<i>p</i> -aminobenzoic acid)	Precursor of folic acid
Cobalt (Co)	Vitamin B ₁₂ ; transcarboxylase (only in propionic acid bacteria)	Folic acid	One-carbon metabolism; methyltransfers
Copper (Cu)	In respiration, cytochrome <i>c</i> oxidase; in photosynthesis, plastocyanin, some superoxide dismutases	Biotin	Fatty acid biosynthesis; some CO ₂ fixation reactions
Iron (Fe) ^b	Cytochromes; catalases; peroxidases; iron–sulfur proteins; oxygenases; all nitrogenases	B ₁₂ (Cobalamin)	One-carbon metabolism; synthesis of deoxyribose
Manganese (Mn)	Activator of many enzymes; component of certain superoxide dismutases and of the water-splitting enzyme in oxygenic phototrophs (photosystem II)	B ₁ (Thiamine)	Decarboxylation reactions
Molybdenum (Mo)	Certain flavin-containing enzymes; some nitrogenases, nitrate reductases, sulfite oxidases, DMSO–TMAO reductases; some formate dehydrogenases	B ₆ (Pyridoxal)	Amino acid/keto acid transformations
Nickel (Ni)	Most hydrogenases; coenzyme F ₄₃₀ of methanogens; carbon monoxide dehydrogenase; urease	Nicotinic acid (Niacin)	Precursor of NAD ⁺
Selenium (Se)	Formate dehydrogenase; some hydrogenases; the amino acid selenocysteine	Riboflavin	Precursor of FMN, FAD
Tungsten (W)	Some formate dehydrogenases; oxotransferases of hyperthermophiles	Pantothenic acid	Precursor of coenzyme A
Vanadium (V)	Vanadium nitrogenase; bromoperoxidase	Lipoic acid	Decarboxylation of pyruvate and α-ketoglutarate
Zinc (Zn)	Carbonic anhydrase; nucleic acid polymerases; many DNA-binding proteins	Vitamin K	Electron transport

^aNot all trace elements or growth factors are needed by all organisms.

^bIron is typically needed in larger amounts than the other trace metals shown.

MINIQUIZ

- Which four of the chemical elements make up the bulk of a cell's dry weight?
- Which two classes of macromolecules contain most of a cell's nitrogen?
- Differentiate between "trace elements" and "growth factors."

3.2 Media and Laboratory Culture

A **culture medium** is a nutrient solution used to grow microorganisms. Because laboratory culture is required for the detailed study of any microorganism, careful attention must be paid to the selection and preparation of media for laboratory culture to be successful.

Classes of Culture Media

Two broad classes of culture media are used in microbiology: defined media and complex media. **Defined media** are prepared by adding precise amounts of pure inorganic or organic chemicals to distilled water. Therefore, the *exact composition* of a defined medium (in both a qualitative and quantitative sense) is known. Of major importance in any culture medium is the carbon source because all cells need large amounts of carbon to make new cell material (Figure 3.1). The particular carbon source and its concentration depend on the organism to be cultured. **Table 3.2**

lists recipes for four culture media. Some defined media, such as the one listed for *Escherichia coli*, are considered "simple" because they contain only a single carbon source. In this medium, cells of *E. coli* make all organic molecules from glucose.

For culturing many microorganisms, knowledge of the exact composition of a medium is not essential. In these instances complex media may suffice and may even be advantageous. **Complex media** are made from digests of microbial, animal, or plant products, such as casein (milk protein), beef (beef extract), soybeans (tryptic soy broth), yeast cells (yeast extract), or any of a number of other highly nutritious substances. Such digests are commercially available in dehydrated form and need only be hydrated to form a culture medium. However, the disadvantage of a complex medium is that its nutritional composition is not known precisely. An *enriched medium*, used for the culture of nutritionally demanding (fastidious) microorganisms, many of which are pathogens, starts as a complex medium and then is embellished with additional highly nutritious substances such as serum or blood.

Culture media are sometimes prepared that are selective or differential (or both), especially media used in diagnostic microbiology. A *selective medium* contains compounds that inhibit the growth of some microorganisms but not others. For example, selective media are available for the isolation of certain pathogens, such as strains of *Salmonella* or *Escherichia coli* that cause food-borne illnesses. A *differential medium* is one in which an indicator, typically a dye, is added, which reveals by a color change whether a

particular metabolic reaction has occurred during growth. Differential media are useful for distinguishing bacteria and are widely used in clinical diagnostics and systematic microbiology. Differential and selective media are further discussed in Chapter 27.

Nutritional Requirements and Biosynthetic Capacity

Of the four recipes in Table 3.2, three are defined and one is complex. The complex medium is easiest to prepare and supports growth of both *Escherichia coli* and *Leuconostoc mesenteroides*, the examples used in the table. By contrast, the simple defined medium supports growth of *E. coli* but not of *L. mesenteroides*. Growth of the latter in a defined medium requires the addition of several nutrients not needed by *E. coli*. The nutritional needs of *L. mesenteroides* can be satisfied by preparing either a highly supplemented defined medium, a rather laborious undertaking because of all the individual nutrients that need to be added (Table 3.2), or by preparing a complex medium, a much less demanding operation.

The fourth medium listed in Table 3.2 supports growth of the sulfur bacterium *Thiobacillus thioparus*; this medium would not support growth of any of the other organisms. This is because *T. thioparus* is both a chemolithotroph and an autotroph and thus has no organic carbon requirements. *T. thioparus* derives all of its carbon from CO₂ and obtains its energy from the oxidation of the sulfur compound thiosulfate (Na₂S₂O₃). Thus, *T. thioparus* has the greatest biosynthetic capacity of all the organisms listed in the table, surpassing even *E. coli* in this regard.

The take-home lesson from Table 3.2 is that different microorganisms can have vastly different nutritional requirements. For successful cultivation, it is necessary to understand an organism's nutritional requirements and then supply it with the nutrients it needs in both the proper form and amount.

Laboratory Culture

Once a culture medium has been prepared and made sterile to render it free of all life forms, organisms can be inoculated and the culture can be incubated under conditions that will support growth (Figure 3.2). In a laboratory situation, inoculation will typically be with a pure culture and into either liquid or solid culture medium. Liquid culture media are solidified with agar, typically at 1–2%. Solid media immobilize cells, allowing them to grow and form visible, isolated masses called *colonies* (Figure 3.2). Microbial colonies are of various shapes and sizes depending on the organism, the culture conditions, the nutrient supply, and other physiological parameters. Some microorganisms produce pigments that cause the entire colony to be colored (Figure 3.2). Colonies permit the microbiologist to visualize the composition and presumptive purity of a culture. Plates that contain more than one kind of colony signal a contaminated culture.

Culture media must be sterilized before use, and sterilization is achieved by heating the medium in an *autoclave*. We

Figure 3.2 **Bacterial colonies.** Colonies are visible masses of cells formed from the division of one or a few cells and can contain over a billion (10^9) individual cells. (a) *Serratia marcescens*, grown on MacConkey agar. (b) Close-up of colonies outlined in part a. (c) *Pseudomonas aeruginosa*, grown on trypticase soy agar. discuss the operation and principles of the autoclave in Section 5.17, along with other methods for sterilization. Once a sterile culture medium has been prepared, it is ready for inoculation. This requires **aseptic technique** (Figures 3.3 and 3.4), a series of steps to prevent contamination during manipulations of cultures and sterile culture media. A mastery of aseptic technique is required for maintaining pure cultures, as airborne contaminants are virtually everywhere (Figures 3.3 and 3.4). Picking an isolated colony and restreaking it is the main method for obtaining pure cultures from liquid samples containing several different organisms and is a common procedure in the microbiology laboratory. Other techniques for obtaining pure cultures have been developed that are especially suited for particular groups

of bacteria with unusual growth requirements and these will be discussed in Section 18.2.

MINIQUIZ

- Why would a complex culture medium for *Leuconostoc mesenteroides* be easier to prepare than a chemically defined medium?
- In which medium shown in Table 3.2, defined or complex, do you think *E. coli* would grow the fastest? Why? *E. coli* will not grow in the medium described for *Thiobacillus thioparus*. Why?
- What is meant by the word sterile? Why is aseptic technique necessary for successful cultivation of pure cultures in the laboratory?

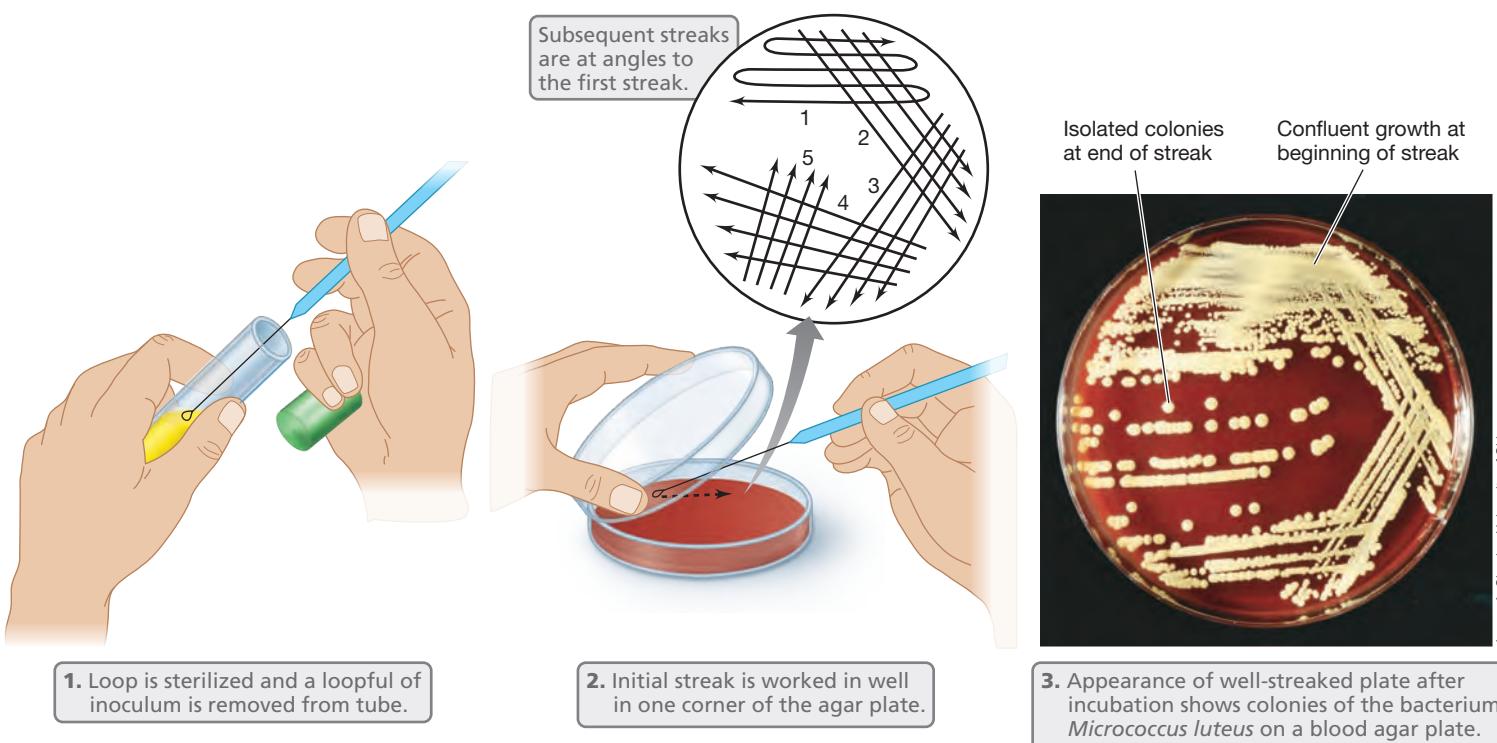

Figure 3.4 Making a streak plate to obtain pure cultures. The plate cover should be opened just enough to permit streaking manipulations.

II • Energetics, Enzymes, and Redox

All microorganisms must conserve some of the energy released in their energy-yielding reaction(s) in order to grow. Here we discuss the principles of energy conservation including the different energy classes of microorganisms, and use some simple laws of chemistry and physics to guide our understanding of bioenergetics.

3.3 Energy Classes of Microorganisms

Energy-yielding reactions are a part of metabolism called **catabolism**. Here we discuss the various energy classes of microorganisms, pointing out their similarities and differences. The terms used to describe the energy classes of microorganisms are important ones and will appear many times in this book.

Chemoorganotrophs and Chemolithotrophs

Organisms that conserve energy from chemicals are called **chemotrophs**, and those that use *organic* chemicals are called **chemoorganotrophs** (Figure 3.5). Most microorganisms that have been brought into laboratory culture are chemoorganotrophs. Many different organic chemicals can be used by one or another microorganism, and in virtually all cases, energy is conserved from the *oxidation* of the compound. The conserved energy is trapped in the cell in the form of energy-rich bonds of the compound adenosine triphosphate (ATP).

Some microorganisms can obtain energy from an organic compound only in the presence of oxygen; these organisms are called *aerobes*. Others can obtain energy only in the absence of oxygen (*anaerobes*). Still others can break down organic compounds in either the presence or absence of oxygen (*facultative aerobes*). We will deal with these options in more detail in Section 5.16.

Many *Bacteria* and *Archaea* can tap the energy available from the oxidation of *inorganic* compounds. This form of metabolism is called **chemolithotrophy** and was discovered by the Russian microbiologist Sergei Winogradsky (► Section 1.9). Organisms that carry out chemolithotrophic reactions are called **chemolithotrophs** (Figure 3.5). Several inorganic compounds can be oxidized, for example, H₂, H₂S (hydrogen sulfide), NH₃ (ammonia), and Fe²⁺ (ferrous iron). Related groups of chemolithotrophs typically specialize in the oxidation of a related group of inorganic compounds, and thus we have the “sulfur” bacteria, the “iron” bacteria, the “nitrifying” bacteria, and so on.

The capacity to conserve energy from the oxidation of inorganic chemicals is a good metabolic strategy because competition from chemoorganotrophs is not a concern. In addition, many of the inorganic compounds oxidized by chemolithotrophs, for example H₂ and H₂S, are actually the waste products of chemoorganotrophs. Thus, many chemolithotrophs have evolved strategies for exploiting resources that chemoorganotrophs cannot, and so it is not unusual for species of these two physiological groups to live in close association with one another.

Phototrophs

Phototrophic microorganisms contain pigments that allow them to convert light energy into chemical energy and thus unlike chemotrophs, **phototrophs** do not require chemicals as a source of energy. This is a significant metabolic advantage because competition between phototrophs and chemotrophs for energy sources is not an issue and at least some sunlight is available in most microbial habitats.

Two major forms of phototrophy are known in prokaryotes. In one form, called *oxygenic* photosynthesis, oxygen (O₂) is produced. Among microorganisms, oxygenic photosynthesis is characteristic of cyanobacteria, which are prokaryotes, and algae, which are eukaryotes. The other form, *anoxygenic* photosynthesis, occurs in the purple and green bacteria and the heliobacteria (all *Bacteria*), and does not yield O₂. However, both oxygenic and anoxygenic phototrophs show great similarities in the mechanism for ATP synthesis, a result of the fact that oxygenic photosynthesis evolved from the simpler anoxygenic form some 3 billion years ago (► Sections 1.3 and 12.2).

Heterotrophs and Autotrophs

Regardless of how a microorganism conserves energy, we have already seen that all cells require carbon in large amounts in order to make new cell materials (Figure 3.1). If an organism is a **heterotroph**, its cell carbon is obtained from some organic chemical. An **autotroph**, by contrast, uses carbon dioxide (CO₂) as its carbon source. Chemoorganotrophs are by definition also heterotrophs. By contrast, most chemolithotrophs and phototrophs are autotrophs. Autotrophs are also called *primary producers* because they synthesize new organic matter from CO₂. Virtually all organic matter on Earth has been synthesized by primary producers, in particular, the phototrophs.

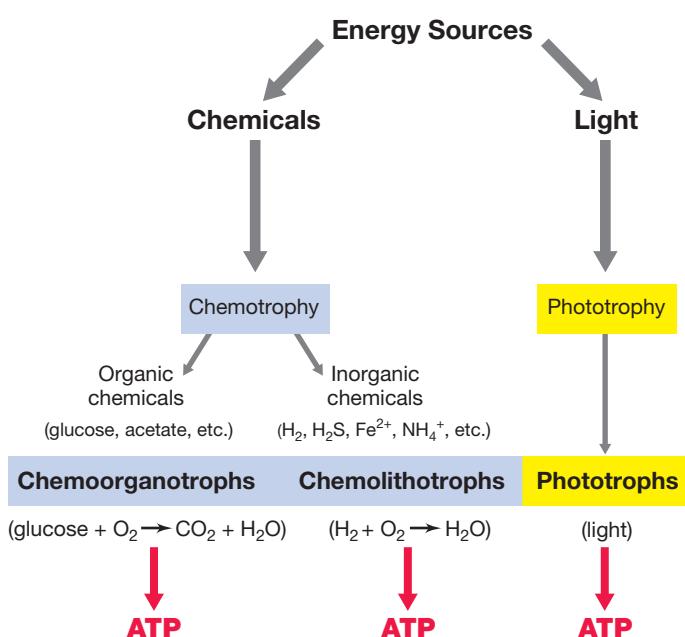

Figure 3.5 Metabolic options for conserving energy. All three energy-conserving metabolisms are found within the microbial world.

MINIQUIZ

- In terms of energy generation, how does a chemoorganotroph differ from a chemolithotroph? A chemotroph from a phototroph?
- In terms of carbon acquisition, how does an autotroph differ from a heterotroph?

3.4 Bioenergetics

Energy is defined as the ability to do work. In microbiology, energy transformations are measured in kilojoules (kJ), a unit of heat energy. All chemical reactions in a cell are accompanied by *changes* in energy, energy being either required for a reaction to occur or released as a reaction occurs. To identify which reactions release energy and which require energy, we need to understand some bioenergetic principles, and we focus on these here.

Basic Energetics

Although in any chemical reaction some energy is lost as heat, in microbiology we are interested in **free energy** (abbreviated G), which is the energy available to do work. The *change* in free energy during a reaction is expressed as $\Delta G^0'$, where the symbol Δ is read as “change in.” The “0” and “prime” superscripts indicate that the free-energy value is for standard conditions: pH 7, 25°C, 1 atmosphere of pressure, and all reactants and products at molar concentrations.

Consider the reaction

If $\Delta G^0'$ for this reaction is *negative* in arithmetic sign, then the reaction will proceed with the *release* of free energy, energy that the cell may conserve as ATP. Such energy-yielding reactions are called **exergonic**. However, if $\Delta G^0'$ is *positive*, the reaction *requires* energy in order to proceed. Such reactions are called **endergonic**. Thus, exergonic reactions *release* energy whereas endergonic reactions *require* energy.

Free Energy of Formation and Calculating Free Energy Changes ($\Delta G^0'$)

To calculate the free-energy yield of a reaction, one first needs to know the free energy of its reactants and products. This is the free energy of formation (G_f^0), the energy released or required during the formation of a given molecule from the elements. **Table 3.3** gives a few examples of G_f^0 . By convention, the free energy of formation of the *elements* in their elemental and electrically neutral form (for instance, C, H₂, N₂) is zero. However, the free energies of formation of *compounds* are not zero. If the formation of a compound from its elements proceeds exergonically, then the G_f^0 of the compound is negative (energy is released). If the reaction is endergonic, then the G_f^0 of the compound is positive (energy is required).

For most compounds G_f^0 is negative. This reflects the fact that compounds tend to form spontaneously (that is, with energy being released) from their elements. However, the positive G_f^0 for nitrous oxide (N₂O) (+104.2 kJ/mol, Table 3.3) indicates that this compound does not form spontaneously. Instead, over time it decomposes spontaneously to yield N₂ and O₂. The free energies of formation of more compounds of microbiological interest are given in Appendix 1.

Table 3.3 Free energy of formation for a few compounds of biological interest

Compound	Free energy of formation (G_f^0) ^a
Water (H ₂ O)	-237.2
Carbon dioxide (CO ₂)	-394.4
Hydrogen gas (H ₂)	0
Oxygen gas (O ₂)	0
Ammonium (NH ₄ ⁺)	-79.4
Nitrous oxide (N ₂ O)	+104.2
Acetate (C ₂ H ₃ O ₂ ⁻)	-369.4
Glucose (C ₆ H ₁₂ O ₆)	-917.3
Methane (CH ₄)	-50.8
Methanol (CH ₃ OH)	-175.4

^aThe free energy of formation values are in kJ/mol. See Table A1.1 in Appendix 1 for a more complete list of free energies of formation.

Using free energies of formation, it is possible to calculate $\Delta G^0'$ of a given reaction. For the reaction A + B → C + D, $\Delta G^0'$ is calculated by subtracting the sum of the free energies of formation of the reactants (A + B) from that of the products (C + D). Thus

$$\Delta G^0' = G_f^0[C + D] - G_f^0[A + B]$$

The value obtained for $\Delta G^0'$ tells us whether the reaction is exergonic or endergonic. The phrase “products minus reactants” is a simple way to recall how to calculate changes in free energy during chemical reactions. However, before free-energy calculations can be made, it is first necessary to balance the reaction. Appendix 1 details the steps in balancing reactions and calculating free energies for any hypothetical reaction.

$\Delta G^0'$ versus ΔG

Although calculations of $\Delta G^0'$ are reasonable estimates of actual free-energy changes, in some cases they are not. We will see later in this book that the actual concentrations of products and reactants in nature, which are rarely at the molar levels used in calculations of $\Delta G^0'$, can change the results of bioenergetic calculations, sometimes in significant ways. What is most relevant to a bioenergetic calculation is not $\Delta G^0'$, but ΔG , the free-energy change that occurs *under the actual conditions* in which the organism is growing. The equation for ΔG takes into account the actual concentrations of reactants and products in the organism’s habitat and is

$$\Delta G = \Delta G^0' + RT \ln K$$

where R and T are physical constants and K is the equilibrium constant for the reaction (Appendix 1). We distinguish between $\Delta G^0'$ and ΔG in important ways in Chapter 13 where we consider catabolic diversity in more detail. But for our purposes here, the expression $\Delta G^0'$ will tell us whether a given reaction yields energy or requires energy, and knowing this is sufficient for a basic understanding of energy flow in microbial systems. Only reactions that are exergonic yield energy that can be conserved by the cell, and this will be our focus in the next few sections.

MINIQUIZ

- What is free energy?
- Does glucose formation from the elements release or require energy?
- Using Table 3.3, calculate $\Delta G^0'$ for the reaction $\text{CH}_4 + \frac{1}{2}\text{O}_2 \rightarrow \text{CH}_3\text{OH}$.

3.5 Catalysis and Enzymes

Free-energy calculations reveal only whether energy is released or required in a given reaction. The value obtained says nothing about the *rate* of the reaction. If the rate of a reaction is very slow, it may be of no value to a cell. For example, consider the formation of water from O_2 and H_2 . The energetics of this reaction are quite favorable: $\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$, $\Delta G^0' = -237 \text{ kJ}$. However, if O_2 and H_2 were mixed in a sealed bottle, no measurable amount of water would form, even after years. This is because the bonding of O_2 and H_2 to form H_2O requires that their chemical bonds first be broken. The breaking of these bonds requires some energy, and this energy is called **activation energy**.

Activation energy is the energy required to bring all molecules in a chemical reaction into the reactive state. For a reaction that proceeds with a net release of free energy (that is, an exergonic reaction), the situation is as diagrammed in **Figure 3.6**. Although the activation energy barrier is virtually insurmountable in the absence of a catalyst, in the presence of the proper catalyst, this barrier is greatly reduced. The concept of activation energy naturally leads us to consider the topic of catalysis and enzymes.

Enzymes

A **catalyst** is a substance that lowers the activation energy of a reaction (Figure 3.6), thereby increasing the reaction rate. Catalysts facilitate reactions but are not consumed or transformed by them. Moreover, catalysts do not affect the energetics or the equilibrium

of a reaction; catalysts affect only the *rate* at which reactions proceed. Biological catalysts are called **enzymes**.

Most cellular reactions do not proceed at significant rates without catalysis. Enzymes are proteins (or in a few cases, RNAs) that are highly specific for the reactions they catalyze. That is, each enzyme catalyzes only a single type of chemical reaction, or in the case of a few enzymes, a single class of closely related reactions. This specificity is a function of the precise three-dimensional structure of the enzyme molecule. In an enzyme-catalyzed reaction, the enzyme (E) combines with the reactant, called a *substrate* (S), forming an enzyme–substrate complex (E—S). Then, as the reaction proceeds, the *product* (P) is released and the enzyme is returned to its original state:

The enzyme is generally much larger than the substrate(s), and the portion of the enzyme to which substrate binds is the enzyme's *active site*; the entire enzymatic reaction, from substrate binding to product release, may take only a few milliseconds.

Many enzymes contain small nonprotein molecules that participate in catalysis but are not themselves substrates. These small molecules can be divided into two classes based on the way they associate with the enzyme: *prosthetic groups* and *coenzymes*. Prosthetic groups bind very tightly to their enzymes, usually covalently and permanently. The heme group present in cytochromes such as cytochrome *c* (Section 3.10) is an example of a prosthetic group. **Coenzymes**, by contrast, are loosely bound to enzymes, and a single coenzyme molecule may associate with a number of different enzymes. Most coenzymes are derivatives of vitamins, and NAD^+ , a derivative of the vitamin niacin (Table 3.1), is a good example.

Enzyme Catalysis

To catalyze a specific reaction, an enzyme must do two things: (1) bind its substrate and (2) position the substrate relative to specific amino acids in the enzyme's active site. The enzyme–substrate complex (**Figure 3.7**) serves both functions by aligning reactive groups and placing strain on specific bonds in the substrate(s). This reduces the activation energy required to make the reaction proceed from substrate(s) to product(s). This is shown in Figure 3.7 for the enzyme lysozyme, an enzyme whose substrate is the polysaccharide backbone of the bacterial cell wall polymer, peptidoglycan ([Figure 2.25](#)).

The reaction depicted in Figure 3.7 is exergonic because the free energy of formation of the substrates is greater than that of the products. By contrast, some enzymes catalyze reactions that require energy, effectively converting energy-poor substrates into energy-rich products. In these cases, however, not only must an activation energy barrier (Figure 3.6) be overcome, but sufficient free energy must also be put into the reaction to raise the energy level of the substrates to that of the products. This is done by *coupling* the energy-requiring reaction to an energy-yielding one, such as the hydrolysis of ATP, the overall reaction proceeding with a free energy change that is either negative or near zero.

Theoretically, all enzymes are reversible in their activity. However, enzymes that catalyze highly exergonic or highly endergonic reactions typically function in only one direction. If a particularly

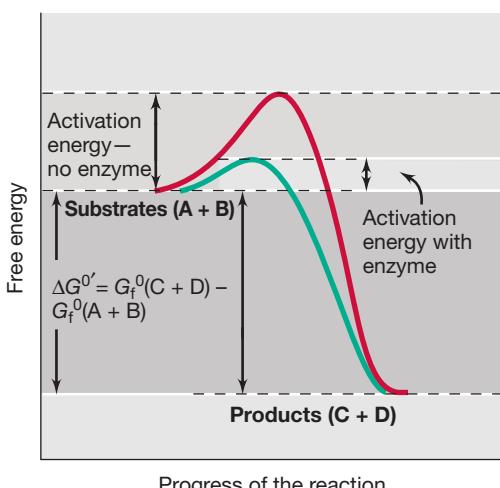

Figure 3.6 Activation energy and catalysis. Even chemical reactions that release energy may not proceed spontaneously until they are activated. Once the reactants are activated, the reaction proceeds spontaneously. Catalysts such as enzymes lower the required activation energy.

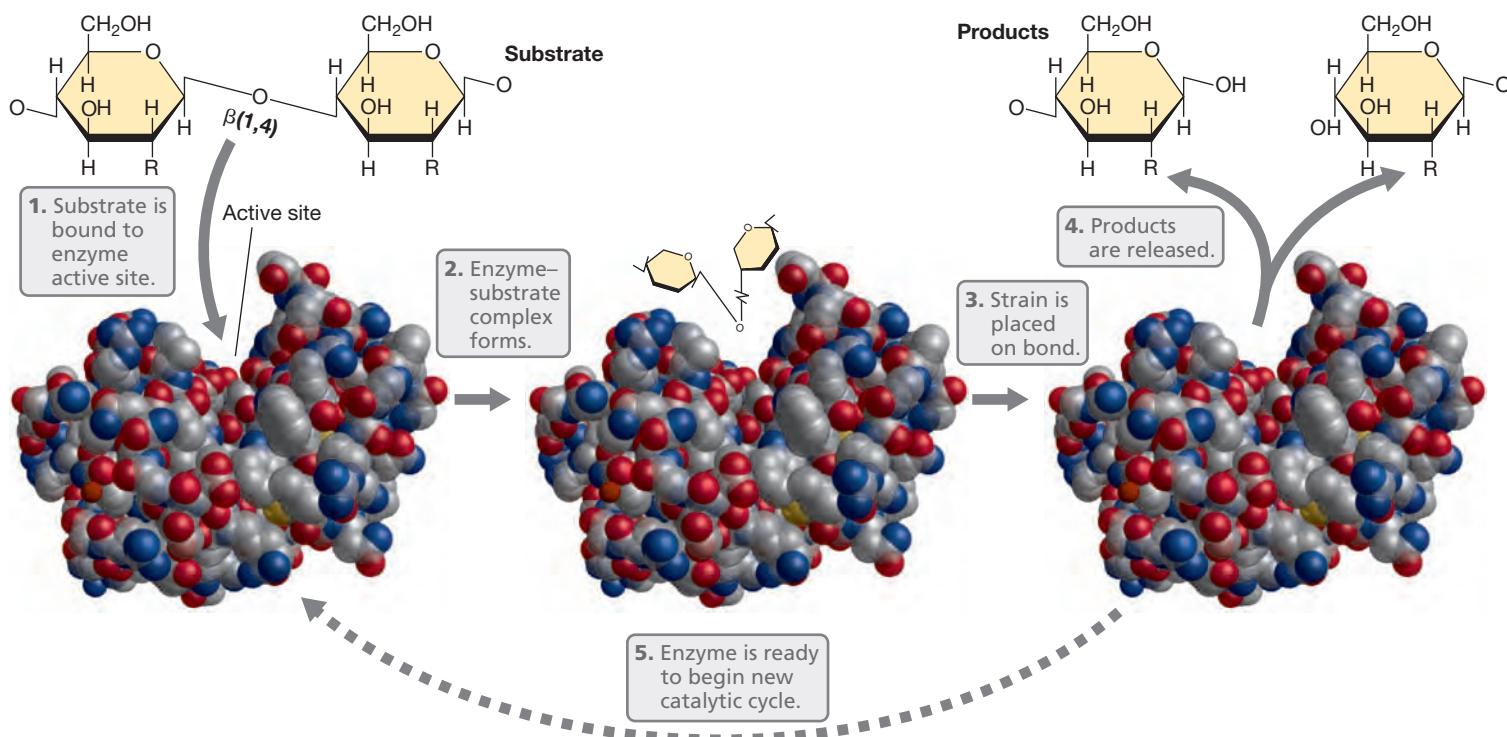

Figure 3.7 The catalytic cycle of an enzyme. The enzyme depicted here, lysozyme, catalyzes the cleavage of the β -1,4-glycosidic bond in the polysaccharide backbone of peptidoglycan. Following binding in the enzyme's active site, strain is placed on the bond, and this favors breakage. Space-filling model of lysozyme courtesy of Richard Feldmann.

exergonic or endergonic reaction needs to be reversed, a different enzyme usually catalyzes the reverse reaction.

MINIQUIZ

- What is the function of a catalyst? What are enzymes made of?
- Where on an enzyme does the substrate bind?
- What is activation energy?

3.6 Electron Donors and Acceptors

Cells conserve energy released from catabolic reactions by coupling it to the synthesis of energy-rich compounds, such as ATP. Reactions that release sufficient energy to form ATP are typically of an oxidation–reduction type. An *oxidation* is the removal of an electron (or electrons) from a substance, and a *reduction* is the addition of an electron (or electrons) to a substance. The term *redox* is commonly used as an abbreviation to indicate oxidation–reduction.

Redox Reactions

Redox reactions occur in pairs. For example, hydrogen gas (H_2) can release electrons and protons and become oxidized (Figure 3.8). However, electrons cannot exist alone in solution; they must be part of atoms or molecules. Thus the oxidation of H_2 is only a *half reaction*, a term that implies the need for a second half reaction. This is because for any substance to be oxidized, another substance must be reduced.

The oxidation of H_2 can be coupled to the reduction of many different substances, including oxygen (O_2), in a second half reaction.

This reductive half reaction, when coupled to the oxidation of H_2 , yields the overall balanced net reaction (Figure 3.8). In reactions of this type, we refer to the substance *oxidized* (in this case, H_2) as the **electron donor**, and the substance *reduced* (in this case, O_2) as the **electron acceptor**. Electron donors are also commonly called *energy sources*. Many potential electron donors exist in nature, including a wide variety of organic and inorganic compounds. Many electron acceptors exist as well, including O_2 , many oxidized compounds of nitrogen and sulfur, such as NO_3^- and SO_4^{2-} , and many organic compounds.

If a redox reaction is to occur, the presence of a suitable electron acceptor is just as important as the presence of a suitable electron donor. Lacking one or the other, the overall reaction cannot proceed. We will see that the concept of electron donors and electron acceptors is very important in microbiology and underlies virtually all aspects of energy metabolism.

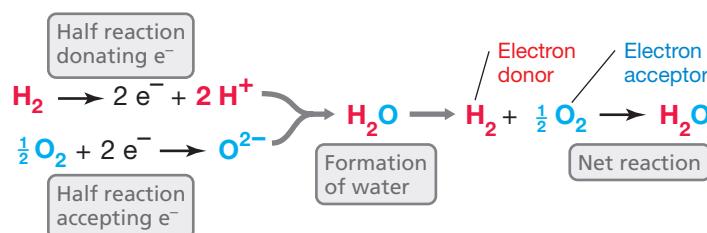

Figure 3.8 Example of an oxidation–reduction reaction. Each half reaction makes up half of the net reaction.

Reduction Potentials and Redox Couples

Substances differ in their inherent tendency to donate or accept electrons. This tendency is expressed as their **reduction potential** (E_0' , standard conditions), measured in volts (V) in reference to that of a standard substance, H₂ (Figure 3.9). By convention, reduction potentials are given for half reactions written as *reductions*, with reactions at pH 7 because the cytoplasm of most cells is neutral, or nearly so.

A substance can be either an electron donor or an electron acceptor under different circumstances, depending on the substances with which it reacts. The constituents on each side of the arrow in half reactions are called a *redox couple*, such as 2 H⁺/H₂, or $\frac{1}{2}$ O₂/H₂O (Figure 3.8). By convention, in writing a redox couple, the *oxidized* form of the couple is always placed on the left, before the forward slash, followed by the *reduced* form after the forward slash. In the example of Figure 3.8, the E_0' of the 2 H⁺/H₂ couple is −0.42 V and that of the $\frac{1}{2}$ O₂/H₂O couple is +0.82 V. We will learn shortly that these values mean that O₂ is an excellent electron *acceptor* and H₂ is an excellent electron *donor*.

In reactions between two redox couples, the *reduced* substance of the couple whose E_0' is more *negative* donates electrons to the *oxidized* substance of the couple whose E_0' is more *positive*. Thus, in the couple 2 H⁺/H₂, H₂ has a greater tendency to donate electrons than the tendency of 2 H⁺ to accept them, and in the couple $\frac{1}{2}$ O₂/H₂O, H₂O has a very weak tendency to donate electrons, whereas O₂ has a great tendency to accept them. It then follows that in a reaction of H₂ and O₂, H₂ will be the electron *donor* and become oxidized, and O₂ will be the electron *acceptor* and become reduced (Figure 3.8).

As previously mentioned, all half reactions are written as reductions. However, in an actual reaction between two redox couples, the half reaction with the more negative E_0' proceeds as an oxidation and is therefore written in the opposite direction. For example, in the reaction between H₂ and O₂ shown in Figure 3.8, H₂ is oxidized and is written in the reverse direction from its formal half reaction.

The Redox Tower and Its Relationship to $\Delta G^0'$

A convenient way of viewing electron transfer reactions is to imagine a vertical tower (Figure 3.9). The tower represents the range of reduction potentials possible for redox couples in nature, from those with the most negative E_0' on the top to those with the most positive E_0' at the bottom, and is thus a *redox tower*. The *reduced* substance in the redox couple at the top of the redox tower has the greatest tendency to donate electrons, whereas the *oxidized* substance in the redox couple at the bottom of the redox tower has the greatest tendency to accept electrons.

Using the tower analogy, imagine electrons from an electron donor near the top of the tower falling and being “caught” by electron acceptors at various levels. The difference in reduction potential between the donor and acceptor redox couples is quantified as $\Delta E_0'$. The further an electron drops before it is caught by an acceptor, the greater is the $\Delta E_0'$ between the two redox couples and the greater is the amount of energy released in the net reaction. That is, $\Delta E_0'$ is proportional to $\Delta G^0'$ (Figure 3.9). Oxygen (O₂), at the bottom of the redox tower, is the strongest electron acceptor of any significance in nature. In the middle of

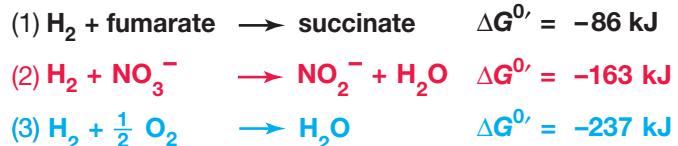

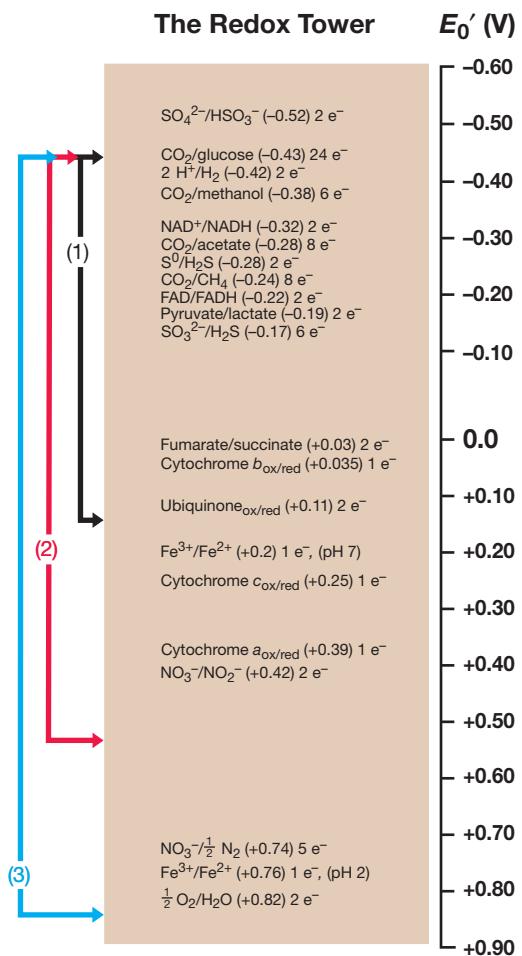

Figure 3.9 The redox tower. Redox couples are arranged from the strongest donors at the top to the strongest acceptors at the bottom. Electrons can be “caught” by acceptors at any intermediate level as long as the donor couple is more negative than the acceptor couple. The greater the difference in reduction potential between electron donor and electron acceptor, the more free energy is released. Note the differences in energy yield when H₂ reacts with three different electron acceptors, fumarate, nitrate, and oxygen.

the redox tower, redox couples can be either electron donors or acceptors depending on whom they react with. For instance, the 2 H⁺/H₂ couple (−0.42 V) can react with the fumarate/succinate couple (+0.03 V), the NO₃⁻/NO₂⁻ couple (+0.42 V), or the $\frac{1}{2}$ O₂/H₂O (+0.82 V) couple, with increasing amounts of energy being released, respectively (Figure 3.9).

Electron Carriers and NAD/NADH Cycling

Redox reactions in microbial cells are mediated by small molecules. A very common redox intermediary is the coenzyme nicotinamide adenine dinucleotide (NAD⁺); the reduced form is written NADH (Figure 3.10). NAD⁺/NADH is an electron plus proton carrier, transporting 2 e⁻ and 2 H⁺ at the same time. The reduction potential of

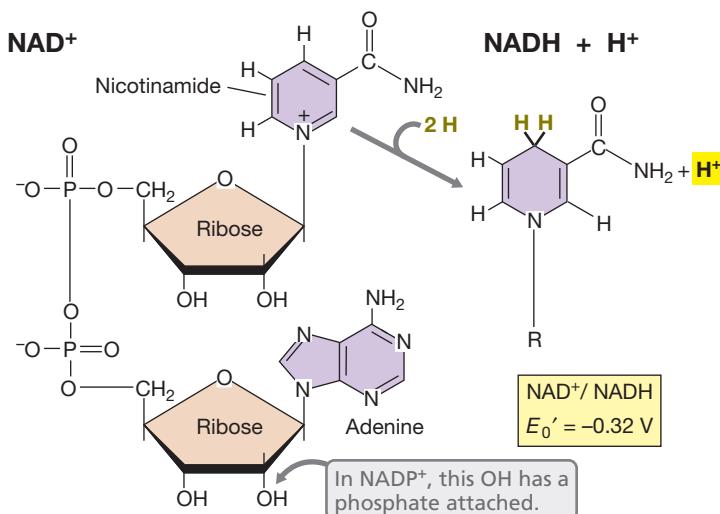

Figure 3.10 The oxidation-reduction coenzyme nicotinamide adenine dinucleotide (NAD⁺). NAD⁺ undergoes oxidation-reduction as shown and is freely diffusible. “R” is the adenine dinucleotide portion of NAD⁺.

the NAD⁺/NADH couple is -0.32 V , which places it fairly high on the electron tower; that is, NADH is a good electron donor while NAD⁺ is a rather weak electron acceptor (Figure 3.9).

Coenzymes such as NAD⁺/NADH increase the diversity of redox reactions possible in a cell by allowing chemically dissimilar electron donors and acceptors to interact, with the coenzyme acting as the intermediary. For example, electrons removed from an electron donor can reduce NAD⁺ to NADH, and the latter can be converted back to NAD⁺ by donating electrons to the electron acceptor. Figure 3.11 shows an example of such electron shuttling by NAD⁺/NADH. In this reaction, NAD⁺ and NADH facilitate the overall redox reaction but are not consumed in a net fashion as are the original donor and terminal acceptor. In other words, although

a cell requires relatively large amounts of a primary electron donor (the substance that was oxidized to yield NADH) and a terminal electron acceptor (such as O₂), it needs only a tiny amount of NAD⁺ and NADH because they are constantly being recycled (Figure 3.11).

NADP⁺ is a related redox coenzyme in which a phosphate group is added to NAD⁺. NADP⁺/NADPH typically participate in redox reactions distinct from those that use NAD⁺/NADH, most commonly in anabolic (biosynthetic) reactions in which oxidations and reductions occur (Sections 3.14–3.16).

MINIQUIZ

- In the reaction $\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$, what is the electron donor and what is the electron acceptor?
- Why is nitrate (NO₃⁻) a better electron acceptor than fumarate?
- Is NADH a better electron donor than H₂? Is NAD⁺ a better acceptor than 2 H⁺? How do you determine this?

3.7 Energy-Rich Compounds

Energy released from redox reactions must be conserved by the cell if it is to be used to drive energy-requiring cell functions. In living organisms, chemical energy released in redox reactions is conserved primarily in phosphorylated compounds. The free energy released upon removal (hydrolysis) of the phosphate in these *energy-rich compounds* is significantly greater than that of the average covalent bond in the cell, and it is this released energy that is used by the cell.

Phosphate can be bonded to organic compounds by either *ester* or *anhydride* bonds, as illustrated in Figure 3.12. However, not all phosphate bonds are energy-rich. As seen in the figure, the ΔG^{0'} of hydrolysis of the phosphate ester bond in glucose 6-phosphate is only -13.8 kJ/mol . By contrast, the ΔG^{0'} of hydrolysis of the phosphate anhydride bond in phosphoenolpyruvate is -51.6 kJ/mol ,

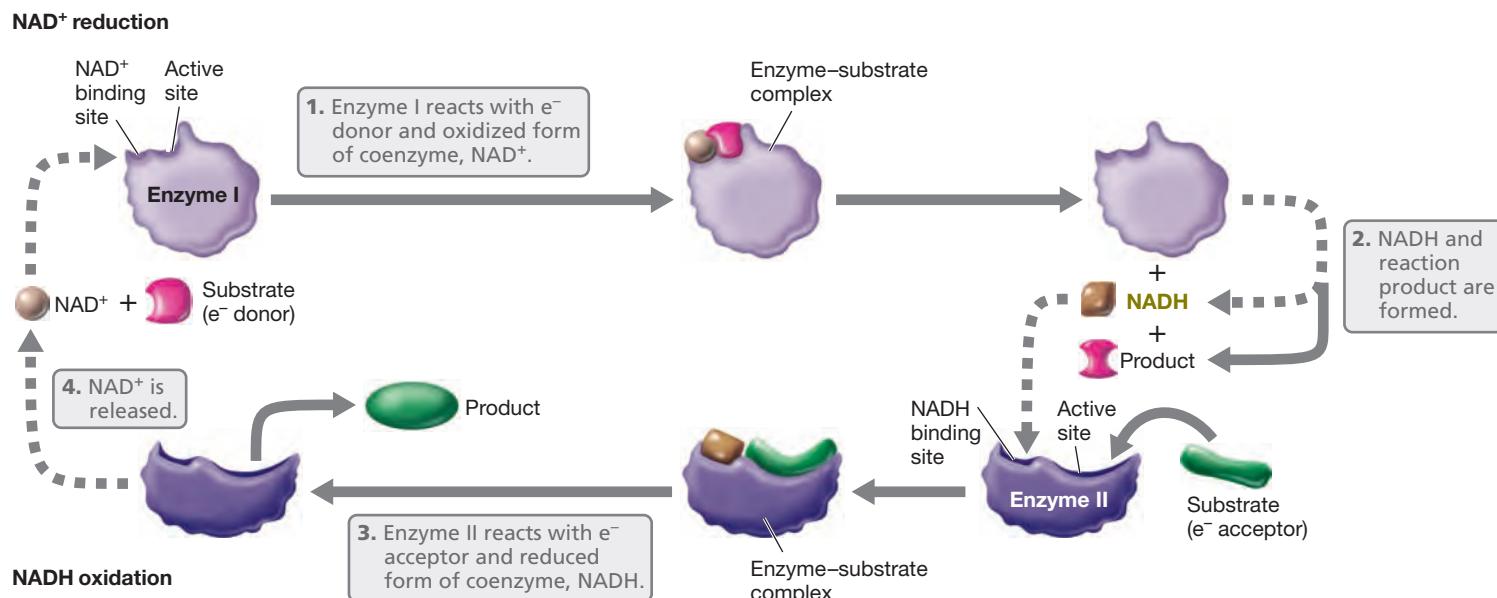

Figure 3.11 NAD⁺/NADH cycling. A schematic example of redox reactions in which two different enzymes are linked by their requirement for either NAD⁺ or NADH.

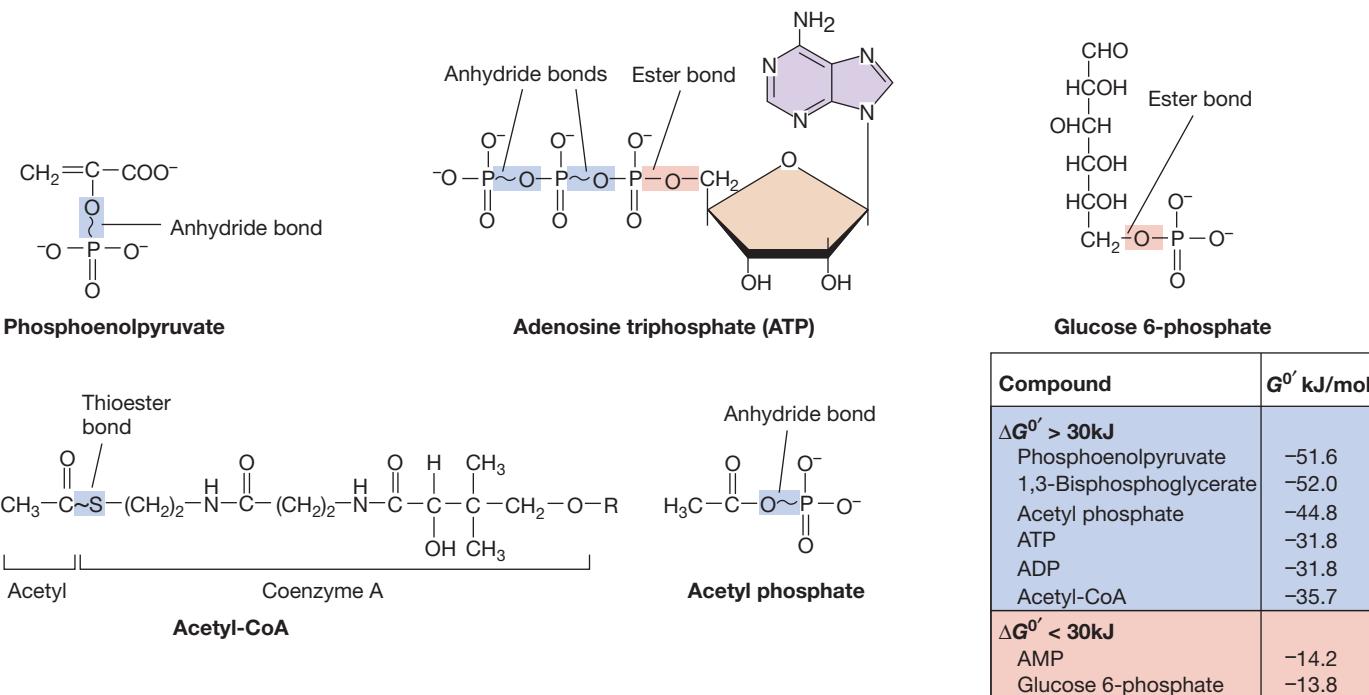

Figure 3.12 Phosphate bonds in compounds that conserve energy in bacterial metabolism. Notice, by referring to the table, the range in free energy of hydrolysis of the phosphate bonds highlighted in the compounds. The “R” group of acetyl-CoA is a 3'-phospho ADP group.

almost four times that of glucose 6-phosphate. Although theoretically either compound could be hydrolyzed in energy metabolism, cells typically use a small group of compounds whose $\Delta G^{\circ'}$ of hydrolysis is greater than -30 kJ/mol as energy “currencies” in the cell. Thus, phosphoenolpyruvate is energy-rich whereas glucose 6-phosphate is not.

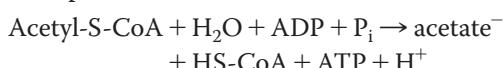

Adenosine Triphosphate

The most important energy-rich phosphate compound in cells is **adenosine triphosphate (ATP)**. ATP consists of the ribonucleoside adenosine to which three phosphate molecules are bonded in series. ATP is the prime energy currency in all cells, being generated during exergonic reactions and consumed in endergonic reactions. From the structure of ATP (Figure 3.12), it can be seen that only two of the phosphate bonds ($\text{ATP} \rightarrow \text{ADP} + \text{P}_i$ and $\text{ADP} \rightarrow \text{AMP} + \text{P}_i$) are phosphoanhydrides and thus have free energies of hydrolysis greater than -30 kJ . By contrast, AMP is not energy-rich because its free energy of hydrolysis is only about half that of ADP or ATP (Figure 3.12).

Although the energy released in ATP hydrolysis is -32 kJ , a caveat must be introduced here to define more precisely the energy requirements for the synthesis of ATP. In an actively growing *Escherichia coli* cell, the ratio of ATP to ADP is maintained at about 7:1, and this affects the energy requirements for ATP synthesis. In an actively growing cell, the actual energy expenditure (that is, the ΔG , Section 3.4) for the synthesis of 1 mole of ATP is on the order of -55 to -60 kJ . Nevertheless, for the purposes of learning and applying the basic principles of bioenergetics, we will assume that reactions conform to “standard conditions” ($\Delta G^{\circ'}$), and thus we will assume that the energy required for synthesis or hydrolysis of ATP is 32 kJ/mol .

Coenzyme A

Cells can use the free energy available in the hydrolysis of energy-rich compounds other than phosphorylated compounds. These include, in particular, derivatives of **coenzyme A** (for example, acetyl-CoA; see structure in Figure 3.12). Coenzyme A derivatives contain **thioester** bonds. Upon hydrolysis, these yield sufficient free energy to drive the synthesis of an energy-rich phosphate bond. For example, in the reaction

the energy released in the hydrolysis of coenzyme A is conserved in the synthesis of ATP. Coenzyme A derivatives (acetyl-CoA is just one of many) are especially important to the energetics of anaerobic microorganisms, in particular those whose energy metabolism depends on fermentation (see Table 3.4). We will return to the importance of coenzyme A derivatives in bacterial bioenergetics many times in Chapter 13.

Energy Storage

ATP is a dynamic molecule in the cell; it is continuously being broken down to drive anabolic reactions and resynthesized at the expense of catabolic reactions. For longer-term energy storage, microorganisms produce insoluble polymers that can be catabolized later for the production of ATP.

Examples of energy storage polymers in prokaryotes include glycogen, poly- β -hydroxybutyrate and other polyhydroxyalkanoates, and elemental sulfur, stored from the oxidation of H_2S by sulfur chemolithotrophs. These polymers are deposited within the cell as granules that can be seen with the light or electron

microscope (see Section 2.14). In eukaryotic microorganisms, starch (polyglucose) and simple fats are the major reserve materials. In the absence of an external energy source, a cell can break down these polymers to make new cell material or to supply the very low amount of energy, called *maintenance energy*, needed to maintain cell integrity when it is in a nongrowing state.

MINIQUIZ

- How much energy is released per mole of ATP converted to ADP + P_i under standard conditions? Per mole of AMP converted to adenosine and P_i?
- During periods of nutrient abundance, how can cells prepare for periods of nutrient starvation?

III • Fermentation and Respiration

Fermentation and respiration are two major strategies for energy conservation in chemoorganotrophs. **Fermentation** is a form of anaerobic catabolism in which an organic compound is both an electron donor and an electron acceptor. By contrast, **respiration** is the form of aerobic or anaerobic catabolism in which an electron donor is oxidized with O₂ or an O₂ substitute as the terminal electron acceptor.

One can look at fermentation and respiration as alternative metabolic options. When O₂ is available, respiration will take place because, as we will see, much more ATP is produced in respiration than in fermentation. But if conditions will not support respiration, fermentation can supply enough energy for an organism to thrive. We begin by examining a major metabolic pathway for microbial fermentations, the glycolytic pathway.

3.8 Glycolysis

A nearly universal pathway for the catabolism of glucose is **glycolysis**, which breaks down glucose into pyruvate. Glycolysis is also called the *Embden–Meyerhof–Parnas pathway* for its major discoverers. Whether glucose is fermented or respired, it travels through this pathway. In fermentation, ATP is synthesized by **substrate-level phosphorylation**. In this process, ATP is synthesized directly from energy-rich intermediates during steps in the catabolism of the fermentable substrate (Figure 3.13a). This is in contrast to **oxidative phosphorylation**, which occurs in respiration; ATP is synthesized here at the expense of the proton motive force (Figure 3.13b).

The fermentable substrate in a fermentation is both the electron donor and electron acceptor; not all compounds can be fermented, but sugars, especially hexoses such as glucose, are excellent fermentable substrates. The fermentation of glucose through the glycolytic pathway can be divided into three stages, each requiring several independent enzymatic reactions. Stage I comprises “preparatory” reactions; these are not redox reactions and do not release energy but instead form a key intermediate of the pathway. In Stage II, redox reactions occur, energy is conserved, and two molecules of pyruvate are formed. In Stage III, redox balance is achieved and fermentation products are formed (Figure 3.14).

Stage I: Preparatory Reactions

In Stage I, glucose is phosphorylated by ATP, yielding glucose 6-phosphate. The latter is then isomerized to fructose 6-phosphate, and a second phosphorylation leads to the production of fructose 1,6-bisphosphate. The enzyme aldolase then splits fructose 1,6-bisphosphate into two 3-carbon molecules, *glyceraldehyde*

3-phosphate and its isomer, *dihydroxyacetone phosphate*, which is converted into glyceraldehyde 3-phosphate. To this point, all of the reactions, including the consumption of ATP, have proceeded without any redox changes.

Stage II: Production of NADH, ATP, and Pyruvate

The first redox reaction of glycolysis occurs in Stage II during the oxidation of glyceraldehyde 3-phosphate to 1,3-bisphosphoglyceric acid. In this reaction (which occurs twice, once for each of the two molecules of glyceraldehyde 3-phosphate produced from glucose), the enzyme glyceraldehyde-3-phosphate dehydrogenase reduces its coenzyme NAD⁺ to NADH. Simultaneously, each glyceraldehyde 3-phosphate molecule is phosphorylated by the addition of a molecule of inorganic phosphate. This reaction, in which inorganic phosphate is converted to organic form, sets the stage for energy conservation. ATP formation is possible because 1,3-bisphosphoglyceric acid is an energy-rich compound (Figure 3.12). ATP is then synthesized when (1) each molecule

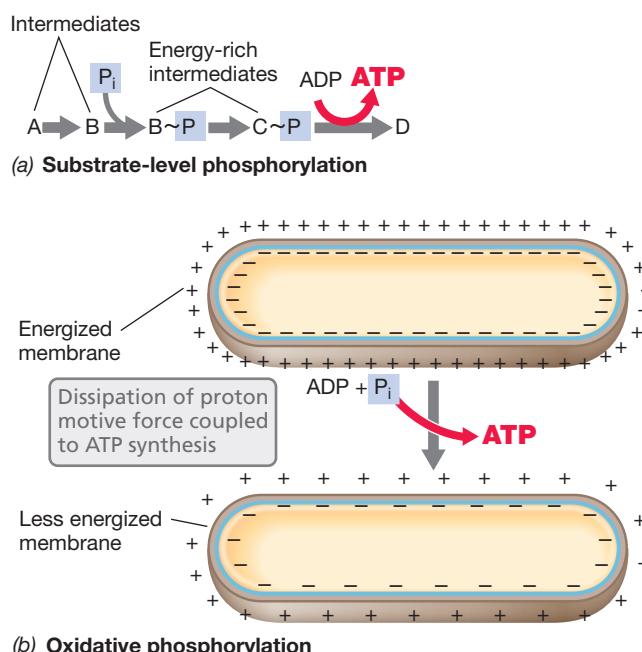

Figure 3.13 Energy conservation in fermentation and respiration. (a) In fermentation, substrate-level phosphorylation produces ATP. (b) In respiration, the cytoplasmic membrane, energized by the proton motive force, dissipates energy to synthesize ATP from ADP + P_i by oxidative phosphorylation.

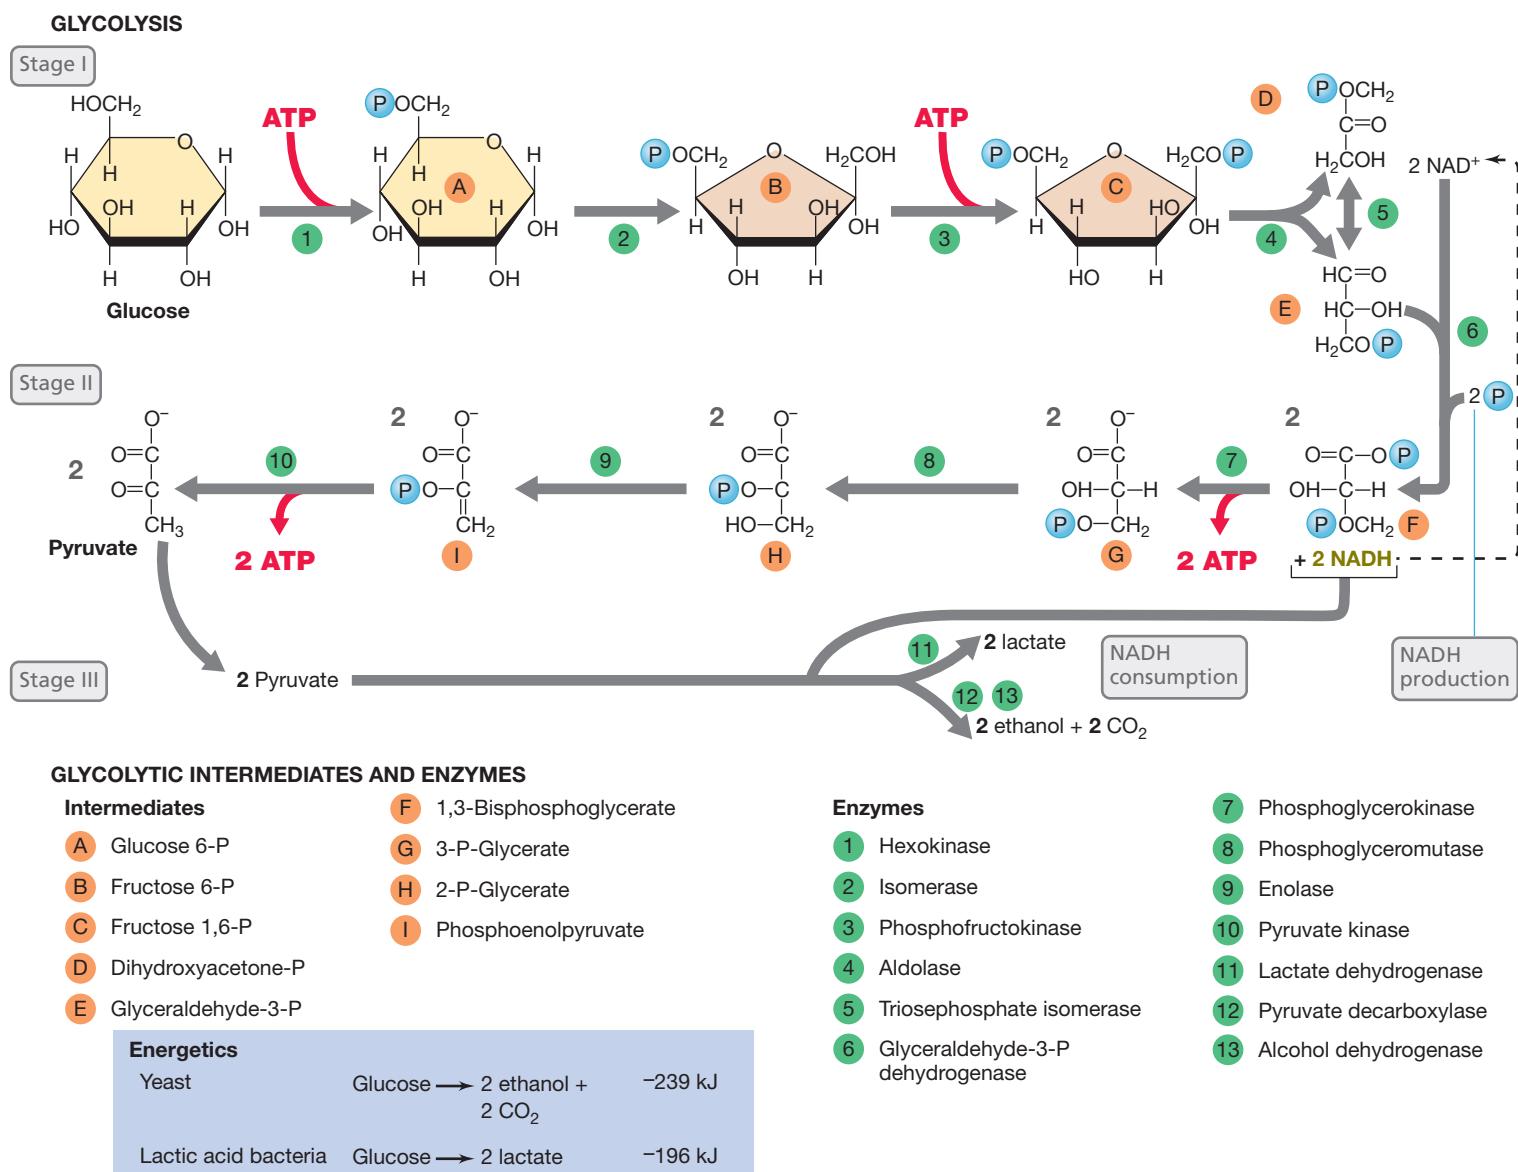

Figure 3.14 Embden–Meyerhof–Parnas pathway (glycolysis). (Top) The sequence of reactions in the catabolism of glucose to pyruvate and then on to fermentation products. Pyruvate is the end product of glycolysis, and fermentation products are made from it. (Bottom) Intermediates, enzymes, and contrasting fermentation balances of yeast and lactic acid bacteria.

of 1,3-bisphosphoglyceric acid is converted to 3-phosphoglyceric acid, and (2) each molecule of phosphoenolpyruvate is converted to pyruvate (Figure 3.14).

During Stages I and II of glycolysis, *two* ATP molecules are consumed and *four* ATP molecules are synthesized (Figure 3.14). Thus, the net energy yield in glycolysis is *two molecules of ATP per molecule of glucose fermented*.

Stage III: Redox Balance and the Production of Fermentation Products

During the formation of two 1,3-bisphosphoglyceric acid molecules, two NAD⁺ are reduced to NADH (Figure 3.14). However, recall that NAD⁺ is only an electron shuttle, not a net (terminal) acceptor of electrons. Thus, the NADH produced in glycolysis

must be oxidized back to NAD⁺ in order for another round of glycolysis to occur, and this is accomplished when pyruvate is reduced by NADH to fermentation products (Figure 3.14). For example, in fermentation by yeast, pyruvate is reduced to ethanol (ethyl alcohol) with the subsequent production of carbon dioxide (CO₂). By contrast, lactic acid bacteria reduce pyruvate to lactate. Many other possibilities for pyruvate reduction exist depending on the organism (see next section), but the end result is the same: NADH is reoxidized to NAD⁺, and this allows earlier reactions of the pathway that require NAD⁺ to continue.

Catabolism of Other Sugars and Polysaccharides

Many microorganisms can ferment disaccharides. For example, lactose (milk sugar) and sucrose (table sugar) are common

disaccharides widely used by fermentative anaerobes. With either substrate, the first step in its fermentation is to break the disaccharide into its components. For lactose, this is glucose and galactose as a result of activity of the enzyme β -galactosidase, and for sucrose, this is glucose and fructose resulting from invertase activity. Fructose and galactose are then converted to glucose by isomerase enzymes and fermented by the glycolytic pathway.

Polysaccharides are important structural components of microbial cell walls, capsules, slime layers, and storage products, and many polysaccharides can be fermented. Cellulose and starch are two of the most abundant natural polysaccharides. Although both these polysaccharides are polymers of glucose, the glucose units in the polymer are bonded differently. This makes cellulose more insoluble than starch and less rapidly digested. Cellulose is attacked by the enzyme cellulase and starch by the enzyme amylase. The activities of these enzymes release glucose from the polymer; the glucose can then be fermented. Many other sugars can also be fermented. But since glucose is the starting substrate of the glycolytic pathway, these sugars have to be converted to glucose first before they enter the pathway.

MINIQUIZ

- Which reactions in glycolysis involve oxidations and reductions?
- What is the role of NAD⁺/NADH in glycolysis?
- Why are fermentation products made during glycolysis?

3.9 Fermentative Diversity and the Respiratory Option

Besides using the glycolytic pathway to ferment glucose to ethanol plus CO₂, as in yeast, or to lactic acid, as in lactic acid bacteria (Figure 3.14), many other fermentative bacteria use the glycolytic pathway as a mechanism for conserving energy and generating fermentation products. We conclude our focus on fermentations by briefly considering fermentative diversity and then introduce

a second option for catabolizing glucose—respiration—by contrasting the metabolic patterns of the common baker's yeast, an organism that can either ferment or respire, depending on its environmental conditions.

Fermentative Diversity

Fermentations are classified by either the substrate fermented or the products formed, and with rare exception, all generate ATP by substrate-level phosphorylation. Table 3.4 lists some of the major fermentations of glucose on the basis of the products formed, including the production of alcohol or lactic acid, as we have just detailed. Other categories include propionic acid, mixed acid (acetic acid, formic acid, lactic acid), butyric acid, or butanol. All of the organisms listed in Table 3.4 use the glycolytic pathway to catabolize glucose, the major difference in the fermentations being in what happens to pyruvate (Figure 3.14). The mechanism for the reduction of pyruvate by each organism is what leads to the different fermentation products (Table 3.4).

In addition to the two ATP produced in glycolysis, some of the fermentations listed in Table 3.4 allow for additional ATP to be formed. This occurs when the fermentation product is a fatty acid because the fatty acid is formed from a coenzyme-A precursor. Recall that CoA derivatives of fatty acids, such as acetyl-CoA, are energy-rich (Section 3.7 and Figure 3.12). Thus, when *Clostridium butyricum* forms butyric acid, the final reaction is

This can significantly increase the yield of ATP from the fermentation of glucose, although the yield falls far shy of what we will see is possible in glucose respiration.

Some fermentations are classified on the basis of the substrate fermented rather than the fermentation products generated, and these fermentations typically occur through pathways other than glycolysis. For instance, some endospore-forming anaerobic bacteria (genus *Clostridium*) ferment amino acids, the breakdown products of proteins, and others ferment purines and pyrimidines, the products

Table 3.4 Common bacterial fermentations and some of the organisms carrying them out

Type	Reaction	Organisms
Alcoholic	Hexose ^a → 2 ethanol + 2 CO ₂	Yeast, <i>Zymomonas</i>
Homolactic	Hexose → 2 lactate ⁻ + 2 H ⁺	<i>Streptococcus</i> , some <i>Lactobacillus</i>
Heterolactic	Hexose → lactate ⁻ + ethanol + CO ₂ + H ⁺	<i>Leuconostoc</i> , some <i>Lactobacillus</i>
Propionic acid	3 Lactate ⁻ → 2 propionate ⁻ + acetate ⁻ + CO ₂ + H ₂ O	<i>Propionibacterium</i> , <i>Clostridium propionicum</i>
Mixed acid ^{b,c}	Hexose → ethanol + 2,3-butanediol + succinate ²⁻ + lactate ⁻ + acetate ⁻ + formate ⁻ + H ₂ + CO ₂	Enteric bacteria including <i>Escherichia</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Klebsiella</i> , <i>Enterobacter</i>
Butyric acid ^c	Hexose → butyrate ⁻ + 2 H ₂ + 2 CO ₂ + H ⁺	<i>Clostridium butyricum</i>
Butanol ^c	2 Hexose → butanol + acetone + 5 CO ₂ + 4 H ₂	<i>Clostridium acetobutylicum</i>
Caproate/Butyrate	6 Ethanol + 3 acetate ⁻ → 3 butyrate ⁻ + caproate ⁻ + 2 H ₂ + 4 H ₂ O + H ⁺	<i>Clostridium kluyveri</i>
Acetogenic	Fructose → 3 acetate ⁻ + 3 H ⁺	<i>Clostridium aceticum</i>

^aGlucose is the starting substrate for glycolysis. However, many other C₆ sugars (hexoses) can be fermented following their conversion to glucose.

^bNot all organisms produce all products. In particular, butanediol production is limited to only certain enteric bacteria. The reaction is not balanced.

^cOther products include some acetate and a small amount of ethanol (butanol fermentation only).

Figure 3.15 Common food and beverage products resulting from the alcoholic fermentation of *Saccharomyces cerevisiae*.

of nucleic acid breakdown. Some fermentative anaerobes even ferment aromatic compounds. In many cases, these fermentations are carried out by a single group of anaerobic bacteria; in a few cases, only a single bacterium is known to ferment a particular substance. These bacteria are metabolic specialists, having evolved the capacity to ferment a substrate not catabolized by other bacteria. Although they may seem to be metabolic oddballs, these and other fermentative bacteria are of great ecological importance in degrading the remains of dead plants, animals, and other microorganisms in anoxic environments in nature. We investigate the principles behind some of these unusual fermentations in Chapter 13.

***Saccharomyces cerevisiae*: Fermentation or Respiration?**

During glycolysis, glucose is consumed, ATP is made, and fermentation products are generated. For the organism the crucial product is ATP; fermentation products are merely waste products. However, fermentation products are not waste products to humans. Instead, they are the foundation of the baking and fermented beverage industries (Figure 3.15) and are key ingredients in many fermented foods. In the baking and alcohol industries, the metabolic capacities of the key player, the baker's and brewer's yeast *Saccharomyces cerevisiae*, are on center stage. However, *S. cerevisiae* can carry out two modes of glucose catabolism, *fermentation*, as we have discussed, and *respiration*, which we will consider next.

As a rule, cells carry out that form of metabolism that most benefits them energetically. The energy available from a molecule of glucose is much greater if it is resired to CO₂ than if it is fermented. This is because unlike CO₂, organic fermentation products such as ethanol still contain a significant amount of free energy. Thus, when O₂ is available, yeast respire glucose rather

than ferment it, and the major product is CO₂ (from activities of the citric acid cycle, see Figure 3.22). Only when conditions are anoxic do yeasts switch to fermentation.

This fact has practical significance. Since the brewer and baker need the *products* of yeast fermentation rather than yeast cells themselves, care must be taken to ensure that the yeast is forced into a fermentative lifestyle. For example, when grapes are squeezed to make wine, the yeast at first respire, making the juice anoxic. Following this, the vessel is sealed against the introduction of air and fermentation begins. Yeast also serves as the leavening agent in bread, although here it is not the alcohol that is important, but CO₂, the *other* product of the alcohol fermentation (Table 3.4). The CO₂ raises the dough, and the alcohol produced along with it is volatilized during the baking process. We discuss fermented foods in more detail in Chapter 31.

MINIQUIZ

- Which fermentation products are produced by *Lactobacillus* and which by *Clostridium* species? Which would you find in fermented milk products, such as yogurt?
- Which yeast fermentation product is the desired agent in bread and what is its function in bread-making?

3.10 Respiration: Electron Carriers

Fermentation is an anaerobic process and releases only a small amount of energy. By contrast, if pyruvate is fully oxidized to CO₂ rather than reduced to some fermentation product, a far higher yield of ATP is possible. Oxidation using O₂ as the terminal electron acceptor is called *aerobic respiration*; oxidation using other acceptors under anoxic conditions is called *anaerobic respiration* (Section 3.13).

Our discussion of respiration covers both carbon transformations and redox reactions and focuses on two issues: (1) how electrons are transferred from the primary electron donor to the terminal electron acceptor and how this process is coupled to energy conservation, and (2) the pathway by which organic carbon is oxidized into CO₂. We begin with a consideration of electron transport, the series of reactions that lead to the proton motive force.

NADH Dehydrogenases and Flavoproteins

Electron transport occurs in the membrane, and several types of oxidation–reduction enzymes participate in electron transport. These include *NADH dehydrogenases*, *flavoproteins*, *iron–sulfur proteins*, and *cytochromes*. Also participating are nonprotein electron carriers called *quinones*. The carriers are arranged in the membrane in order of increasingly more positive reduction potential, with NADH dehydrogenase first and the cytochromes last (Figure 3.9).

NADH dehydrogenases are proteins bound to the inside surface of the cytoplasmic membrane and have an active site that binds NADH. The 2 e⁻ + 2 H⁺ from NADH are transferred from the dehydrogenase to a flavoprotein, the next carrier in the chain. This forms NAD⁺ that is released from the dehydrogenase and can react with another enzyme (Figure 3.11).

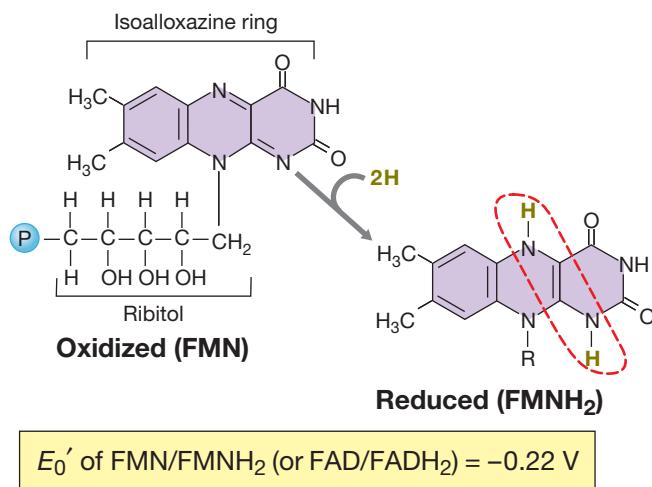

Figure 3.16 Flavin mononucleotide (FMN), a hydrogen atom carrier. The site of oxidation–reduction (dashed red circle) is the same in FMN and the related coenzyme flavin adenine dinucleotide (FAD, not shown). FAD contains an adenosine group bonded through the phosphate group on FMN.

Flavoproteins contain a derivative of the vitamin riboflavin (Figure 3.16). The flavin portion, which is bound to a protein, is a prosthetic group (Section 3.5) that is reduced as it accepts $2 e^- + 2 H^+$ and oxidized when $2 e^-$ are passed on to the next carrier in the chain. Note that flavoproteins *accept* $2 e^- + 2 H^+$ but *donate* only electrons. We will consider what happens to the $2 H^+$ later. Two flavins are commonly found in cells, flavin mononucleotide (FMN, Figure 3.16) and flavin adenine dinucleotide (FAD). In the latter, FMN is bonded to ribose and adenine through a second phosphate. Riboflavin, also called vitamin B₂, is a source of the parent flavin molecule in flavoproteins and is a required growth factor for some organisms (Table 3.1).

Cytochromes, Other Iron Proteins, and Quinones

The cytochromes are proteins that contain heme prosthetic groups (Figure 3.17). Cytochromes undergo oxidation and reduction through loss or gain of a single electron by the iron atom in the heme of the cytochrome:

Several classes of cytochromes are known, differing widely in their reduction potentials (Figure 3.9). Different classes of cytochromes are designated by letters, such as cytochrome *a*, cytochrome *b*, cytochrome *c*, and so on, depending upon the type of heme they contain. The cytochromes of a given class in one organism may differ slightly from those of another, and so there are designations such as cytochromes *a*₁, *a*₂, *a*₃, and so on among cytochromes of the same class. Cytochromes of different classes also differ in their reduction potentials (Figure 3.9). Occasionally, cytochromes form complexes with other cytochromes or with iron–sulfur proteins. An important example is the cytochrome *bc*₁ complex, which contains two different *b*-type cytochromes and one *c*-type cytochrome. The cytochrome *bc*₁ complex plays an important role in energy metabolism, as we will see later.

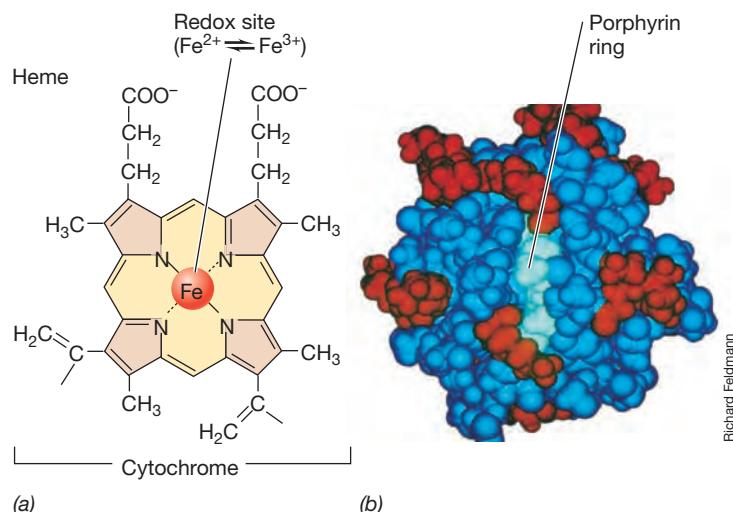

Figure 3.17 Cytochrome and its structure. (a) Structure of heme, the iron-containing portion of cytochromes. Cytochromes carry electrons only, and the redox site is the iron atom, which can alternate between the Fe^{2+} and Fe^{3+} oxidation states. (b) Space-filling model of cytochrome *c*; heme (light blue) is covalently linked via disulfide bridges to cysteine residues in the protein (dark blue). Cytochromes are tetrapyrroles, composed of four pyrrole rings.

In addition to the cytochromes, in which iron is bound to heme, one or more proteins with nonheme iron typically participate in electron transport chains. These proteins contain prosthetic groups made up of clusters of iron and sulfur atoms, with Fe_2S_2 and Fe_4S_4 clusters being the most common (Figure 3.18). *Ferredoxin*, a common nonheme iron–sulfur protein, has an Fe_2S_2 configuration. The reduction potentials of iron–sulfur proteins vary over a wide range depending on the number of iron and sulfur atoms present and how the iron centers are embedded in the protein. Thus, different iron–sulfur proteins can function at different locations in the electron transport chain. Like cytochromes, nonheme iron–sulfur proteins carry electrons only.

Quinones (Figure 3.19) are hydrophobic molecules that lack a protein component. Because they are small and hydrophobic, quinones are free to move about within the membrane. Like the flavins (Figure 3.16), quinones accept $2 e^- + 2 H^+$ but transfer only $2 e^-$ to the next carrier in the chain; quinones typically participate as links between iron–sulfur proteins and the first cytochromes in the electron transport chain.

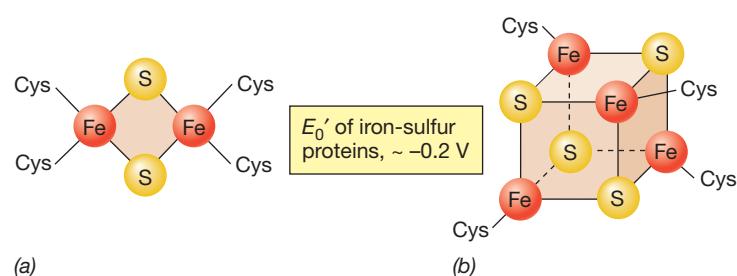

Figure 3.18 Arrangement of the iron–sulfur centers of nonheme iron–sulfur proteins. (a) Fe_2S_2 center. (b) Fe_4S_4 center. The cysteine (Cys) linkages are from the protein portion of the molecule.

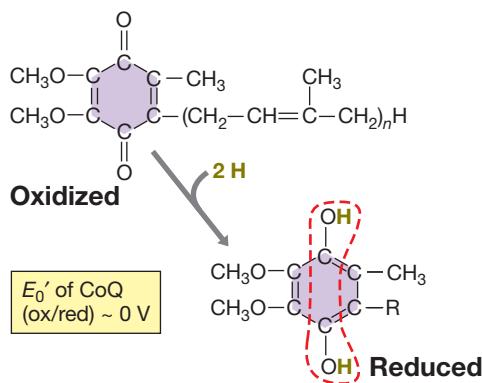

Figure 3.19 Structure of oxidized and reduced forms of coenzyme Q, a quinone. The five-carbon unit in the side chain (an isoprenoid) occurs in multiples, typically 6–10. Oxidized quinone requires $2 e^-$ and $2 H^+$ to become fully reduced (dashed red circles).

MINIQUIZ

- In what major way do quinones differ from other electron carriers in the membrane?
- Which electron carriers described in this section accept $2 e^- + 2 H^+$? Which accept electrons only?

3.11 Respiration: The Proton Motive Force

The conservation of energy in respiration is linked to an energized state of the membrane (Figure 3.13b), and this energized state is established by electron transport. To understand how electron transport is linked to ATP synthesis, we must first understand how the electron transport system is organized in the cytoplasmic membrane. The electron transport carriers we just discussed (Figures 3.16–3.19) are oriented in the membrane in such a way that, as electrons are transported, protons are separated from electrons. Two electrons plus two protons enter the electron transport chain from NADH (through NADH dehydrogenase) to initiate the process. Carriers in the electron transport chain are arranged in the membrane in order of their *increasingly positive* reduction potential, with the final carrier in the chain donating the electrons plus protons to a terminal electron acceptor such as O_2 .

During electron transport, H^+ are extruded to the outer surface of the membrane. These originate from two sources: (1) NADH and (2) the dissociation of H_2O into H^+ and OH^- in the cytoplasm. The extrusion of H^+ to the environment results in the accumulation of OH^- on the inside of the membrane. However, despite their small size, neither H^+ nor OH^- can diffuse through the membrane because they are charged and highly polar (Section 2.8). As a result of the separation of H^+ and OH^- , the two sides of the membrane differ in both charge and pH; this forms an *electrochemical potential* across the membrane. This potential, along with the difference in pH across the membrane, is called the **proton motive force (pmf)** and causes the membrane to be energized, much like a battery (Figure 3.13b). Some of the potential energy in the pmf is then conserved in the formation of ATP. However, besides driving ATP synthesis, the pmf can also be

tapped to do other forms of work for the cell, such as transport reactions, flagellar rotation, and other energy-requiring reactions in the cell.

Figure 3.20 shows a bacterial electron transport chain, one of many different carrier sequences known. Nevertheless, three features are characteristic of *all* electron transport chains regardless of which specific carriers they contain: (1) the carriers are arranged in order of increasingly more positive E_0' , (2) there is an alternation of electron-only and electron-plus-proton carriers in the chain, and (3) the net result is reduction of a terminal electron acceptor and generation of a proton motive force.

Generation of the Proton Motive Force: Complexes I and II

The proton motive force develops from the activities of flavins, quinones, the cytochrome bc_1 complex, and the terminal cytochrome oxidase. Following the oxidation of $NADH + H^+$ to form $FMNH_2$, $4 H^+$ are released to the outer surface of the membrane when $FMNH_2$ donates $2 e^-$ to a series of nonheme iron proteins (Fe/S), forming the group of electron transport proteins called *Complex I* (Figure 3.20). These groups are called *complexes* because each consists of several proteins that function as a unit. For example, Complex I in *Escherichia coli* contains 14 separate proteins. Complex I is also called *NADH: quinone oxidoreductase* because the overall reaction is one in which NADH is oxidized and quinone is reduced. Two H^+ from the cytoplasm are taken up by coenzyme Q when it is reduced by the Fe/S protein in Complex I (Figure 3.20).

Complex II simply bypasses Complex I and feeds electrons from $FADH_2$ directly into the quinone pool. Complex II is also called the *succinate dehydrogenase complex* because of the specific substrate, succinate (a product of the citric acid cycle, Section 3.12), that it oxidizes. However, because Complex II bypasses Complex I (where electrons enter at a more negative reduction potential), fewer protons are pumped per $2 e^-$ that enter at Complex II than enter at Complex I (Figure 3.20); this reduces the ATP yield by one per two electrons consumed.

Complexes III and IV: bc_1 and α -Type Cytochromes

Reduced coenzyme Q (QH_2) passes electrons one at a time to the cytochrome bc_1 complex (*Complex III*, Figure 3.20). Complex III consists of several proteins that contain two different b -type hemes (b_L and b_H), one c -type heme (c_1), and one iron–sulfur center. The bc_1 complex is present in the electron transport chain of almost all organisms that can respire and also plays a role in photosynthetic electron flow in phototrophic organisms (Sections 13.3 and 13.4).

The major function of the cytochrome bc_1 complex is to move e^- from quinones to cytochrome c . Electrons travel from the bc_1 complex to cytochrome c , located in the periplasm. Cytochrome c functions as a shuttle to transfer e^- to the high-redox-potential cytochromes α and α_3 (*Complex IV*, Figure 3.20). Complex IV functions as the terminal oxidase and reduces O_2 to H_2O in the final step of the electron transport chain. Complex IV also pumps protons to the outer surface of the membrane, thereby increasing the strength of the proton motive force (Figure 3.20).

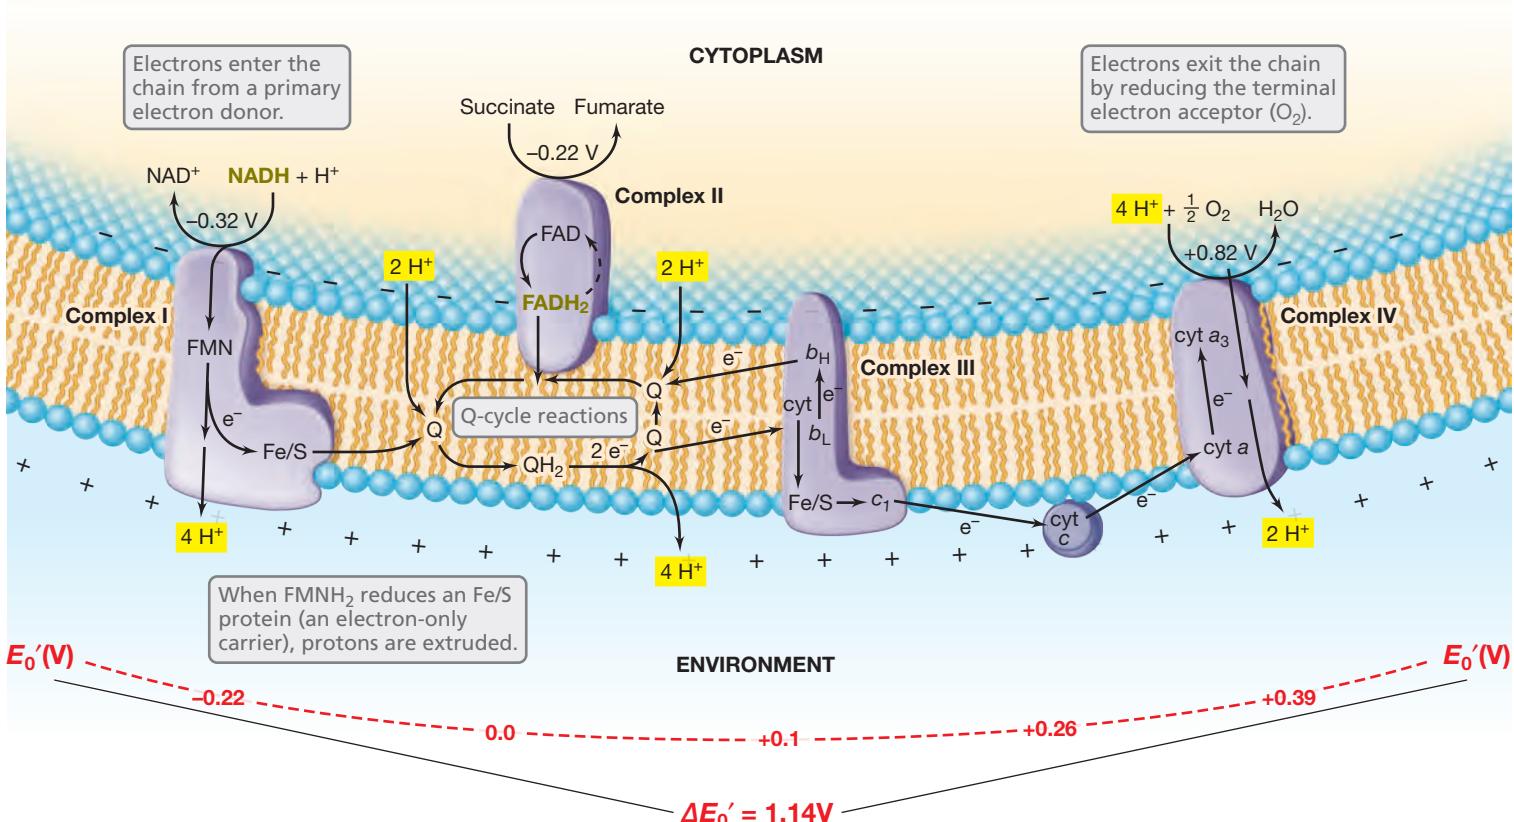

Figure 3.20 Generation of the proton motive force during aerobic respiration. The orientation of electron carriers in the membrane of *Paracoccus denitrificans*, a model organism for studies of respiration. The + and - charges at the edges of the membrane represent H^+ and OH^- , respectively. Abbreviations: FMN, flavin mononucleotide; FAD, flavin adenine dinucleotide; Q, quinone; Fe/S, iron-sulfur-

protein; cyt *a*, *b*, *c*, cytochromes (*b*_L and *b*_H, low- and high-potential *b*-type cytochromes, respectively). At the quinone site, electrons are recycled from Q to *bc*₁ from reactions of the “Q cycle.” Electrons from QH₂ can be split in the *bc*₁ complex between the Fe/S protein and the *b*-type cytochromes. Electrons that travel through the cytochromes reduce Q (in two, one-electron steps) back to QH₂, thus increasing the number of protons

pumped at the Q-*bc*₁ site. Electrons that travel to the Fe/S protein proceed to reduce cytochrome *c*₁, and from there cytochrome *c*. Complex II, the succinate dehydrogenase complex, bypasses Complex I and feeds electrons directly into the quinone pool at a more positive E'_0 than NADH (see the electron tower in Figure 3.9).

Besides transferring e^- to cytochrome *c*, the cytochrome *bc*₁ complex can also interact with quinones in such a way that on average, two additional H^+ are pumped at the Q-*bc*₁ site. This happens in a series of electron exchanges between cytochrome *bc*₁ and Q, called the *Q cycle*. Because quinone and *bc*₁ have roughly the same E'_0 (near 0 V, Figure 3.9), quinone molecules can alternately become oxidized and reduced using electrons fed back to quinones from the *bc*₁ complex. This mechanism allows on average a total of 4 H^+ (instead of 2 H^+) to be pumped to the outer surface of the membrane at the Q-*bc*₁ site for every 2 e^- that enter the chain in Complex I (Figure 3.20). This strengthens the proton motive force, and as we will see now, it is the proton motive force that drives ATP synthesis.

ATP Synthase

How does the proton motive force generated by electron transport (Figure 3.20) actually drive ATP synthesis? Interestingly, a strong parallel exists between the mechanism of ATP synthesis and the mechanism behind the motor that drives rotation of the bacterial flagellum (Section 2.17). In analogy to how dissipation of the pmf applies torque that rotates the bacterial flagellum,

the pmf also creates torque in a large membrane protein complex that makes ATP. This complex is called **ATP synthase**, or **ATPase** for short.

ATPases consist of two components, a multiprotein complex called F_1 that sticks into the cytoplasm and carries out ATP synthesis, and a membrane-integrated component called F_o that carries out the ion-translocating function (Figure 3.21). ATPase catalyzes a reversible reaction between ATP and ADP + P_i as shown in the figure. The structure of ATPase proteins is highly conserved throughout all the domains of life, indicating that this mechanism of energy conservation was a very early evolutionary invention.

F_1 and F_o are actually two rotary motors. The movement of H^+ through F_o into the cytoplasm is coupled to the rotation of its *c* proteins. This generates a torque that is transmitted to F_1 via the coupled rotation of the $\gamma\epsilon$ subunits (Figure 3.21). The rotation causes conformational changes in the β subunits of F_1 and this allows them to bind ADP + P_i. ATP is synthesized when the β subunits return to their original conformation. As this occurs, the free energy of their rotated state is released and is coupled to ATP synthesis. Quantitative measures of the number of H^+ consumed by ATPase per ATP produced yield a number between 3 and 4.

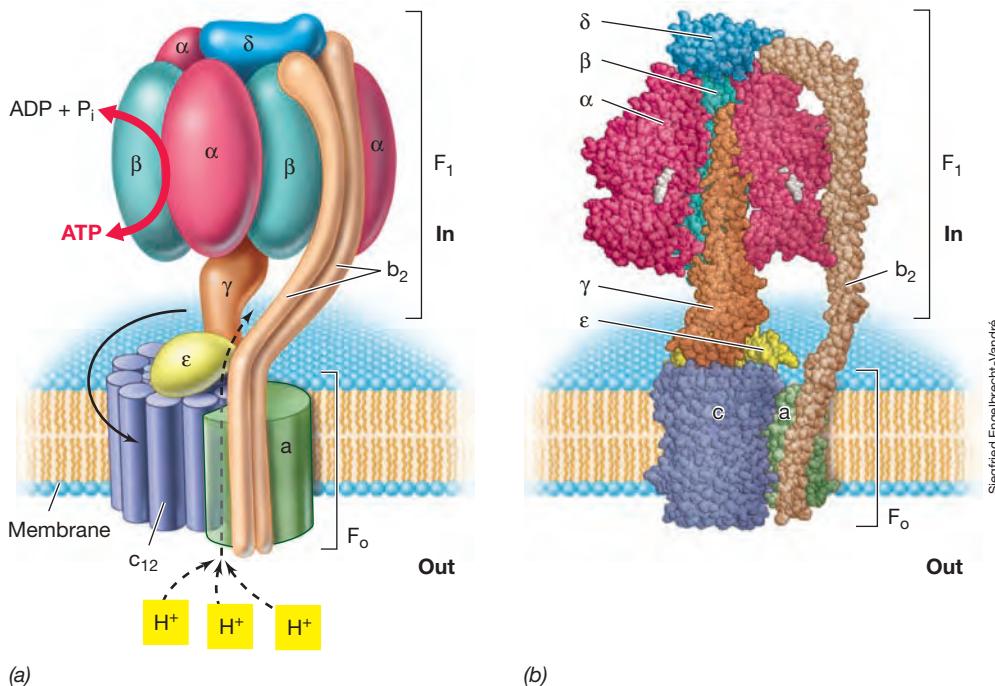

Figure 3.21 Structure and function of the reversible ATP synthase (ATPase) in *Escherichia coli*. (a) Schematic. F₁ consists of five different polypeptides forming an $\alpha_3\beta_3\gamma$ δ complex, the stator. F₁ is the catalytic complex responsible for the interconversion of ADP + P_i and ATP. F₀, the rotor, is integrated in the membrane and consists of three polypeptides in an ab₂c₁₂ complex. As protons enter, the dissipation of the proton motive force drives ATP synthesis (3 H⁺/ATP). (b) Space-filling model. The color-coding corresponds to the art in part a. Since proton translocation from outside the cell to inside the cell leads to ATP synthesis by ATPase, it follows that proton translocation from inside to outside in the electron transport chain (Figure 3.20) represents work done on the system and a source of potential energy.

Reversibility of ATPase

ATPase is reversible. The hydrolysis of ATP supplies torque for γ to rotate in the opposite direction from that in ATP synthesis, and this pumps H⁺ from the cytoplasm to the environment through F_o (Figure 3.21). The net result in this case is *generation* of instead of *dissipation* of the proton motive force. Reversibility of the ATPase explains why strictly fermentative bacteria that lack electron transport chains and are unable to carry out oxidative phosphorylation still contain ATPases. Many important reactions in the cell, such as flagellar rotation and some forms of transport, are coupled to energy from the pmf rather than directly from ATP. Thus, the ATPase of organisms incapable of respiration, such as the strictly fermentative lactic acid bacteria, functions unidirectionally to generate this required pmf from ATP formed during substrate-level phosphorylation in fermentation.

MINIQUIZ

- How do electron transport reactions generate the proton motive force?
 - What is the ratio of H^+ extruded per NADH oxidized through the electron transport chain of *Paracoccus* shown in Figure 3.20? At which sites in the chain is the proton motive force being established?
 - What structure in the cell converts the proton motive force to ATP? How does it function?

3.12 Respiration: Citric Acid and Glyoxylate Cycles

Now that we have a feeling for how ATP synthesis is coupled to electron transport, we need to consider another important aspect

of respiration—the production of CO₂. Our focus here will be on the citric acid cycle (Krebs cycle), a key pathway in virtually all cells, and the glyoxylate cycle, a variation on the citric acid cycle necessary when two-carbon electron donors are respired.

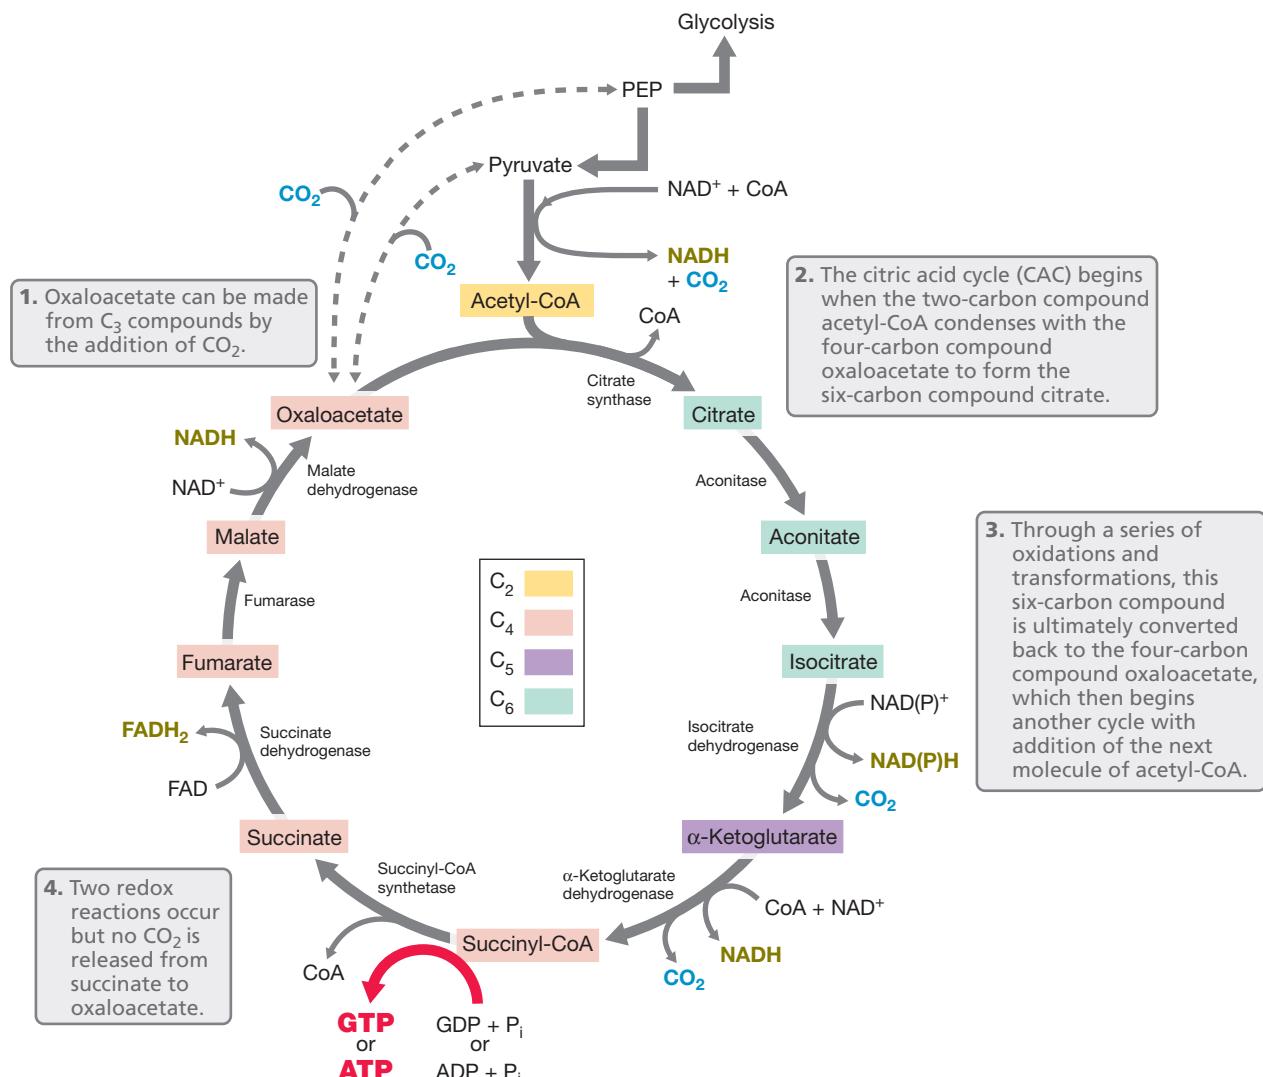

Respiration of Glucose

The early biochemical steps in the respiration of glucose are the same as those of glycolysis; all steps from glucose to pyruvate (Figure 3.14) are the same. However, whereas in fermentation pyruvate is reduced and converted into products that are subsequently excreted, in respiration, pyruvate is oxidized to CO_2 . The pathway by which pyruvate is oxidized to CO_2 is called the **citric acid cycle** (Figure 3.22).

In the citric acid cycle, pyruvate is first decarboxylated, leading to the production of CO_2 , NADH, and the energy-rich substance *acetyl-CoA*. The acetyl group of acetyl-CoA then combines with the four-carbon compound oxaloacetate, forming the six-carbon compound citric acid. A series of reactions follow, and two additional CO_2 molecules, three more NADH, and one FADH are formed. Ultimately, oxaloacetate is regenerated to return as an acetyl acceptor, thus completing the cycle (Figure 3.22).

CO₂ Release and Electron Transport: The Connection

How are reactions of the citric acid cycle and the electron transport chain connected? The oxidation of pyruvate to CO_2 requires the concerted activity of the citric acid cycle and the electron transport chain. For each pyruvate molecule oxidized through the citric acid cycle, three CO_2 molecules are produced (Figure 3.22). Electrons released during the oxidation of intermediates in the citric acid cycle are transferred to NAD^+ to form NADH , or in one reaction, to FAD to form FADH_2 . The combined reactions of the citric acid cycle and electron transport chain allow for the complete oxidation of glucose to CO_2 along

(a) The citric acid cycle

Energetics Balance Sheet for Aerobic Respiration

(1) Glycolysis: Glucose + 2 NAD ⁺	→	2 Pyruvate + 2 ATP + 2 NADH
(a) Substrate-level phosphorylation	2 ADP + P _i → 2 ATP	8 ATP
(b) Oxidative phosphorylation	2 NADH → 6 ATP	
(2) CAC: Pyruvate + 4 NAD ⁺ + GDP + FAD	→	3 CO ₂ + 4 NADH + FADH ₂ + GTP (ATP)
(a) Substrate-level phosphorylation	GDP + P _i → GTP (ADP)	15 ATP (×2)
(b) Oxidative phosphorylation	4 NADH → 12 ATP 1 FADH₂ → 2 ATP	
(3) Sum: Glycolysis plus CAC	→	38 ATP per glucose

(b) Energy yield from the citric acid cycle

Figure 3.22 The citric acid cycle. (a) The citric acid cycle (CAC) begins when the two-carbon compound acetyl-CoA condenses with the four-carbon compound oxaloacetate to form the six-carbon compound citrate. Through a series of oxidations and transformations, citrate is converted to two CO₂ and the acetyl acceptor molecule, oxaloacetate. (b) The overall balance sheet of fuel (NADH/FADH₂) for the electron transport chain and CO₂ generated in the citric acid cycle. NADH and FADH₂ feed into electron transport chain Complexes I and II, respectively (Figure 3.20).

with a much greater yield of energy. Whereas only 2 ATP are produced per glucose fermented in alcoholic or lactic acid fermentations (Figure 3.14 and Table 3.4), a total of 38 ATP can be made by aerobically respiring the same glucose molecule to $\text{CO}_2 + \text{H}_2\text{O}$ (Figure 3.22b).

Biosynthesis and the Citric Acid Cycle

Besides its role in combusting pyruvate to CO_2 , the citric acid cycle plays another important role in the cell. The cycle is composed of several key intermediates, small amounts of which are drawn off during growth for biosynthetic purposes. Particularly important in this regard are α -ketoglutarate and oxaloacetate, which are precursors of several amino acids (Section 3.15), and succinyl-CoA, needed to form cytochromes, chlorophyll, and several other tetrapyrroles (compounds composed of four pyrrole rings; see Figure 3.17). Oxaloacetate is also important because it can be converted to phosphoenolpyruvate, a precursor of glucose. In addition, acetate provides the starting material for fatty acid biosynthesis (Section 3.16, and see Figure 3.30). The citric acid cycle thus plays two major roles in the cell: *energy conservation* and *biosynthesis*. Much the same can be said about the glycolytic pathway, as certain intermediates from this pathway can be drawn off for biosynthetic needs as well (Sections 3.14 and 3.15).

The Glyoxylate Cycle

Citrate, malate, fumarate, and succinate are common natural products, and organisms that use these C₄ or C₆ compounds as energy sources use the citric acid cycle for their catabolism. By contrast, two-carbon compounds such as acetate cannot be used as growth substrates by the citric acid cycle alone. This is because the citric acid cycle can continue to operate only if oxaloacetate is regenerated at each turn of the cycle; any siphoning off of oxaloacetate (or any other citric acid cycle intermediates) for biosynthesis would starve the cycle of what it needs to continue functioning (Figure 3.22). Thus, when acetate is used as an electron donor, a variation on the citric acid cycle called the **glyoxylate cycle** (Figure 3.23) is employed, so named because the C₂ compound glyoxylate is a key intermediate. The glyoxylate cycle is composed of most citric acid cycle reactions plus two additional enzymes: *isocitrate lyase*, which splits isocitrate into succinate and glyoxylate, and *malate synthase*, which converts glyoxylate and acetyl-CoA to malate (Figure 3.23). The splitting of isocitrate yields succinate, which can be used for biosynthesis, and glyoxylate. The latter combines with acetyl-CoA (C₂) to yield malate (C₄). From malate, the acceptor molecule oxaloacetate is produced and can enter a new round of acetyl-CoA oxidation in the citric acid cycle (Figure 3.22).

Three-carbon compounds such as pyruvate or compounds that are converted to pyruvate (for example, lactate or carbohydrates) also cannot be catabolized through the citric acid cycle alone. But here the glyoxylate cycle is unnecessary because any shortage of citric acid cycle intermediates is corrected by synthesizing oxaloacetate from pyruvate or phosphoenolpyruvate. This occurs by the addition of CO_2 to pyruvate or phosphoenolpyruvate by the enzymes *pyruvate carboxylase* or *phosphoenolpyruvate carboxylase*, respectively (Figure 3.22).

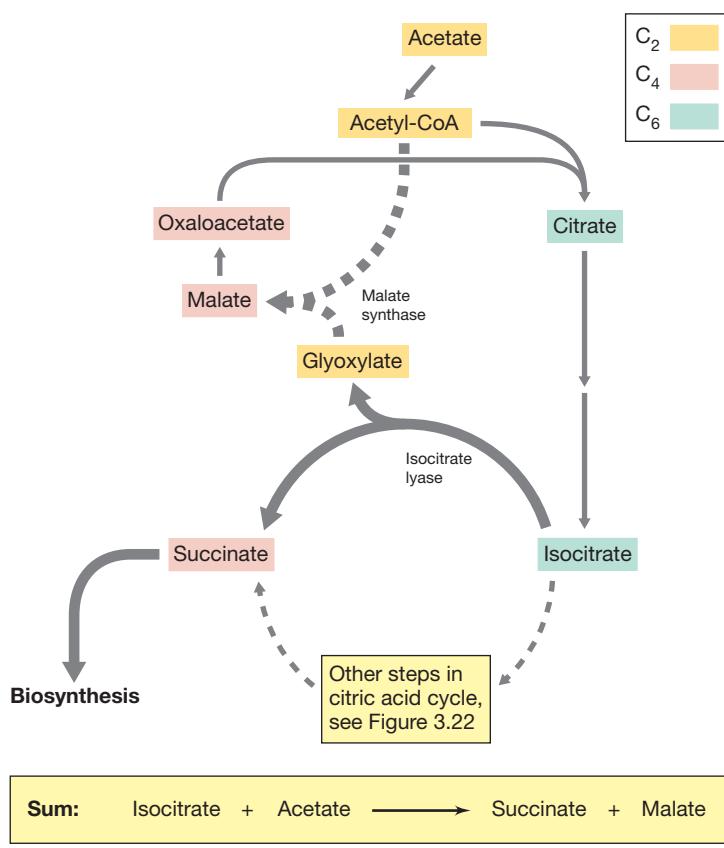

Figure 3.23 The glyoxylate cycle. These reactions occur in conjunction with the citric acid cycle when cells grow on two-carbon electron donors, such as acetate. The glyoxylate cycle regenerates oxaloacetate (from malate) to continue the citric acid cycle.

MINIQUIZ

- How many molecules of CO_2 and pairs of electrons are released per pyruvate that enters the citric acid cycle?
- What two major roles do the citric acid cycle and glycolysis have in common?
- Why is the glyoxylate cycle necessary for growth on acetate but not on succinate?

3.13 Catabolic Diversity

Thus far in this chapter we have dealt only with catabolism by chemoorganotrophs. We now briefly consider catabolic diversity and some of the alternatives to fermentation or respiration. These include *anaerobic respiration*, *chemolithotrophy*, and *phototrophy* (Figure 3.24).

Anaerobic Respiration

Under anoxic conditions, electron acceptors other than oxygen support respiration in certain prokaryotes. This is called **anaerobic respiration**. Some of the electron acceptors used in anaerobic respiration include nitrate (NO_3^- , reduced to nitrite, NO_2^- , by *Escherichia coli* or to N_2 by *Pseudomonas* species), ferric iron (Fe^{3+} , reduced to Fe^{2+} by *Geobacter* species), sulfate (SO_4^{2-} , reduced to hydrogen sulfide, H_2S , by *Desulfovibrio* species), carbonate (CO_3^{2-} , reduced to methane, CH_4 , by methanogens or to acetate

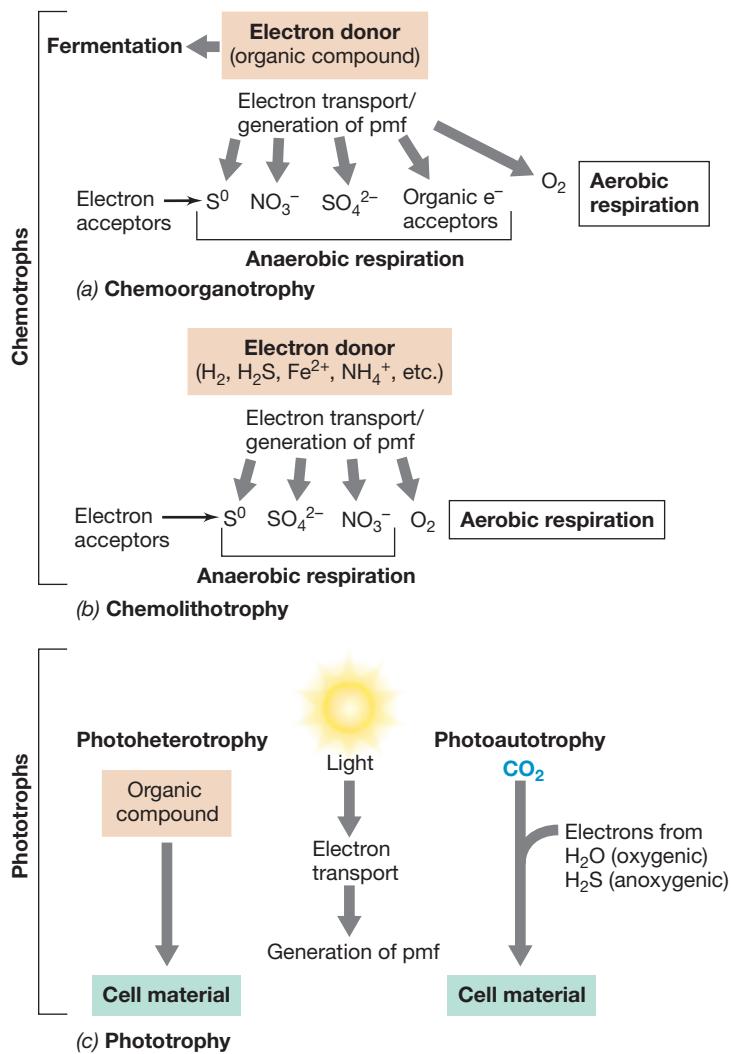

Figure 3.24 Catabolic diversity. (a) Chemoorganotrophs. (b) Chemolithotrophs. (c) Phototrophs. Note the importance of the formation of the proton motive force driven by electron transport in both forms of respiration and in photosynthesis.

by acetogens), and even certain organic compounds, such as the citric acid cycle intermediate fumarate.

Because of the positions of these alternative electron acceptors on the redox tower (none has an E_{red}° as positive as the O_2/H_2O couple; Figure 3.9), less energy is conserved when they are reduced compared to when O_2 is reduced (recall that ΔG° is proportional to ΔE° ; Section 3.4 and Figure 3.9). Nevertheless, because O_2 is often limiting or even totally absent in many microbial habitats, anaerobic respirations can be very important means of energy generation. As in aerobic respiration, anaerobic respirations require electron transport, generate a proton motive force, and employ ATPase to make ATP (Sections 3.10–3.12).

Chemolithotrophy and Phototrophy

Organisms able to use *inorganic* chemicals as electron donors are called *chemolithotrophs* (Section 3.3). Examples of relevant inorganic electron donors include H_2S , hydrogen gas (H_2), Fe^{2+} , and NH_3 .

Chemolithotrophic metabolisms are typically aerobic and begin with the oxidation of the inorganic electron donor by an electron transport chain. This results in a proton motive force, as we have already considered for the oxidation of organic electron donors by chemoorganotrophs (Figure 3.20). However, another important distinction between chemolithotrophs and chemoorganotrophs is their source of carbon for biosynthesis. Chemoorganotrophs are heterotrophs and thus use organic compounds (glucose, acetate, and the like) as carbon sources. By contrast, chemolithotrophs use carbon dioxide (CO_2) as a carbon source and are therefore autotrophs.

In the process of photosynthesis, carried out by *phototrophs*, light is used in place of a chemical to generate a proton motive force. During phototrophic metabolism, ATP is synthesized from ATPase activity during **photophosphorylation**, the light-driven analog of oxidative phosphorylation (Section 3.8). Most phototrophs assimilate CO_2 as their carbon source and are therefore *photoautotrophs*. However, some phototrophs use organic compounds as carbon sources with light as the energy source; these are the *photoheterotrophs* (Figure 3.24).

The PMF and Catabolic Diversity

With the exception of fermentation, in which substrate-level phosphorylation occurs (Section 3.8), all other mechanisms for energy conservation employ the proton motive force. Whether electrons come from the oxidation of organic or inorganic chemicals or from light-driven processes, in all forms of respiration and photosynthesis, energy conservation is linked to the establishment of a pmf and its dissipation by ATPase to form ATP (Figure 3.24). Respiration and anaerobic respiration can thus be viewed as variations on a theme of *different electron acceptors*. Likewise, chemoorganotrophy, chemolithotrophy, and photosynthesis are variations on a theme of *different electron donors*. Electron transport and the pmf link all of these processes, bringing these seemingly quite different forms of energy metabolism into a common focus. We pick up on this theme and explore it in more depth in Chapter 13.

MINIQUIZ

- In terms of their electron donors, how do chemoorganotrophs differ from chemolithotrophs?
- What is the carbon source for autotrophic organisms?
- Why can it be said that the proton motive force is a unifying theme in most of bacterial metabolism?

IV • Biosyntheses

We close this chapter with a brief consideration of biosynthesis. Our focus here will be an overview of the biosynthesis of the building blocks of the four classes of macromolecules—sugars

(polysaccharides), amino acids (proteins), nucleotides (nucleic acids), and fatty acids (lipids). Collectively, these biosyntheses are that part of metabolism called **anabolism**. We will also touch on

polysaccharide and lipid biosyntheses here, and see how some prokaryotes can assimilate gaseous nitrogen (N_2) as their source of cell nitrogen.

3.14 Sugars and Polysaccharides

Polysaccharides are key components of microbial cell walls and cells often store carbon and energy reserves in the form of the polysaccharides glycogen or starch (Chapter 2). How are such large molecules made?

Polysaccharide Biosyntheses and Gluconeogenesis

Polysaccharides are synthesized from *activated* forms of glucose, either uridine diphosphoglucose (UDPG; Figure 3.25a) or adenosine diphosphoglucose (ADPG). UDPG is the precursor of several glucose derivatives needed for the biosynthesis of structural polysaccharides in the cell, such as *N*-acetylglucosamine and *N*-acetylmuramic acid in peptidoglycan or the lipopolysaccharide component of the gram-negative outer membrane (Sections 2.10 and 2.11). Storage polysaccharides are made by adding activated glucose to preexisting polymer. For example, glycogen is synthesized as ADPG + glycogen \rightarrow ADP + glycogen-glucose.

When a cell is growing on a hexose such as glucose, obtaining glucose for polysaccharide synthesis is obviously not a problem. But when the cell is growing on other carbon compounds, glucose must be synthesized. This process, called *gluconeogenesis*, uses phosphoenolpyruvate, one of the intermediates of glycolysis, as starting material and travels backwards through the glycolytic pathway to form glucose (Figure 3.14). Phosphoenolpyruvate can be synthesized from oxaloacetate, a citric acid cycle intermediate (Figure 3.22). An overview of gluconeogenesis is shown in Figure 3.25b.

Pentose Metabolism and the Pentose Phosphate Pathway

Pentoses are formed by the removal of one carbon atom from a hexose, typically as CO_2 . The pentoses needed for nucleic acid synthesis, ribose (in RNA) and deoxyribose (in DNA), are formed

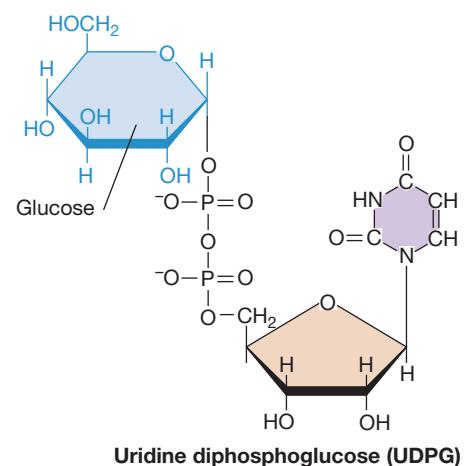

as shown in Figure 3.25c. The enzyme ribonucleotide reductase converts ribose into deoxyribose by reduction of the hydroxyl ($-OH$) group on the 2' carbon of the 5-carbon pentose ring. This reaction occurs after, not before, synthesis of nucleotides. Thus, ribonucleotides are biosynthesized, and some of them are later reduced to deoxyribonucleotides for use as precursors of DNA.

Pentoses are made from hexose sugars, and the major pathway for this process is the **pentose phosphate pathway** (Figure 3.26). In this pathway, glucose is oxidized to CO_2 , NADPH, and the key intermediate, *ribulose 5-phosphate*; from the latter, various pentose derivatives are formed. When pentoses are used as electron donors, they feed directly into the pentose phosphate pathway, typically becoming phosphorylated to form ribose phosphate or a related compound before being further catabolized (Figure 3.26).

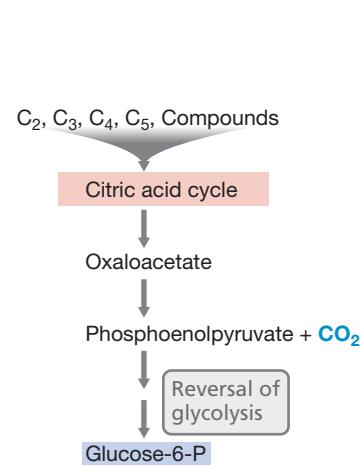

Besides its importance in pentose metabolism, the pentose phosphate pathway is also responsible for producing many important nonpentose sugars in the cell, including C₄–C₇ sugars. These sugars can eventually be converted to hexoses for either catabolic purposes or for biosynthesis (Figure 3.26). A final important aspect of the pentose phosphate pathway is that it generates NADPH, a coenzyme used for many reductive biosyntheses, in particular, as a reductant for the production of deoxyribonucleotides (Figure 3.25c). Although many cells have an exchange mechanism for converting NADH into NADPH, the pentose phosphate pathway is the major means for the direct synthesis of this important coenzyme.

MINIQUIZ

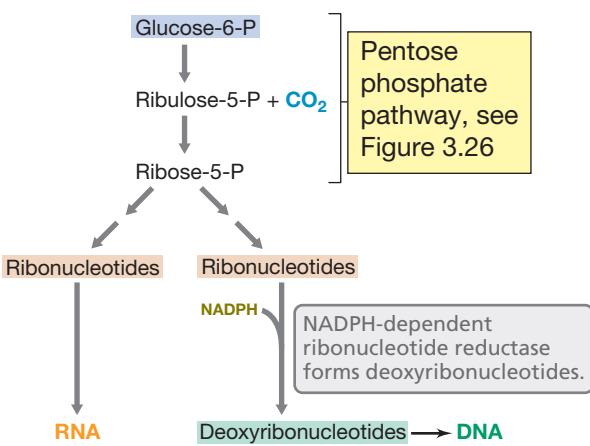

- What form of activated glucose is used in the biosynthesis of glycogen by bacteria?
- What is gluconeogenesis?
- What functions does the pentose phosphate pathway play in the cell?

(a)

(b)

(c)

Figure 3.25 Sugar metabolism. (a) Polysaccharides are synthesized from activated forms of hexoses such as UDPG. (b) Gluconeogenesis. When glucose is needed, it can be biosynthesized from other carbon compounds, generally by the reversal of steps in glycolysis. (c) Pentoses for nucleic acid synthesis are formed by decarboxylation of hexoses such as glucose 6-phosphate. Note how the precursors of DNA are produced from the precursors of RNA by the enzyme ribonucleotide reductase.

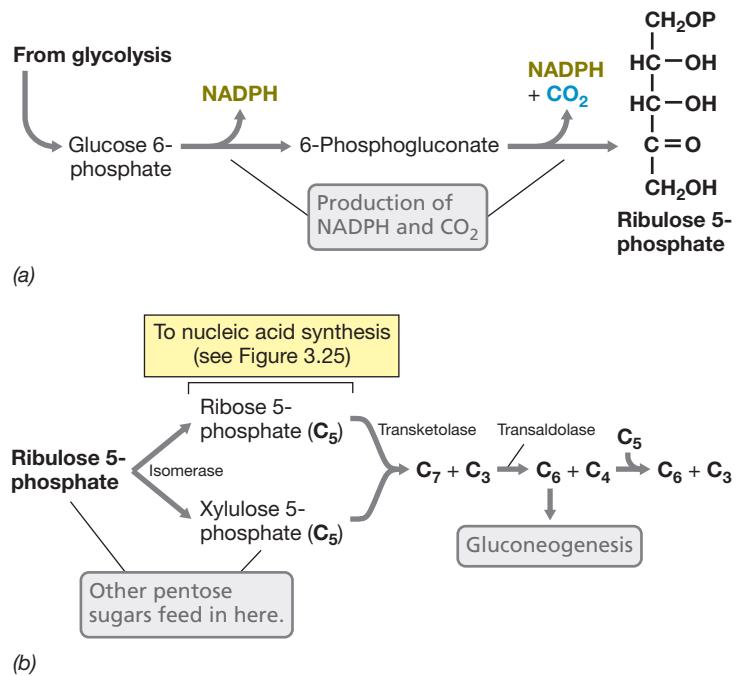

Figure 3.26 Pentose phosphate pathway. This pathway generates pentoses from other sugars for biosynthesis and also functions to catabolize pentose sugars. (a) Production of the key intermediate, ribulose 5-phosphate. (b) Other reactions in the pentose phosphate pathway.

3.15 Amino Acids and Nucleotides

The monomers in proteins and nucleic acids are the amino acids and nucleotides, respectively. Their biosyntheses are typically multistep biochemical pathways that we need not consider here. Instead, we identify the key carbon skeletons needed for the biosynthesis of amino acids and nucleotides and summarize the mechanism by which they are made.

Monomers of Proteins: Amino Acids

Organisms that cannot obtain some or all of their amino acids preformed from the environment must synthesize them from

glucose or other sources. Amino acids are grouped into structurally related *families* that share several biosynthetic steps. The carbon skeletons for amino acids come almost exclusively from intermediates of glycolysis or the citric acid cycle (Figure 3.27).

The amino group of amino acids is typically derived from some inorganic nitrogen source in the environment, such as ammonia (NH₃). Ammonia is most often incorporated during formation of the amino acids glutamate or glutamine by the enzymes *glutamate dehydrogenase* and *glutamine synthetase*, respectively (Figure 3.28). When NH₃ is present at high levels, glutamate dehydrogenase or other amino acid dehydrogenases are used. However, when NH₃ is present at low levels, glutamine synthetase, with its energy-consuming reaction mechanism (Figure 3.28b) and correspondingly high affinity for substrate, is employed.

Once ammonia is incorporated into glutamate or glutamine, the amino group can be transferred to form other nitrogenous compounds. For example, glutamate can donate its amino group to oxaloacetate in a transaminase reaction, producing α-ketoglutarate and aspartate (Figure 3.28c). Alternatively, glutamine can react with α-ketoglutarate to form two molecules of glutamate in an aminotransferase reaction (Figure 3.28d). The end result of these types of reactions is the shuttling of ammonia into various carbon skeletons from which further biosynthetic reactions occur to form all 22 of the amino acids needed to make proteins (Figure 4.30) and other nitrogen-containing biomolecules.

Monomers of Nucleic Acids: Nucleotides

The biochemistry behind purine and pyrimidine biosynthesis is quite complex. Purines are constructed literally atom by atom from several carbon and nitrogen sources, including even CO₂ (Figure 3.29). The first key purine, inosinic acid (Figure 3.29b), is the precursor of the purine nucleotides adenine and guanine. Once these are synthesized (in their triphosphate forms) and attached to ribose, they are ready to be incorporated into DNA (following ribonucleotide reductase activity, Figure 3.25c) or RNA.

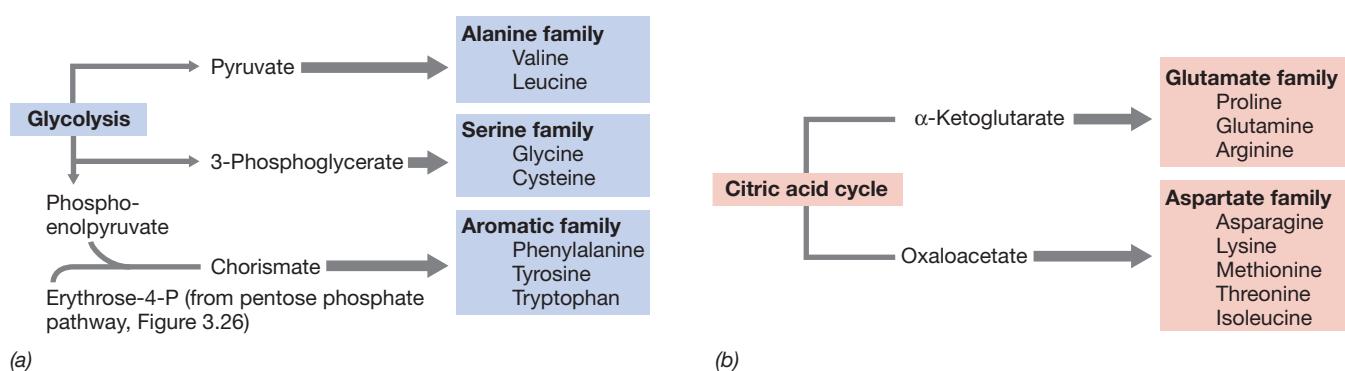

Figure 3.27 Amino acid families. Glycolysis (a) and the citric acid cycle (b) provide the carbon skeletons for most amino acids. Synthesis of the various amino acids in a family may require many steps starting with the parent amino acid (shown in bold as the name of the family).

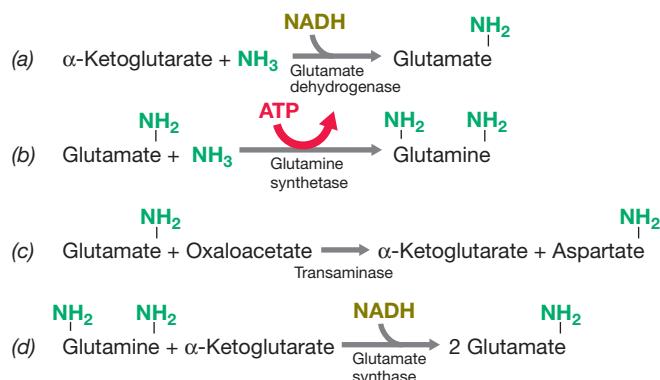

Figure 3.28 Ammonia incorporation in bacteria. Ammonia (NH_3) and the amino groups of all amino acids are shown in green. Two major pathways for NH_3 assimilation in bacteria are those catalyzed by the enzymes (a) glutamate dehydrogenase and (b) glutamine synthetase. (c) Transaminase reactions transfer an amino group from an amino acid to an organic acid. (d) The enzyme glutamate synthase forms two glutamates from one glutamine and one α -ketoglutarate.

Like the purine ring, the pyrimidine ring is also constructed from several sources (Figure 3.29c). The first key pyrimidine is the compound uridylate (Figure 3.29d), and from this the pyrimidines thymine, cytosine, and uracil are derived. Structures of all of the purines and pyrimidines are shown in the next chapter (Figure 4.1).

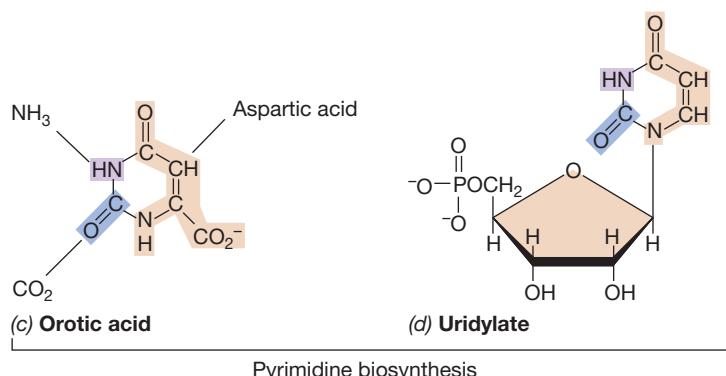

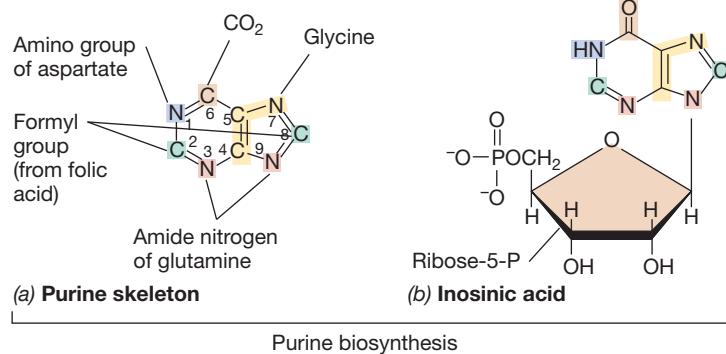

Figure 3.29 Biosynthesis of purines and pyrimidines. (a) Components of the purine skeleton. (b) Inosinic acid, the precursor of all purine nucleotides. (c) Components of the pyrimidine skeleton, orotic acid. (d) Uridylate, the precursor of all pyrimidine nucleotides. Uridylate is formed from orotate following a decarboxylation and the addition of ribose 5-phosphate.

MINIQUIZ

- What is an amino acid family?
- List the steps required for the cell to incorporate NH_3 into amino acids.
- Which nitrogen bases are purines and which are pyrimidines?

3.16 Fatty Acids and Lipids

Lipids are major components of the cytoplasmic membrane of all cells and the outer membrane of gram-negative bacteria; lipids can also be carbon and energy reserves (Figure 2.35). Fatty acids are major components of microbial lipids. However, recall that fatty acids are found only in *Bacteria* and *Eukarya*. *Archaea* do not contain fatty acids in their lipids but instead have hydrophobic isoprenoid side chains that play a similar structural role (Figure 2.17). The biosynthesis of these side chains is distinct from that of fatty acids and will not be covered here.

Fatty Acid Biosynthesis

Fatty acids are biosynthesized two carbon atoms at a time by the activity of a protein called *acyl carrier protein* (ACP). ACP holds the growing fatty acid as it is being constructed and releases it once it has reached its final length (Figure 3.30). Although fatty acids are constructed *two* carbons at a time, each C_2 unit originates from the *three*-carbon compound malonate, which is attached

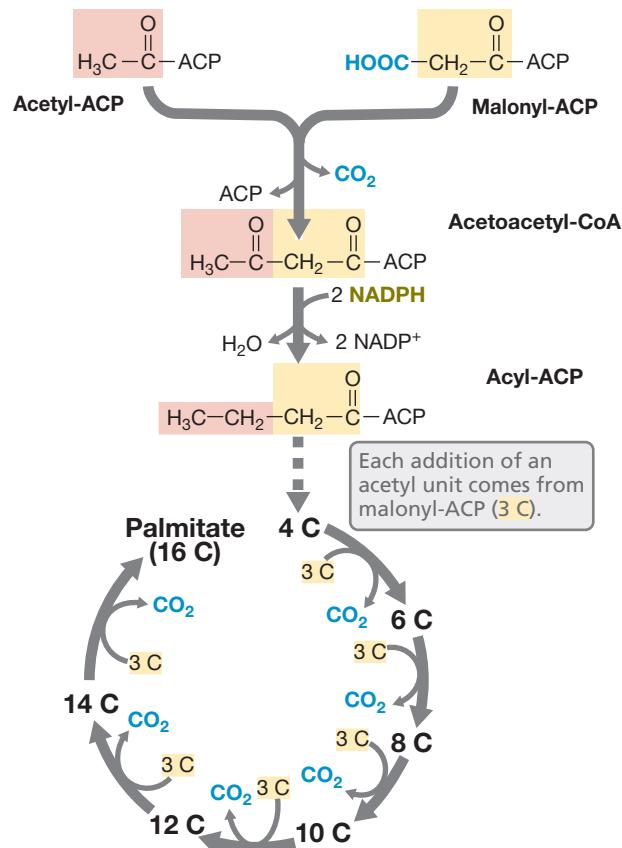

Figure 3.30 The biosynthesis of the C_{16} fatty acid palmitate. The condensation of acetyl-ACP and malonyl-ACP forms acetoacetyl-CoA. Each successive addition of an acetyl unit comes from malonyl-ACP.

to the ACP to form malonyl-ACP. As each malonyl residue is donated, one molecule of CO_2 is released (Figure 3.30).

The fatty acid composition of cells varies from species to species and can also vary in a pure culture due to differences in growth temperature. Growth at low temperatures promotes the biosynthesis of shorter-chain fatty acids whereas growth at higher temperatures promotes longer-chain fatty acids (☞ Sections 5.12 and 5.13). The most common fatty acids in lipids of *Bacteria* are those with chain lengths of C_{12} – C_{20} .

In addition to saturated, even-carbon-number fatty acids, fatty acids can also be unsaturated, branched, or have an odd number of carbon atoms. Unsaturated fatty acids contain one or more double bonds in the long hydrophobic portion of the molecule. The number and position of these double bonds is often species-specific or group-specific, and double bonds are typically formed by desaturation of a saturated fatty acid. Branched-chain fatty acids are biosynthesized using a branched-chain initiating molecule, and odd-carbon-number fatty acids (for example, C_{13} , C_{15} , C_{17} , etc.) are biosynthesized using an initiating molecule that contains a propionyl (C_3) group.

Lipid Biosynthesis

In the assembly of lipids in cells of *Bacteria* and *Eukarya*, fatty acids are first added to a molecule of glycerol. For simple triglycerides (fats), all three glycerol carbons are esterified with fatty acids. To form complex lipids, one of the carbon atoms in glycerol is embellished with a molecule of phosphate, ethanolamine, carbohydrate, or some other polar substance (☞ Figure 2.14a). Although in *Archaea*, membrane lipids are constructed from isoprene to form the phytanyl (C_{15}) or biphytanyl (C_{30}) side chains, the glycerol backbone of archaeal membrane lipids typically contains a polar group (sugar, phosphate, sulfate, or polar organic compound) as well. Polar groups are important in lipids for forming the standard membrane architecture: a hydrophobic interior with hydrophilic surfaces (☞ Figure 2.17).

MINIQUIZ

- Explain how fatty acids are constructed two carbon atoms at a time while the immediate donor of these carbons is a three-carbon compound.
- What differences exist in lipids from the three domains of life?

3.17 Nitrogen Fixation

We conclude our coverage of biosyntheses by considering the formation of ammonia (NH_3) from gaseous dinitrogen (N_2), a process called **nitrogen fixation**. The ammonia produced is assimilated into organic form in amino acids and nucleotides. The ability to fix nitrogen frees an organism from dependence on fixed nitrogen in its environment and confers a significant ecological advantage when fixed nitrogen is limiting. The process of nitrogen fixation is also of enormous agricultural importance, as it supports the nitrogen needs of key crops, such as soybeans.

Only certain species of *Bacteria* and *Archaea* can fix nitrogen, and a list of some important nitrogen-fixing organisms is given in **Table 3.5**. Some nitrogen-fixing bacteria are *free-living* and carry

Table 3.5 Some nitrogen-fixing organisms^a

Free-living aerobes		
Chemoorganotrophs	Phototrophs	Chemolithotrophs
Azotobacter, Azomonas, Azospirillum, Klebsiella, ^b Methylomonas	Cyanobacteria (e.g., <i>Anabaena</i> , <i>Nostoc</i> , <i>Gloeothecae</i> , <i>Aphanizomenon</i>)	<i>Alcaligenes</i> <i>Acidithiobacillus</i>
Free-living anaerobes		
Chemoorganotrophs	Phototrophs	Chemolithotrophs ^c
<i>Clostridium</i> <i>Desulfotomaculum</i>	Purple bacteria (e.g., <i>Chromatium</i> , <i>Rhodobacter</i>) Green bacteria (e.g., <i>Chlorobium</i>) Heliobacteria	<i>Methanosaerina</i> <i>Methanococcus</i> <i>Methanocaldococcus</i>
Symbiotic		
With leguminous plants	With nonleguminous plants	
Soybeans, peas, clover, etc. with <i>Rhizobium</i> , <i>Bradyrhizobium</i> , <i>Sinorhizobium</i>	Alder, bayberry, autumn olive, many other bushy plants, with the actinomycete <i>Frankia</i>	

^aOnly some common genera are listed in each category; many other nitrogen-fixing genera are known.

^bNitrogen fixation occurs only under anoxic conditions.

^cAll are Archaea.

out the process completely independently. By contrast, others are *symbiotic* and fix nitrogen only in association with certain plants (☞ Section 22.0). However, in symbiotic nitrogen fixation it is the bacterium, not the plant, that fixes N_2 ; no eukaryotic organisms are known to fix nitrogen.

Nitrogenase

Nitrogen fixation is catalyzed by an enzyme complex called **nitrogenase**. Nitrogenase consists of two proteins, *dinitrogenase*

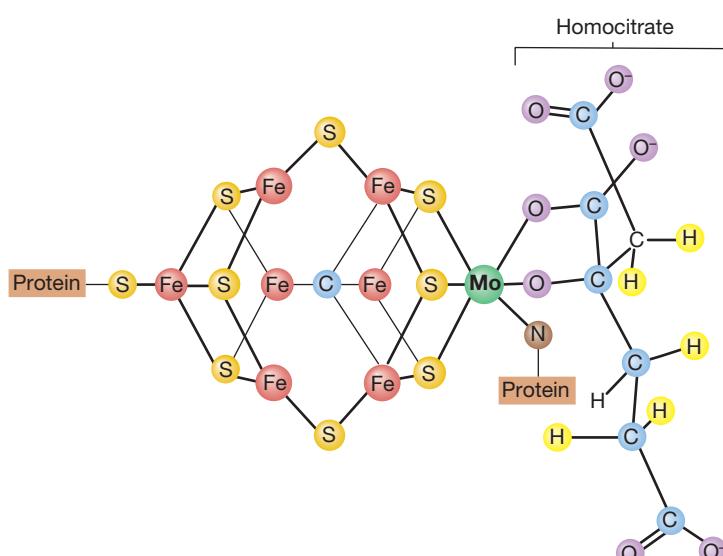

Figure 3.31 FeMo-co, the iron-molybdenum cofactor from nitrogenase. On the left side is the Fe_7S_8 cube that binds to Mo along with O atoms from homocitrate (right side, all O atoms shown in purple) and N and S atoms from dinitrogenase.

and *dinitrogenase reductase*. Both proteins contain iron, and dinitrogenase contains molybdenum as well. The iron and molybdenum in dinitrogenase are part of the enzyme cofactor called the *iron–molybdenum cofactor* (*FeMo-co*), and reduction of N₂ occurs at this site. The composition of FeMo-co is MoFe₇S₈ · homocitrate (Figure 3.31). Two “alternative” nitrogenases are known that lack molybdenum. These contain either vanadium (V) plus iron or iron-only in their cofactors and are made by certain nitrogen-fixing bacteria when molybdenum is absent from their environment (Section 14.12).

With one exception, nitrogen-fixing *Archaea* produce nitrogenases with iron as the only metal in the enzyme. Nitrogen-fixing *Archaea* appear limited to a few methane-producing species (methanogens), at least one of which can grow and fix N₂ at very high temperatures. The species *Methanosarcina barkeri*, a metabolically versatile methanogen (Section 16.2), contains genes encoding molybdenum and vanadium nitrogenases as well as an iron-only nitrogenase, and so it likely contains the full suite of nitrogenase proteins.

Nitrogen fixation is inhibited by oxygen (O₂) because dinitrogenase reductase is irreversibly inactivated by O₂. Nevertheless, many nitrogen-fixing bacteria are obligate aerobes. In these

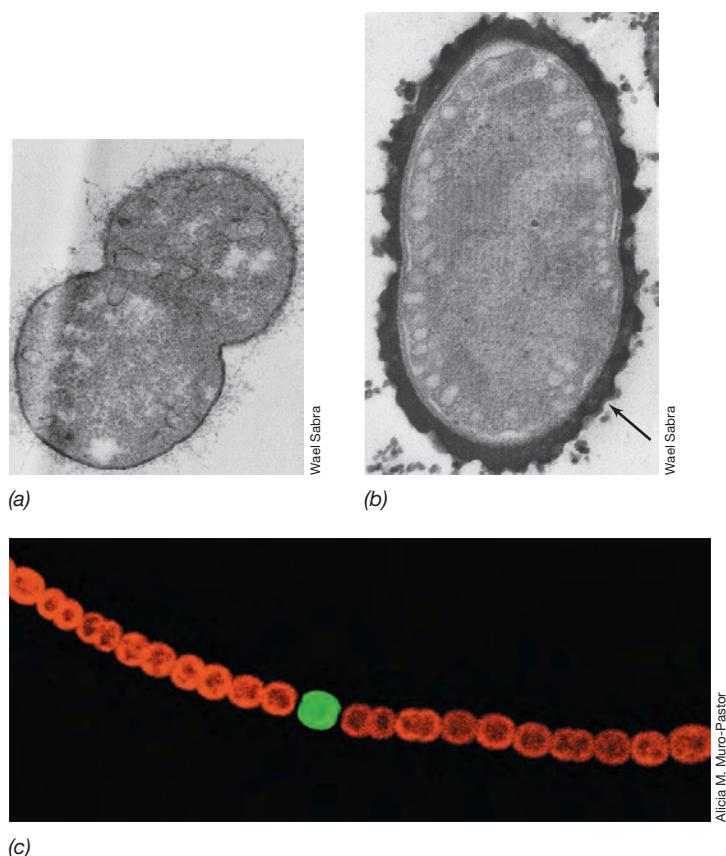

Figure 3.32 Protection of nitrogenase in *Azotobacter vinelandii* and in the cyanobacterium *Anabaena*. (a) Transmission electron micrograph of nitrogen-fixing cells of *A. vinelandii* grown with 2.5% O₂; very little slime is evident. (b) Cells grown in air (21% O₂). Note the extensive darkly staining slime layer (arrow). The slime retards diffusion of O₂ into the filament, thus preventing nitrogenase inactivation by O₂. (c) Fluorescence photomicrograph of a cell of the filamentous cyanobacterium *Anabaena* showing a single heterocyst (green). The heterocyst is a differentiated cell that specializes in nitrogen fixation and protects nitrogenase from O₂ inactivation.

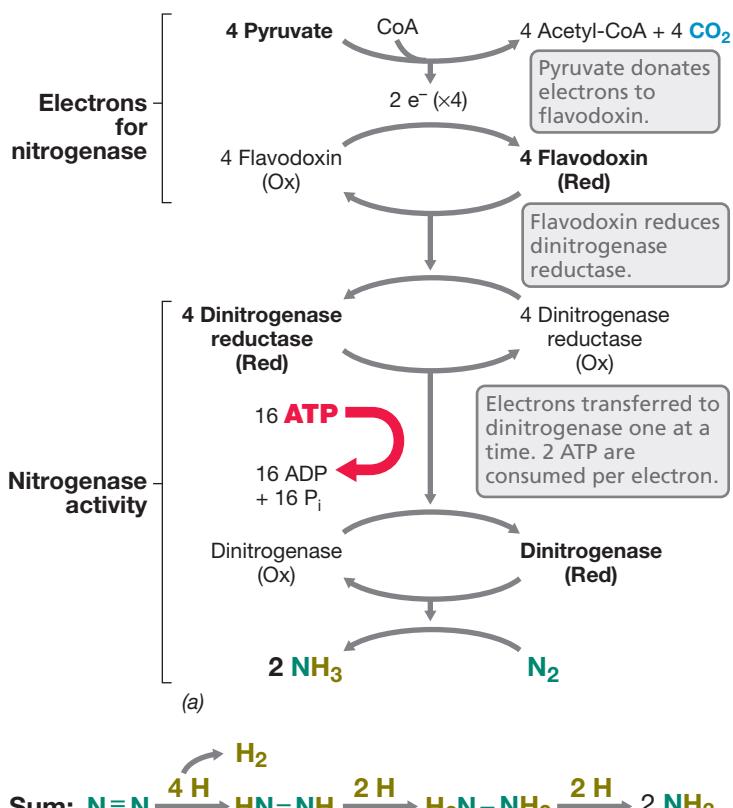

Figure 3.33 Biological nitrogen fixation by nitrogenase. The nitrogenase complex is composed of dinitrogenase and dinitrogenase reductase.

organisms, nitrogenase is protected from oxygen inactivation by a combination of the rapid removal of O₂ by respiration and the production of O₂-retarding slime layers (Figure 3.32a, b). In heterocystous cyanobacteria, nitrogenase is protected by its localization in a differentiated cell called a *heterocyst* (Figure 3.32c; Section 14.3). Inside the heterocyst, conditions are anoxic, while in neighboring vegetative cells, conditions are just the opposite because oxygenic photosynthesis is occurring. Oxygen production is shut down in the heterocyst, thus protecting it as a dedicated site for N₂ fixation.

Electron Flow in Nitrogen Fixation

Owing to the stability of the triple bond in N₂, its activation and reduction is very energy demanding. Six electrons are needed to reduce N₂ to NH₃, and the successive reduction steps occur directly on nitrogenase with no free intermediates accumulating (Figure 3.33). Although only six electrons are necessary to reduce N₂ to two NH₃, eight electrons are actually consumed in the process, two electrons being lost as H₂ for each mole of N₂ reduced. For unknown reasons, H₂ evolution is an obligatory step in nitrogen fixation and occurs in the first round of the nitrogenase reduction cycle. Following this, N₂ is reduced in successive steps and ammonia is the released product (Figure 3.33).

The sequence of electron transfer in nitrogenase is as follows: electron donor → dinitrogenase reductase → dinitrogenase → N₂. The electrons for N₂ reduction are transferred to dinitrogenase

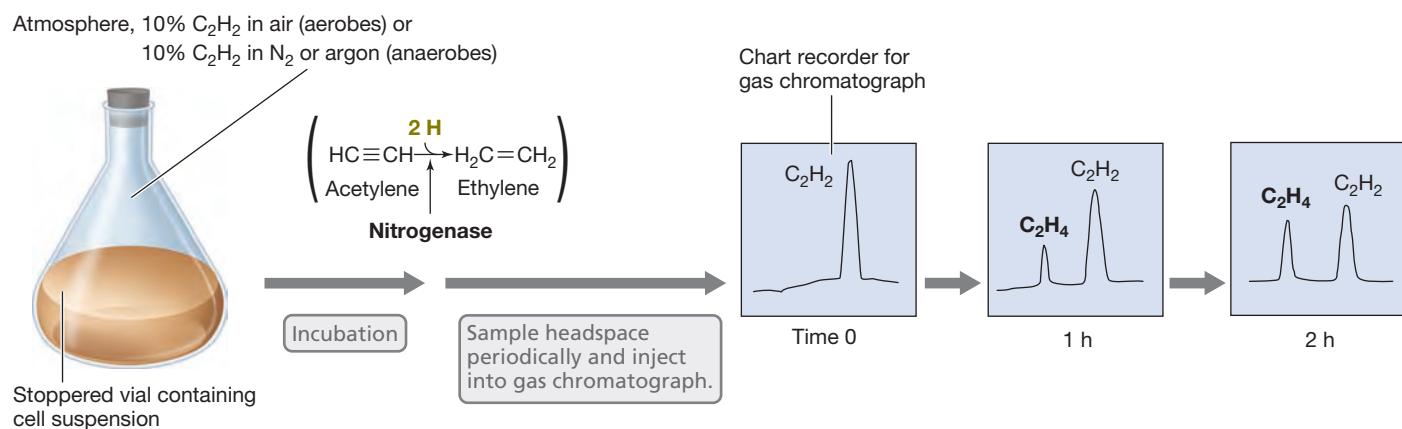

Figure 3.34 The acetylene reduction assay of nitrogenase activity in nitrogen-fixing bacteria. The results show no ethylene (C_2H_4) at time 0 but increasing production of C_2H_4 as the assay proceeds. As C_2H_4 is produced, a corresponding amount of C_2H_2 is consumed.

reductase from the low-potential iron–sulfur proteins ferredoxin or flavodoxin (Section 3.10); these proteins are reduced during the oxidation of pyruvate (Figure 3.33). In addition to electrons, ATP is required for nitrogen fixation. ATP binds to dinitrogenase reductase, and, following its hydrolysis to ADP, lowers the reduction potential of the protein. This allows dinitrogenase reductase to interact with and reduce dinitrogenase. Electrons are transferred from dinitrogenase reductase to dinitrogenase one at a time, and each cycle of reduction requires two ATP. Thus a total of 16 ATP are required for the reduction of N_2 to 2NH_3 (Figure 3.33).

Assaying Nitrogenase: Acetylene Reduction

Nitrogenases are not entirely specific for N_2 and also reduce other triply bonded compounds, such as acetylene ($\text{HC}\equiv\text{CH}$). The reduction of acetylene by nitrogenase is only a two-electron process, and *ethylene* ($\text{H}_2\text{C}=\text{CH}_2$) is the final product. However, the reduction of acetylene to ethylene provides a simple and rapid method for measuring nitrogenase activity (Figure 3.34). This technique, known as the *acetylene reduction assay*, is widely used in microbiology to detect and quantify nitrogen fixation.

Although the reduction of acetylene is taken as strong proof of N_2 fixation, definitive proof requires an isotope of nitrogen, $^{15}\text{N}_2$, as a tracer. If a culture or natural sample is enriched with $^{15}\text{N}_2$ and incubated, the production of $^{15}\text{NH}_3$ is firm evidence of nitrogen fixation. Nevertheless, acetylene reduction is a more rapid and sensitive method for measuring N_2 fixation and can easily be used in laboratory studies of pure cultures or ecological studies of nitrogen-fixing bacteria directly in their habitat. To do this, a sample, which may be soil, water, or a culture, is incubated in a vessel with $\text{HC}\equiv\text{CH}$, and the gas phase is later analyzed by gas chromatography for the presence of $\text{H}_2\text{C}=\text{CH}_2$ (Figure 3.34).

MINIQUIZ

- Write a balanced equation for the reaction catalyzed by nitrogenase.
- What is FeMo-co and what does it do?
- How is acetylene useful in studies of nitrogen fixation?

BIG IDEAS

3.1 • Cells are primarily composed of the elements H, O, C, N, P, and S. The compounds found in a cell are obtained from or formed from nutrients present in the environment. Nutrients required in large amounts are called macronutrients while those required in very small amounts, such as trace elements or growth factors, are micronutrients.

3.2 • Culture media supply the nutritional needs of microorganisms and are either defined or complex. Other media, such as selective, differential, and enriched media, are used for specific purposes. Many microorganisms can

be grown in liquid or solid culture media, and pure cultures can be maintained if aseptic technique is practiced.

3.3 • All microorganisms conserve energy from either the oxidation of chemicals or from light. Chemoorganotrophs use organic chemicals as their electron donors, while chemolithotrophs use inorganic chemicals. Phototrophic organisms convert light energy into chemical energy (ATP) and include both the oxygenic and anoxygenic phototrophs.

3.4 • Chemical reactions in the cell are accompanied by changes in energy, expressed in kilojoules. Reactions either release or consume free energy, or they are energy neutral. $\Delta G^{\circ\prime}$ is a measure of the energy released or consumed in a reaction under standard conditions and reveals which reactions can be used by an organism to conserve energy.

3.5 • Enzymes are protein catalysts that speed up the rate of biochemical reactions by activating the substrates that bind to their active site. Enzymes are highly specific in the reactions they catalyze, and this specificity resides in the three-dimensional structures of the polypeptides that make up the proteins.

3.6 • Oxidation–reduction reactions require electron donors and electron acceptors. The tendency of a compound to accept or release electrons is expressed by its reduction potential (E_0'). Redox reactions in a cell employ intermediaries such as NAD⁺/NADH as electron shuttles.

3.7 • The energy released in redox reactions is conserved in compounds that contain energy-rich phosphate or sulfur bonds. The most common of these compounds is ATP, the prime energy carrier in the cell. Longer-term storage of energy is linked to the formation of polymers, which can be consumed to yield ATP.

3.8 • The glycolytic pathway is used to break glucose down to pyruvate and is a widespread mechanism for energy conservation by fermentative anaerobes. The pathway releases only a small amount of ATP and generates fermentation products (ethanol, lactic acid, and so on) characteristic of the organism. For each glucose fermented by yeast in glycolysis, 2 ATP are produced.

3.9 • Many different fermentations of glucose use the glycolytic pathway, the differences lying in the nature of the fermentation products. Extra ATP can be obtained from glucose fermentation if fatty acids derived from coenzyme-A derivatives are fermentation products. Yeast has two options for glucose catabolism: fermentation and respiration.

3.10 • Electron transport chains are composed of membrane-associated proteins that are arranged in order of their increasing E_0' values and function in an integrated

fashion to carry electrons from the primary electron donor to the terminal electron acceptor (O_2 in aerobic respiration).

3.11 • When electrons are transported through an electron transport chain, protons are extruded to the outside of the membrane, forming the proton motive force. Key electron carriers include flavins, quinones, the cytochrome bc_1 complex, and other cytochromes. The cell uses the proton motive force to make ATP through the activity of ATPase.

3.12 • Respiration offers an energy yield much greater than that of fermentation. The citric acid cycle generates CO_2 and electrons for the electron transport chain and is also a source of biosynthetic intermediates. The glyoxylate cycle is necessary for the catabolism of two-carbon electron donors, such as acetate.

3.13 • When conditions are anoxic, several terminal electron acceptors can substitute for O_2 in anaerobic respiration. Chemolithotrophs use inorganic compounds as electron donors, whereas phototrophs use light energy. The proton motive force supports energy generation by ATPase in all forms of respiration and photosynthesis.

3.14 • Polysaccharides are important structural components of cells and are biosynthesized from activated forms of their monomers. Gluconeogenesis is the production of glucose from nonsugar precursors.

3.15 • Amino acids are formed from carbon skeletons to which ammonia is added from either glutamate, glutamine, or a few other amino acids. Nucleotides are biosynthesized using carbon from several different sources.

3.16 • Fatty acids are synthesized from the three-carbon precursor malonyl-ACP and fully formed fatty acids are attached to glycerol to form lipids. Only the lipids of *Bacteria* and *Eukarya* contain fatty acids, typically C₁₂–C₁₈ in length.

3.17 • The reduction of N_2 to NH_3 is called nitrogen fixation and is catalyzed by the enzyme nitrogenase. Nitrogenase is composed of two proteins, dinitrogenase and dinitrogenase reductase. Nitrogenase can be assayed using the triply bonded compound acetylene as a surrogate of N_2 , which nitrogenase reduces to ethylene.

REVIEW OF KEY TERMS

Activation energy the energy required to bring the substrate of an enzyme to the reactive state	Coenzyme a small and loosely bound nonprotein molecule that participates in a reaction as part of an enzyme	Nitrogenase the enzyme complex required to reduce N ₂ to NH ₃ in biological nitrogen fixation.
Adenosine triphosphate (ATP) a nucleotide that is the primary form in which chemical energy is conserved and utilized in cells	Complex medium a culture medium composed of chemically undefined substances such as yeast and meat extracts	Nitrogen fixation the reduction of N ₂ to NH ₃ by the enzyme nitrogenase
Anabolic reactions (Anabolism) the sum total of all biosynthetic reactions in the cell	Culture medium an aqueous solution of various nutrients suitable for the growth of microorganisms	Oxidative phosphorylation the production of ATP from a proton motive force formed by electron transport of electrons from organic or inorganic electron donors
Anaerobic respiration a form of respiration in which oxygen is absent and alternative electron acceptors are reduced	Defined medium a culture medium whose precise chemical composition is known	Pentose phosphate pathway a series of reactions in which pentoses are catabolized to generate precursors for nucleotide biosynthesis or to synthesize glucose
Aseptic technique manipulations to prevent contamination of sterile objects or microbial cultures during handling	Electron acceptor a substance that can accept electrons from an electron donor, becoming reduced in the process	Photophosphorylation the production of ATP from a proton motive force formed from light-driven electron transport
ATPase (ATP synthase) a multiprotein enzyme complex embedded in the cytoplasmic membrane that catalyzes the synthesis of ATP coupled to dissipation of the proton motive force	Electron donor a substance that can donate electrons to an electron acceptor, becoming oxidized in the process	Phototrophs organisms that use light as their source of energy
Autotroph an organism capable of biosynthesizing all cell material from CO ₂ as the sole carbon source	Endergonic requires energy	Proton motive force (pmf) a source of energy resulting from the separation of protons from hydroxyl ions across the cytoplasmic membrane, generating a membrane potential
Catabolic reactions (Catabolism) biochemical reactions leading to energy conservation (usually as ATP) by the cell	Enzyme a protein that can speed up (catalyze) a specific chemical reaction	Reduction potential (E₀) the inherent tendency, measured in volts under standard conditions, of a compound to donate electrons
Catalyst a substance that accelerates a chemical reaction but is not consumed in the reaction	Exergonic releases energy	Respiration the process in which a compound is oxidized with O ₂ (or an O ₂ substitute) as the terminal electron acceptor, usually accompanied by ATP production by oxidative phosphorylation
Chemolithotroph an organism that can grow with inorganic compounds as electron donors in energy metabolism	Fermentation anaerobic catabolism in which an organic compound is both an electron donor and an electron acceptor and ATP is produced by substrate-level phosphorylation	Substrate-level phosphorylation the production of ATP by the direct transfer of an energy-rich phosphate molecule from a phosphorylated organic compound to ADP
Chemoorganotroph an organism that obtains its energy from the oxidation of organic compounds	Free energy (G) energy available to do work; G ^{0'} is free energy under standard conditions	
Citric acid cycle a cyclical series of reactions resulting in the conversion of acetate to two molecules of CO ₂	Glycolysis a biochemical pathway in which glucose is fermented, yielding ATP and various fermentation products; also called the Embden–Meyerhof–Parnas pathway	
	Glyoxylate cycle a modification of the citric acid cycle in which isocitrate is cleaved to form succinate and glyoxylate during growth on two-carbon electron donors such as acetate	
	Heterotroph an organism that uses organic compounds as a carbon source	

REVIEW QUESTIONS

- Why are carbon and nitrogen macronutrients but cobalt is a micronutrient? (Section 3.1)
- Why would the following medium not be considered a chemically defined medium: glucose, 5 grams (g); NH₄Cl, 1 g; KH₂PO₄, 1 g; MgSO₄, 0.3 g; yeast extract, 5 g; distilled water, 1 liter? (Section 3.2)
- What is aseptic technique and why is it necessary? (Section 3.2)
- To which energy class does *Escherichia coli* belong? *Thiobacillus thioparus*? How do the contents of Table 3.2 tell you this? (Section 3.3)
- Describe how you would calculate ΔG^{0'} for the reaction: glucose + 6 O₂ → 6 CO₂ + 6 H₂O. If you were told that this reaction is highly *exergonic*, what would be the arithmetic sign (negative or positive) of the ΔG^{0'} you would expect for this reaction? (Section 3.4)
- Distinguish between ΔG^{0'}, ΔG, and G_f⁰. (Section 3.4)
- Why are enzymes needed by the cell? (Section 3.5)
- The following is a series of coupled electron donors and electron acceptors (written as donor/acceptor). Using just the data in Figure 3.9, order this series from most energy yielding to least energy yielding: H₂/Fe³⁺, H₂S/O₂, methanol/NO₃⁻ (producing NO₂⁻), H₂/O₂, Fe²⁺/O₂, NO₂⁻/Fe³⁺, and H₂S/NO₃⁻. (Section 3.6)
- What is the reduction potential of the NAD⁺/NADH couple? (Section 3.6)
- Why is acetyl phosphate considered an energy-rich compound but glucose 6-phosphate is not? (Section 3.7)
- How is ATP made in fermentation and in respiration? (Section 3.8)

12. Where in glycolysis is NADH produced? Where is NADH consumed? (Section 3.8)
13. Besides lactic acid and ethanol, list some other fermentation products that can be produced when glucose is fermented through glycolysis. (Section 3.9)
14. List some of the important electron carriers found in electron transport chains. (Section 3.10)
15. What is meant by proton motive force and how is it generated? (Section 3.11)
16. How is rotational energy in the ATPase used to produce ATP? (Section 3.11)
17. How much more ATP is possible in respiration than in fermentation? Write one sentence that accounts for this difference. (Section 3.12)
18. Why can it be said that the citric acid cycle plays two major roles in the cell? (Section 3.12)
19. What is the major difference between respiration and anaerobic respiration? Which metabolic option would yield more energy, and why? (Section 3.13)
20. Which two major catabolic pathways supply carbon skeletons for sugar and amino acid biosyntheses? (Sections 3.14 and 3.15)
21. Describe the process by which a fatty acid such as palmitate (a C₁₆ straight-chain saturated fatty acid) is synthesized in a cell. (Section 3.16)
22. What is the reaction carried out by the enzyme nitrogenase? How might the ability to fix nitrogen help a bacterium be more competitive in its environment? (Section 3.17)

APPLICATION QUESTIONS

1. Design a defined culture medium for an organism that can grow aerobically on acetate as a carbon and energy source. Make sure all the nutrient needs of the organism are accounted for and in the correct relative proportions.
2. *Desulfovibrio* can grow anaerobically with H₂ as electron donor and SO₄²⁻ as electron acceptor (which is reduced to H₂S). Based on this information and the data in Table A1.2 (Appendix 1), indicate which of the following components could not exist in the electron transport chain of this organism and why: cytochrome *c*, ubiquinone, cytochrome *c*₃, cytochrome *aa*₃, ferredoxin.
3. Again using the data in Table A1.2, predict the sequence of electron carriers in the membrane of an organism growing aerobically and producing the following electron carriers: ubiquinone, cytochrome *aa*₃, cytochrome *b*, NADH, cytochrome *c*, FAD.
4. Explain the following observation in light of the redox tower: Cells of *Escherichia coli* fermenting glucose grow faster when NO₃⁻ is supplied to the culture (NO₂⁻ is produced) and then grow even faster (and stop producing NO₂⁻) when the culture is highly aerated.

The Essence of Life: Molecular Microbiology

As you have no doubt discovered, microorganisms possess an astounding range of metabolic capabilities. The genetic blueprint of individual cells is responsible for the distinctive attributes observed for all life forms. While this repository of information must be protected and passed on from generation to generation, the information must also “come alive” to allow cells to perform an ingenious array of fascinating activities. This flow of essential biological information—from fairly inert DNA to the synthesis of proteins and enzymes critical for cellular survival—is known as the central dogma of life.

Molecular microbiology has been the cornerstone for understanding the individual steps of the central dogma: DNA replication, transcription of DNA into RNA, and translation of RNA into proteins. With the advent of cutting-edge techniques, new discoveries regarding these essential biological processes are still occurring. For example, microbiologists can now pinpoint the location of specific molecules in living cells using fluorescent labels and super-resolution fluorescence microscopy. The photo here illustrates the use of fluorescence microscopy and protein tagging in actively growing *Escherichia coli* cells to actually visualize RNA polymerases and ribosomes, two cellular machines essential to the central dogma, in action. The resulting image shows that the majority of ribosomes, the “protein factories,” are located at the ends of the cell and in regions where septa form during cell division (top photo, in green), while RNA polymerases are associated with the chromosomal DNA in the nucleoid region, which is localized in the center of the cell (middle photo, in red). Overlapping the two images (bottom photo) allows us to see that spatial organization of biological information flow does indeed exist in bacterial cells, despite their lacking organelles.

Bakshi, S., A. Siryaporn, M. Goulian, and J. C. Weisshaar. 2012. Superresolution imaging of ribosomes and RNA polymerase in live *Escherichia coli* cells. *Molecular Microbiology* 85: 21–38.

- II **Transmission of Genetic Information: DNA Replication 115**
- III **RNA Synthesis: Transcription 120**
- IV **Protein Synthesis 127**

Central to life is the flow of information. What instructs the cell to reproduce itself and survive in a given environment and what are the processes that dictate the output of cells? Cells can be considered both chemical machines and coding devices. As chemical machines, cells transform their vast array of macromolecules into new cells. As coding devices, they store, process, and use genetic information. Genes, the mechanisms by which they are transferred to new cells, and their expression are the foundation

of molecular biology and the central dogma of life. This chapter highlights the genetic blueprint of cells and the steps the cell takes to transform this information into macromolecules that carry out cellular functions. Our focus here is on these processes as they occur in *Bacteria*, particularly in *Escherichia coli*, a species of *Bacteria* that is the model organism for molecular biology. This bacterium remains the best characterized of any organism, prokaryote or eukaryote.

I • The Blueprint of Life: Structure of the Bacterial Genome

4.1 Macromolecules and Genes

The functional unit of genetic information is the **gene**. All life forms, including microorganisms, contain genes. Physically, genes are located on chromosomes or other large molecules known collectively as **genetic elements**. These elements make up the total complement of genetic information, or the **genome**, in a cell or virus. In modern biology, cells can be characterized in terms of their complement of genes. Thus, if we wish to understand how microorganisms function we must understand how genes encode information.

Genetic information in cells is embedded in the **nucleic acids**. DNA and RNA. **Deoxyribonucleic acid**, DNA, carries the genetic blueprint for the cell while **ribonucleic acid**, RNA, is an intermediary molecule that converts this blueprint into defined amino acid sequences in proteins. Genetic information resides in the sequence of monomers in the nucleic acids. Thus, in contrast to polysaccharides and lipids that are typically composed of long repeating units, nucleic acids are **informational macromolecules**. Because the sequence of monomers in proteins is determined by the sequence of the nucleic acids that encode them, proteins are also informational macromolecules.

The monomers of nucleic acids are called **nucleotides**, consequently, DNA and RNA are **polynucleotides**. A nucleotide has three components: a pentose sugar (either ribose in RNA or deoxyribose in DNA), a nitrogen base, and a molecule of phosphate, PO_4^{3-} . The general structures of nucleotides of both DNA and RNA are very similar (Figure 4.1). The nitrogen bases are either **purines** (*adenine* and *guanine*), which contain two fused heterocyclic rings, or **pyrimidines** (*thymine*, *cytosine*, and *uracil*), which contain a single six-membered heterocyclic ring (Figure 4.1a). Guanine, adenine, and cytosine are present in both DNA and RNA. With minor exceptions, thymine is present only in DNA and uracil is present only in RNA.

The nitrogen bases are attached to the pentose sugar by a glycosidic linkage between carbon atom 1 of the sugar and a nitrogen atom in the base, either nitrogen 1 (in pyrimidine bases) or 9 (in purine bases). A nitrogen base attached to its sugar, but lacking phosphate, is called a **nucleoside**. Nucleotides are nucleosides plus one or more phosphates (Figure 4.1b). Nucleotides play other roles in addition to their role in nucleic acids. Nucleotides, especially adenosine triphosphate (ATP) and guanosine triphosphate (GTP), are important molecules in energy conservation (➡ Section 3.7). Other nucleotides or derivatives function in redox reactions, as carriers of sugars in polysaccharide synthesis, or as regulatory molecules.

The Nucleic Acids: DNA and RNA

The nucleic acid backbone is a polymer of alternating sugar and phosphate molecules. The nucleotides are covalently bonded by

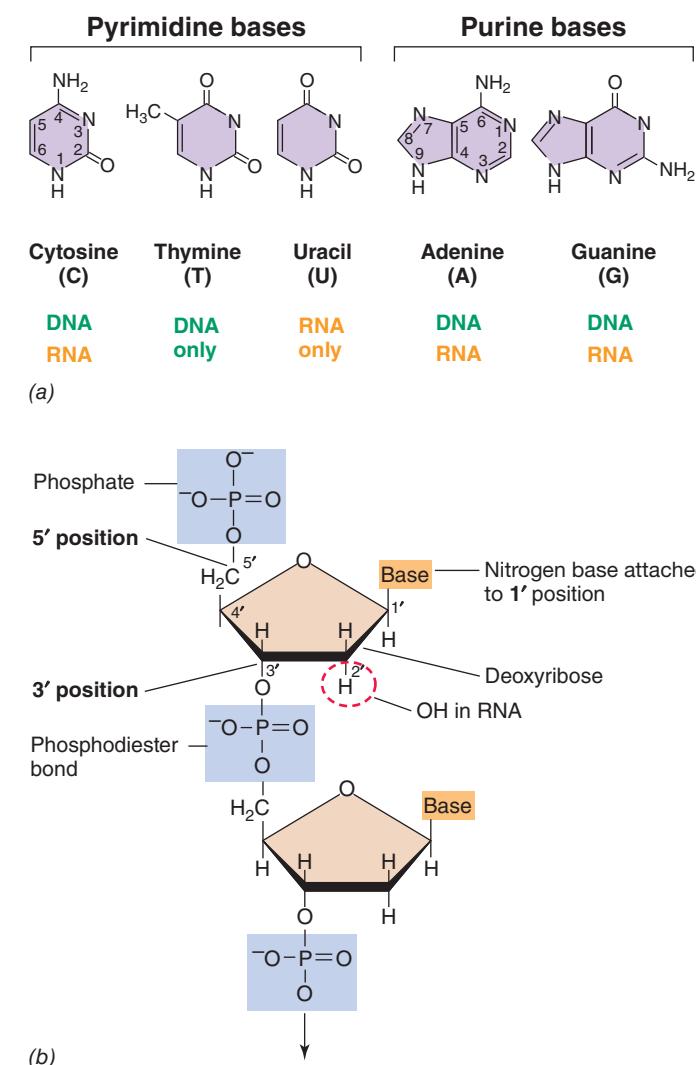

Figure 4.1 Components of the nucleic acids. (a) The nitrogen bases of DNA and RNA. Note the numbering system of the rings. In attaching itself to the 1' carbon of the sugar phosphate, a pyrimidine base bonds through N-1 and a purine base bonds at N-9. (b) Part of a DNA chain. The numbers on the sugar of the nucleotide contain a prime ('') after them because the rings of the nitrogen bases are also numbered. In DNA, a hydrogen is present on the 2'-carbon of the pentose sugar. In RNA, an OH group occupies this position. The nucleotides are linked by a phosphodiester bond.

phosphate between the 3'- (3 prime) carbon of one sugar and the 5'-carbon of the next sugar. (Numbers with prime marks refer to positions on the sugar ring; numbers without primes to positions on the rings of the bases.) The phosphate linkage is called a **phosphodiester bond** because the phosphate connects two sugar molecules by an ester linkage (Figure 4.1b). The sequence of nucleotides in a DNA or RNA molecule is its **primary structure** and the sequence of bases constitutes the genetic information.

In the genome of cells, DNA is *double-stranded*. Each chromosome consists of two strands of DNA, with each strand containing hundreds of thousands to several million nucleotides linked by phosphodiester bonds. The strands are held together by hydrogen bonds that form between the bases in one strand and those of the other strand. When located adjacent to one another, purine and pyrimidine bases can form hydrogen bonds (Figure 4.2). Hydrogen bonding is most thermodynamically stable when guanine (G) bonds with cytosine (C) and adenine (A) bonds with thymine (T). Specific base pairing, A with T and G with C, ensures that the two strands of DNA are *complementary* in base sequence; that is, wherever a G is found in one strand, a C is found in the other, and wherever a T is present in one strand, its complementary strand contains an A.

Genes and the Steps in Information Flow

When genes are expressed, the genetic information stored in DNA is transferred to ribonucleic acid (RNA). While several classes of RNA exist in cells, three main types of RNA take part in protein synthesis. **Messenger RNA (mRNA)** is a single-stranded molecule that carries the genetic information from DNA to the ribosome, the protein-synthesizing machine. **Transfer RNAs (tRNAs)** convert the genetic information in the nucleotide sequences of RNA into a defined sequence of amino acids in proteins. **Ribosomal**

RNAs (rRNAs) are important catalytic and structural components of the ribosome. The molecular processes of genetic information flow can be divided into three stages (Figure 4.3):

- 1. Replication.** During replication, the DNA double helix is duplicated, producing two copies. Replication is carried out by an enzyme called *DNA polymerase*.
- 2. Transcription.** The transfer of genetic information from DNA to RNA is called transcription. Transcription is carried out by an enzyme called *RNA polymerase*.
- 3. Translation.** Synthesis of a protein, using the genetic information in mRNA, is called translation.

The three steps shown in Figure 4.3 are characteristic of all cells and form the central dogma of molecular biology: DNA → RNA → protein. Many different RNA molecules can be transcribed from a relatively short region of the long DNA molecule. In eukaryotes, each gene is transcribed to yield a single mRNA, whereas in prokaryotes, a single mRNA molecule may carry the genetic information from several genes; that is, several protein-coding regions. A linear correspondence exists between the base sequence of a gene and the amino acid sequence of a polypeptide. Each group of three bases on an mRNA molecule encodes a single amino acid, and each such triplet of bases is called a **codon**. Codons are translated into sequences of amino acids by ribosomes (which themselves consist of proteins and RNA), tRNA, and helper proteins called *translation factors*. While the central dogma is invariant in cells, we will see later that some viruses (which are not cells, [Section 1.2](#)) violate this process in interesting ways (Chapters 8 and 9).

MINIQUIZ

- What is a genome?
- What components are found in a nucleotide? How does a nucleoside differ from a nucleotide?
- What three informational macromolecules are involved in genetic information flow?
- In all cells there are three processes involved in genetic information flow. What are they?

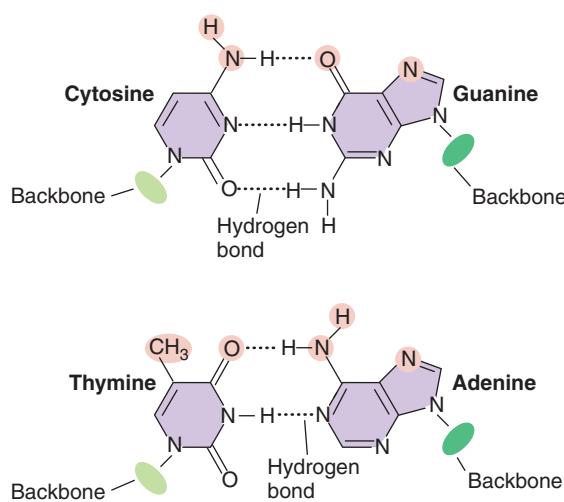

Figure 4.2 Specific pairing between guanine (G) and cytosine (C) and between adenine (A) and thymine (T) via hydrogen bonds. These are the typical base pairs found in double-stranded DNA. Atoms that are found in the major groove of the double helix and that interact with proteins are highlighted in pink. The deoxyribose phosphate backbones of the two strands of DNA are also indicated. Note the different shades of green for the two strands of DNA, a convention used throughout this book.

4.2 The Double Helix

In all cells DNA exists as a double-stranded molecule with two polynucleotide strands whose base sequences are **complementary**. The complementarity of DNA arises because of specific base pairing by hydrogen bonds: adenine always pairs with thymine, and guanine always pairs with cytosine. Each adenine–thymine base pair has *two* hydrogen bonds, while each guanine–cytosine base pair has *three*. This makes GC pairs stronger than AT pairs. The two strands of the double-stranded DNA molecule are arranged in an **antiparallel** fashion (Figure 4.4; DNA strands appear throughout in two shades of green). Thus, the strand on the left runs 5' to 3' from top to bottom, whereas the complementary strand runs 5' to 3' from bottom to top. Although individual hydrogen bonds are very weak, the large number of such bonds between the base pairs of a long DNA molecule confers considerable stability on the molecule, sufficient to hold the two strands together.

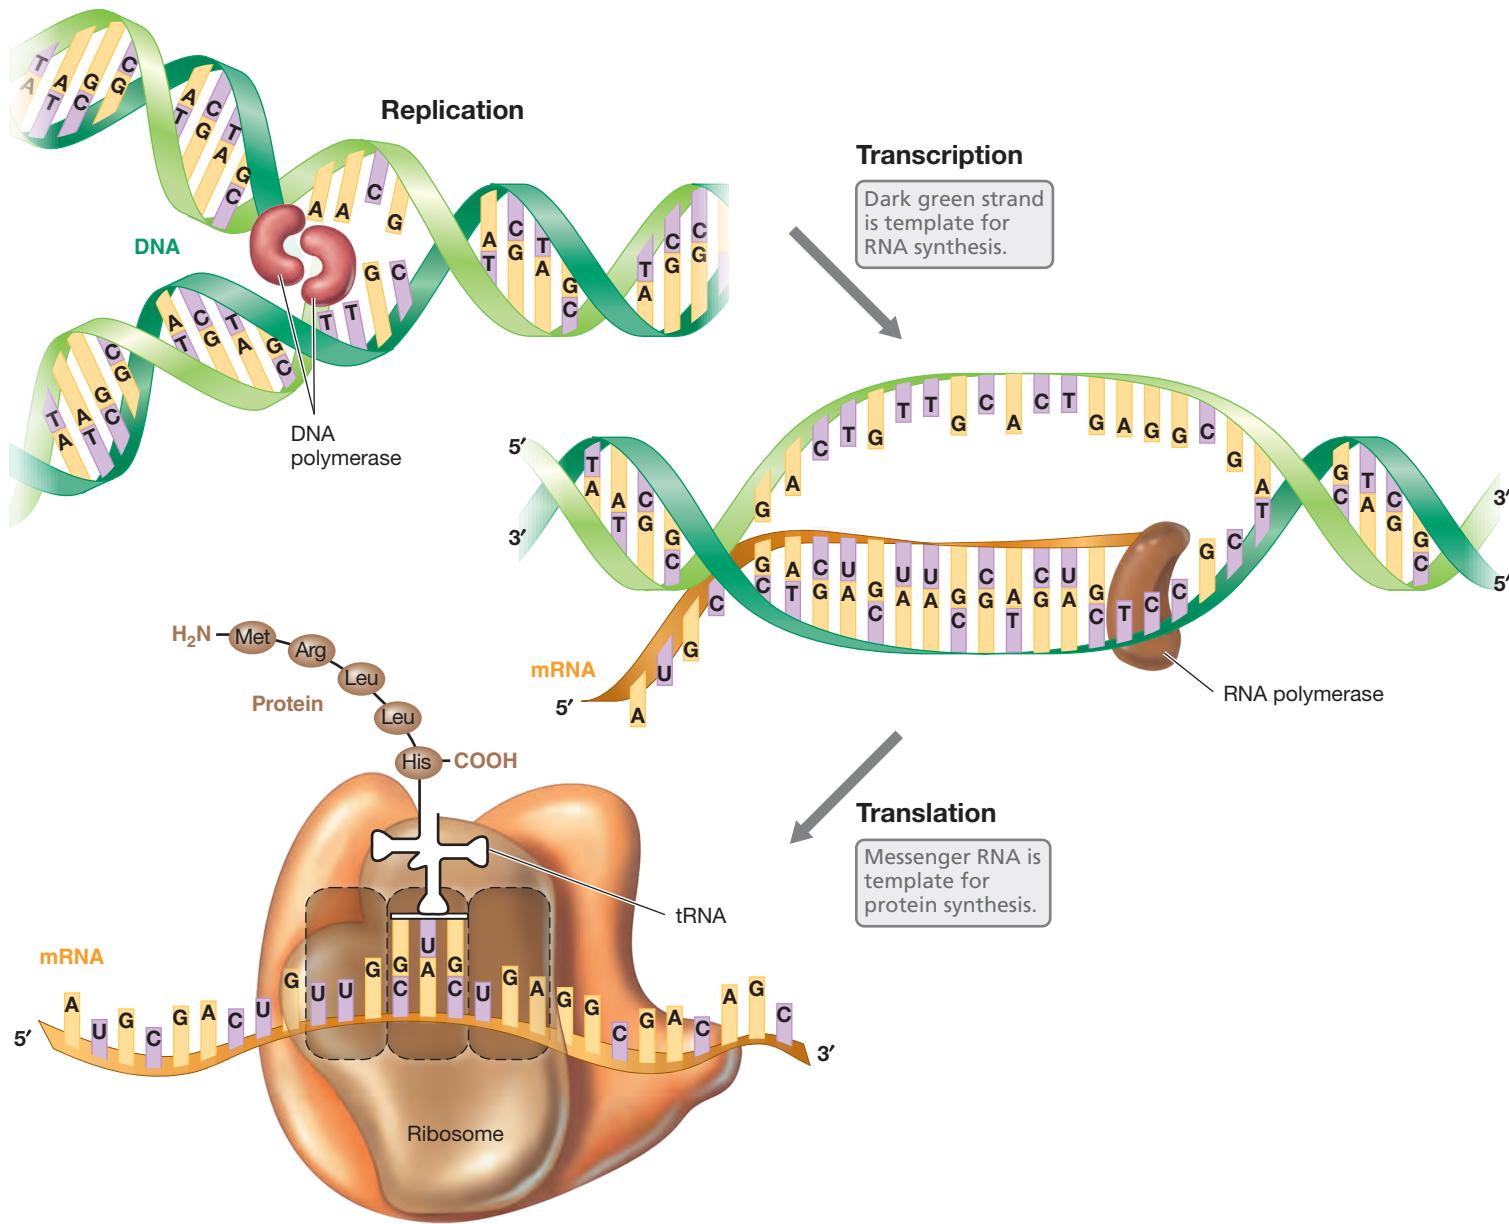

Figure 4.3 Synthesis of the three types of informational macromolecules. Note that for any particular gene only one of the two strands of the DNA double helix is transcribed.

The two strands of DNA are wrapped around each other to form a double helix (Figure 4.5). The helix forms two distinct grooves, the *major groove* and the *minor groove*. Most proteins that interact specifically with DNA bind in the major groove, where there is plenty of space. Because the double helix is a regular structure, some atoms of each base are always exposed in the major groove (and some in the minor groove). Key regions of nucleotides that are important in interactions with proteins are shown in Figure 4.2.

Size and Shape of DNA Molecules

The size of a DNA molecule is expressed as the number of nucleotide bases or base pairs per molecule. Thus, a DNA molecule with 1000 bases is 1 kilobase (kb) of DNA. If the DNA is a double helix, then *kilobase pairs* (kbp) is used. Thus, a double helix 5000 base pairs in size would be 5 kbp. The bacterium *Escherichia coli* has

about 4640 kbp of DNA in its chromosome. When dealing with large genomes, the term *megabase pair* (Mbp) for a million base pairs is used. The genome of *E. coli* is thus 4.64 Mbp.

Each base pair is 0.34 nanometer (nm) in length along the double helix, and each turn of the helix contains approximately 10 base pairs. Therefore, 1 kbp of DNA is 0.34 μm long with 100 helical turns. The *E. coli* genome is thus $4640 \times 0.34 \mu\text{m} = 1.58 \text{ mm}$ long. Since cells of *E. coli* are about 2 μm long, the chromosome is several hundred times longer than the cell itself!

Supercoiling of DNA

Considering the above calculations, how is it possible to pack so much DNA into such a tiny space? The solution is the imposition of a “higher-order” structure on the DNA, in which the double-stranded DNA is further twisted in a process called *supercoiling*.

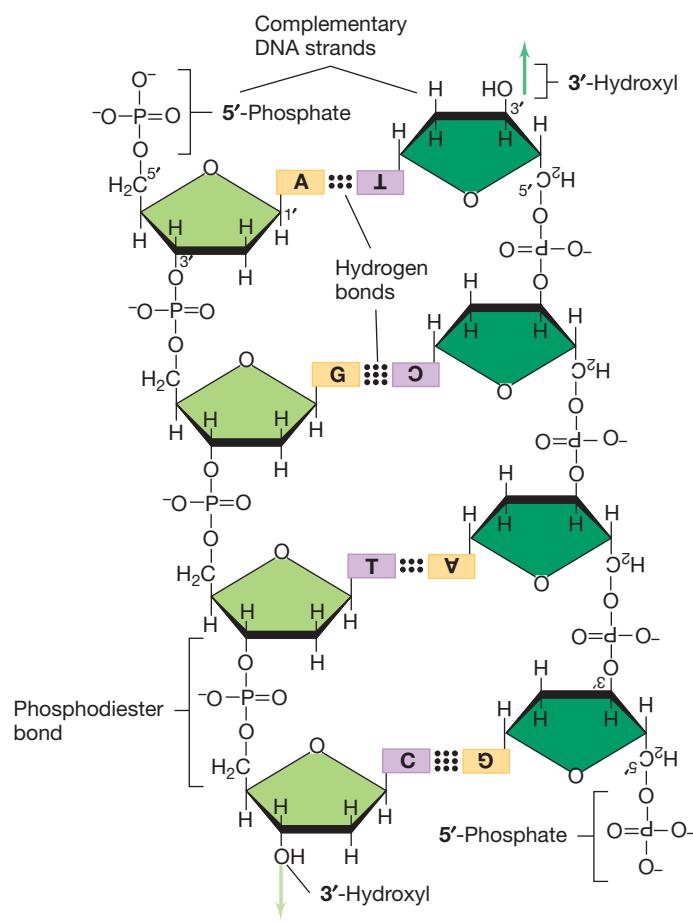

Figure 4.4 **DNA structure.** Complementary and antiparallel nature of DNA. Note that one chain ends in a 5'-phosphate group, whereas the other ends in a 3'-hydroxyl. The purple bases represent the pyrimidines cytosine (C) and thymine (T), and the yellow bases represent the purines adenine (A) and guanine (G).

Figure 4.6 shows how supercoiling occurs in a circular DNA molecule. If a circular DNA molecule is linearized, any supercoiling is lost and the DNA becomes “relaxed.” When relaxed, a DNA molecule has exactly the number of turns of the helix predicted from the number of base pairs.

Supercoils are inserted or removed in DNA by enzymes called *topoisomerases*. The activity of supercoiling puts the DNA molecule under torsion, much like the tension added to a rubber band when it is twisted. DNA can be supercoiled in either a positive or a negative manner. In positive supercoiling the double helix is overwound (contains more than the natural number of turns), whereas in negative supercoiling the double helix is underwound (contains fewer than the natural number of turns). Negative supercoiling results when the DNA is twisted about its axis in the opposite sense from the right-handed double helix. Negatively supercoiled DNA is the form predominantly found in nature. In the *Escherichia coli* chromosome, more than 100 supercoiled domains are thought to exist, each stabilized by specific proteins bound to the DNA. Inserting supercoils into DNA requires energy from ATP, whereas releasing supercoils does not. In *Bacteria* and most *Archaea*, **DNA gyrase** is a type II topoisomerase that inserts negative supercoils into DNA by making double-strand

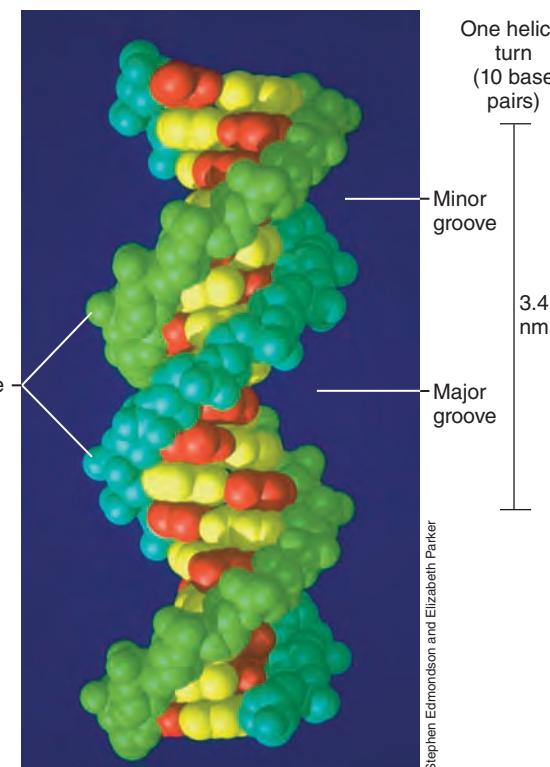

Figure 4.5 A computer model of a short segment of DNA showing the overall arrangement of the double helix. One of the sugar–phosphate backbones is shown in blue and the other in green. The pyrimidine bases are shown in red and the purines in yellow. Note the locations of the major and minor grooves (compare with Figure 4.2). One helical turn contains 10 base pairs.

breaks (Figure 4.7). We will see later that *Archaea* that live at very high temperatures have chromosomes that are positively supercoiled and this feature helps to maintain DNA structure at such temperatures (► Section 16.13). Some antibiotics inhibit the activity of DNA gyrase. These include the quinolones (such as nalidixic acid), the fluoroquinolones (such as ciprofloxacin), and novobiocin.

MINIQUIZ

- What does antiparallel mean in terms of the structure of double-stranded DNA?
- Define the term complementary when used to refer to two strands of DNA.
- What makes GC pairs stronger than AT pairs?
- Why is supercoiling important? What enzyme facilitates supercoiling?

4.3 Genetic Elements: Chromosomes and Plasmids

Structures containing genetic material (DNA in most organisms, but RNA in some viruses) are called *genetic elements*. The main genetic element in prokaryotes is the **chromosome**. Other genetic elements may be found and play important roles in gene function

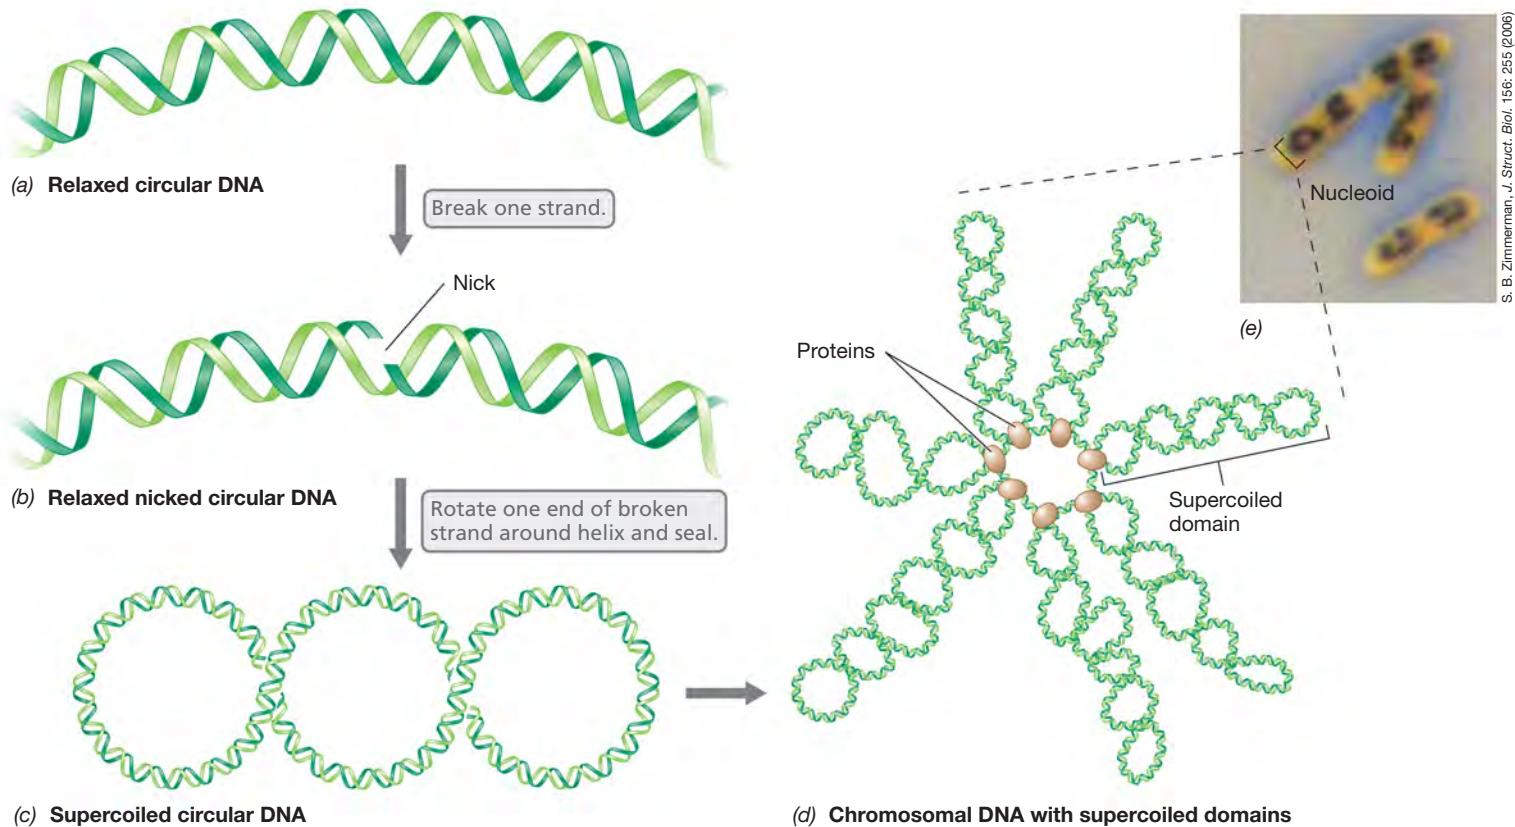

Figure 4.6 Supercoiled DNA. (a–c) Relaxed, nicked, and supercoiled circular DNA. A nick is a break in a phosphodiester bond of one strand. (d) In fact, the double-stranded DNA in the bacterial chromosome is arranged not in one supercoil but in several supercoiled domains, as shown here. (e) Simultaneous phase-contrast and fluorescence image of *E. coli* illustrating the location of the nucleoid within growing cells. Cells were treated with a fluorescent dye specific for DNA and the color was inverted to show the nucleoids as black.

in both prokaryotes and eukaryotes (Table 4.1). These include *virus genomes*, *plasmids*, *organellar genomes*, and *transposable elements*. A typical prokaryote has a single circular DNA chromosome containing all (or most) of the genes found inside the cell. Although a single chromosome is the rule among prokaryotes,

there are exceptions. A few prokaryotes contain two or even three chromosomes. Eukaryotic genomes have multiple chromosomes. Also, the DNA in all known eukaryotic chromosomes is linear in contrast to most prokaryotic chromosomes, which are circular DNA molecules.

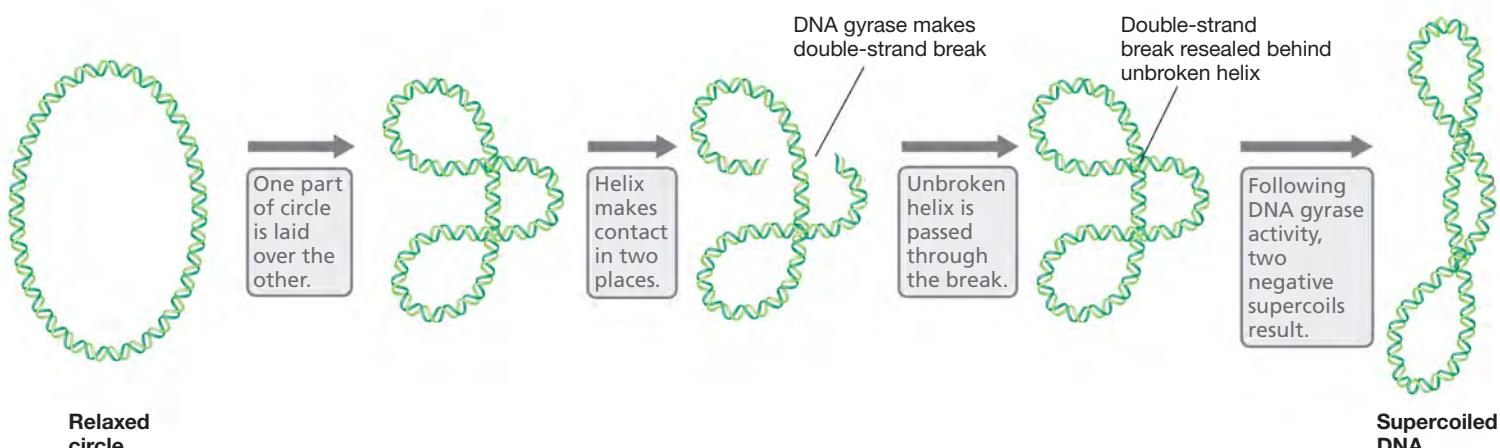

Figure 4.7 DNA gyrase. Introduction of negative supercoiling into circular DNA by the activity of DNA gyrase (topoisomerase II), which makes double-strand breaks.

Table 4.1 Kinds of genetic elements

Organism	Element	Type of nucleic acid	Description
Prokaryote	Chromosome	Double-stranded DNA	Extremely long, usually circular
Eukaryote	Chromosome	Double-stranded DNA	Extremely long, linear
All organisms	Plasmid ^a	Double-stranded DNA	Relatively short circular or linear, extrachromosomal
All organisms	Transposable element	Double-stranded DNA	Always found inserted into another DNA molecule
Mitochondrion or chloroplast	Organellar genome	Double-stranded DNA	Medium length, usually circular
Virus	Virus genome	Single- or double-stranded DNA or RNA	Relatively short, circular or linear

^aPlasmids are uncommon in eukaryotes.

Although considered microorganisms, viruses are not cells, but instead depend on cells for their replication. Nevertheless, viruses contain genomes, of either DNA or RNA, that control their replication and transfer from cell to cell. Both linear and circular viral genomes are known. In addition, the nucleic acid in viral genomes may be single-stranded or double-stranded. **Plasmids** are genetic elements that replicate separately from the chromosome. The great majority of plasmids are double-stranded DNA, and although most plasmids are circular, some are linear. Plasmids are typically much smaller than chromosomes. **Transposable elements** are segments of DNA that can move from one site on a DNA molecule to another, either on the same molecule or on a different DNA molecule. Transposable elements do not exist as separate molecules of DNA but instead are always found inserted into other DNA molecules. Chromosomes, plasmids, virus genomes, and any other type of DNA molecule may act as a host for a transposable element. Transposable elements are found in both prokaryotes and eukaryotes and play important roles in genetic variation (☞ Section 10.11).

Arrangement of Genes on the *Escherichia coli* Chromosome

Many bacterial genomes including that of *Escherichia coli* have been completely sequenced, thus revealing the number and location of the genes they possess. The strain of *E. coli* whose chromosome was originally sequenced, strain MG1655, is a derivative of *E. coli* K-12, the traditional strain used for genetics. A corresponding genetic map of the 4,639,675 bp chromosome is presented in Figure 4.8, with only a few of the several thousand genes in the *E. coli* chromosome depicted. Map distances are given in 100 kilobase pairs of DNA. Genomic analysis has revealed 4288 possible protein-encoding genes that account for 88% of the *E. coli* genome. Approximately 1% of the genome are genes encoding tRNAs and rRNAs. This is in contrast to eukaryotic genomes that typically contain much more DNA than is needed to encode all the proteins required for cell function. For instance, in the human genome only about 3% of the total DNA actually encodes proteins. The “extra” DNA in eukaryotes is present as intervening DNA between coding sequences (which is removed after transcription) or as repetitive sequences, some of which are repeated hundreds or thousands of times.

Genetic mapping of the genes that encode the enzymes that function in the same biochemical pathway in *E. coli* has shown that these genes are often clustered. On the genetic map in Figure 4.8, a few such clusters are shown. Notice, for instance, the *gal*, *trp*, and *his* gene clusters. Each of these gene clusters constitutes an **operon** that is transcribed into a single mRNA encoding several individual proteins. Genes for many other biochemical pathways in *E. coli* are not clustered. For example, genes for maltose degradation (*mal* genes, Figure 4.8) are scattered throughout the chromosome. Sequence analysis of the *E. coli* chromosome has shown that over 70% of the 2584 predicted or known transcriptional units contain only a single gene, and only 6% of operons have four or more genes. Some coding sequences are on one strand of the chromosome while others are on the opposite strand, and genomic analysis has shown that there are about equal numbers of genes on both strands. In contrast to prokaryotes, eukaryotes do not contain operons.

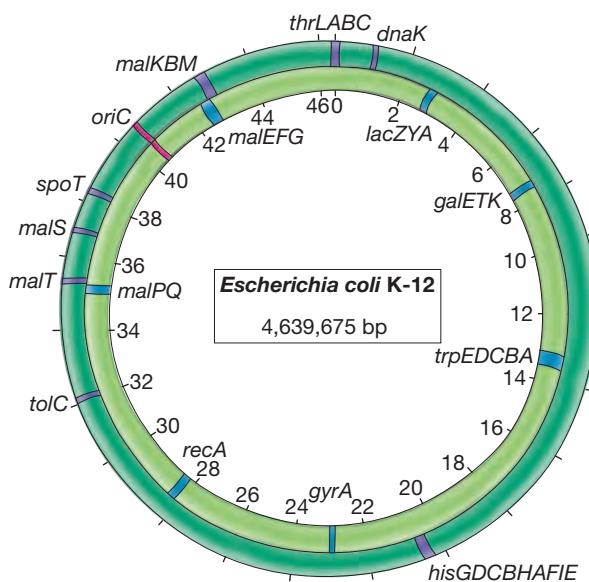

Figure 4.8 The chromosome of *Escherichia coli* strain K-12. Map distances are given in 100 kilobases of DNA. The chromosome contains 4,639,675 base pairs and 4288 open reading frames (genes). Depending on the DNA strand, the locations of a few genes and operons are indicated. Replication (Figure 4.3) proceeds in both directions from the origin of DNA replication, *oriC*, indicated in red.

General Principles of Plasmids

Many prokaryotic cells contain other genetic elements, in particular, plasmids, in addition to the chromosome. While plasmids possess their own origin of replication, they do rely on chromosomally encoded enzymes for their replication. Most plasmids are usually expendable since they rarely contain genes required for growth under all conditions. By contrast, essential genes reside on chromosomes. Unlike viruses, plasmids do not have an extracellular form and exist inside cells as free DNA. Thousands of different plasmids are known. Indeed, over 300 different naturally occurring plasmids have been isolated from strains of *Escherichia coli* alone.

Almost all known plasmids consist of double-stranded DNA. Most are circular, but many linear plasmids are also known. Naturally occurring plasmids vary in size from approximately 1 kbp to more than 1 Mbp. Typical plasmids are circular double-stranded DNA molecules less than 5% the size of the chromosome (Figure 4.9). Most plasmid DNA isolated from cells is supercoiled, this being the most compact form that DNA takes within the cell (Figure 4.6). Some bacteria may contain several different types of plasmids. For example, *Borrelia burgdorferi* (the Lyme disease pathogen, ↗ Section 30.4) contains 17 different circular and linear plasmids!

Cellular replication enzymes also replicate plasmids. The genes encoded by a plasmid function to direct the initiation of replication and partitioning of replicated plasmids between daughter cells. Different plasmids may be present in cells in different numbers called *copy number*. Some plasmids are present in only one

to three copies, whereas others may be present in over 100 copies. Copy number is controlled by genes on the plasmid and by interactions between the host and the plasmid.

Types of Plasmids

Although by definition plasmids do not encode functions essential to the host, plasmids may carry genes that profoundly influence host cell physiology. Among the most widespread and well-studied groups of plasmids are the resistance plasmids, usually just called *R plasmids*, which confer resistance to antibiotics or other growth inhibitors. In general, the resistance genes encode proteins that either inactivate the antibiotic or protect the cell by some other mechanism. Several antibiotic resistance genes can be encoded on a single R plasmid; alternatively, a cell with multiple resistance may contain several different R plasmids. Plasmid R100, for example, is a 94.3-kbp plasmid (Figure 4.10) that encodes resistance to sulfonamides, streptomycin, spectinomycin, fusidic acid, chloramphenicol, and tetracycline. Plasmid R100 also encodes resistance to mercury. Pathogenic bacteria resistant to antibiotics are of considerable medical significance, and their increasing incidence is correlated with the increasing use of antibiotics for treating infectious diseases in humans and animals (↗ Section 27.17).

Pathogenic microorganisms possess a variety of characteristics that enable them to colonize hosts and establish infections. Two major characteristics of the virulence (disease-causing ability) of pathogens are often plasmid encoded: (1) the ability of the pathogen to attach to and colonize specific host tissue

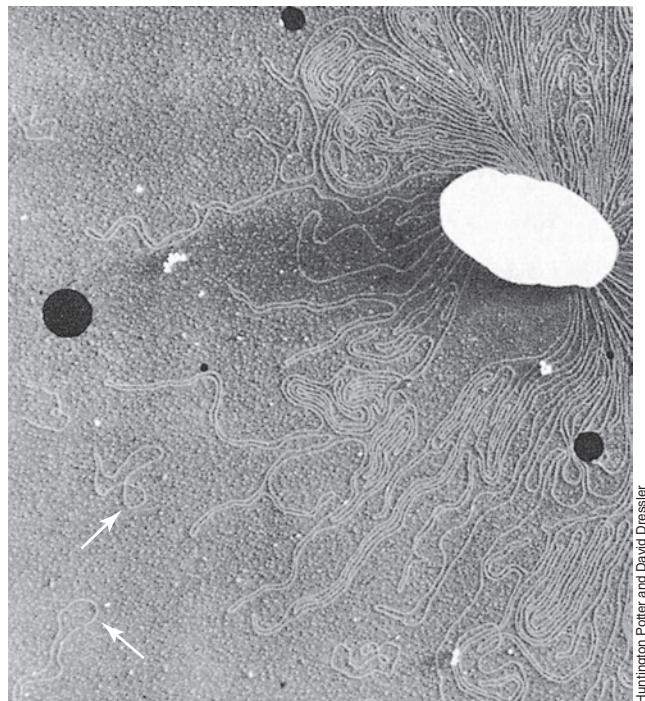

Figure 4.9 The bacterial chromosome and bacterial plasmids, as seen in the electron microscope. The plasmids (arrows) are the circular structures and are much smaller than the main chromosomal DNA. The cell (large, white structure) was broken gently so the DNA would remain intact.

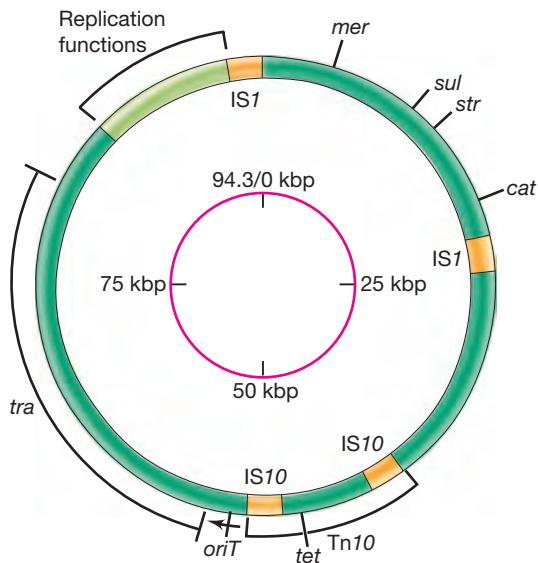

Figure 4.10 Genetic map of the resistance plasmid R100. The inner circle shows the size in kilobase pairs. The outer circle shows the location of major antibiotic resistance genes and other key functions: *mer*, mercuric ion resistance; *sul*, sulfonamide resistance; *str*, streptomycin resistance; *cat*, chloramphenicol resistance; *tet*, tetracycline resistance; *oriT*, origin of conjugative transfer; *tra*, transfer functions. The locations of insertion sequences (IS) and the transposon Tn10 are also shown. Genes for plasmid replication are found in the region from 88 to 92 kbp.

and (2) the production of toxins, enzymes, and other molecules that cause damage to the host. Many bacteria also produce proteins that inhibit or kill closely related species or even different strains of the same species. These agents, called **bacteriocins**, are analogous to antibiotics, but have a narrower spectrum of activity than antibiotics. The genes encoding bacteriocins and the proteins needed for processing and transporting them and for conferring immunity on the producing organism are usually found on plasmids. For example, *E. coli* produces bacteriocins called *colicins* that bind to specific receptors on the surface of susceptible cells and kill them by disrupting membrane function. Other colicins are nucleases that degrade the DNA or RNA of susceptible strains.

In some cases plasmids encode properties fundamental to the ecology of the bacterium. For example, the ability of *Rhizobium* to interact with plants and form nitrogen-fixing root nodules requires certain plasmid functions (➡ Section 22.3). Other plasmids confer special metabolic properties on bacterial cells, such as the ability to degrade toxic pollutants. Some special properties conferred by plasmids are summarized in **Table 4.2**.

MINIQUIZ

- What defines a chromosome in prokaryotes?
- What are viruses and plasmids?
- Approximately how large is the *Escherichia coli* genome in base pairs? How many genes does it contain?
- What properties does an R plasmid confer on its host cell?

Table 4.2 Examples of traits conferred by plasmids in prokaryotes

Traits	Organisms
Antibiotic production	<i>Streptomyces</i>
Conjugation	Wide range of bacteria
Metabolic functions	
Degradation of octane, camphor, naphthalene	<i>Pseudomonas</i>
Degradation of herbicides	<i>Alcaligenes</i>
Formation of acetone and butanol	<i>Clostridium</i>
Lactose, sucrose, citrate, or urea utilization	Enteric bacteria
Pigment production	<i>Erwinia, Staphylococcus</i>
Gas vesicle production	<i>Halobacterium</i>
Resistance	
Antibiotic resistance	Wide range of bacteria
Resistance to toxic metals	Wide range of bacteria
Virulence	
Tumor production in plants	<i>Agrobacterium</i>
Nodulation and symbiotic nitrogen fixation	<i>Rhizobium</i>
Bacteriocin production and resistance	Wide range of bacteria
Animal cell invasion	<i>Salmonella, Shigella, Yersinia</i>
Coagulase, hemolysin, enterotoxin	<i>Staphylococcus</i>
Toxins and capsule	<i>Bacillus anthracis</i>
Enterotoxin, K antigen	<i>Escherichia coli</i>

II • Transmission of Genetic Information: DNA Replication

DNA replication is necessary for cells to divide, whether to reproduce new organisms, as in unicellular microorganisms, or to produce new cells as part of a multicellular organism. To successfully transmit genetic information from a mother cell to an identical daughter cell, DNA replication must be highly accurate. This process requires the activities of a host of special enzymes.

4.4 Templates and Enzymes

As we have seen, DNA exists in cells as a double helix with complementary base pairing (Figures 4.3 and 4.4). If the double helix is opened up, a new strand can be synthesized as the complement of each parental strand. As shown in **Figure 4.11**, replication is a **semiconservative** process, meaning that the two resulting double helices consist of one new strand and one parental strand. The DNA strand that is used to make a complementary daughter strand is called the template strand, and in DNA replication, each parental strand is a template for one newly synthesized strand (Figure 4.11).

The precursor of each new nucleotide in the DNA strand is a deoxynucleoside 5'-triphosphate. During insertion, the two terminal phosphates are removed and the innermost phosphate is then covalently bound to a deoxyribose of the growing chain (**Figure 4.12**). This addition of the incoming nucleotide requires the

presence of a free hydroxyl group, which is available only at the 3' end of the molecule. This leads to the important principle that DNA replication always proceeds *from the 5' end to the 3' end*, the 5'-phosphate of the incoming nucleotide being attached to the 3'-hydroxyl of the previously added nucleotide.

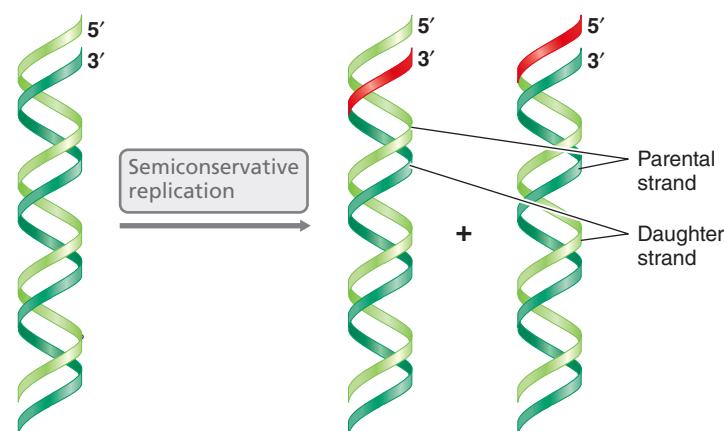

Figure 4.11 Overview of DNA replication. DNA replication is a semiconservative process in all cells. Note that the new double helices each contain one new daughter strand (shown topped in red) and one parental strand.

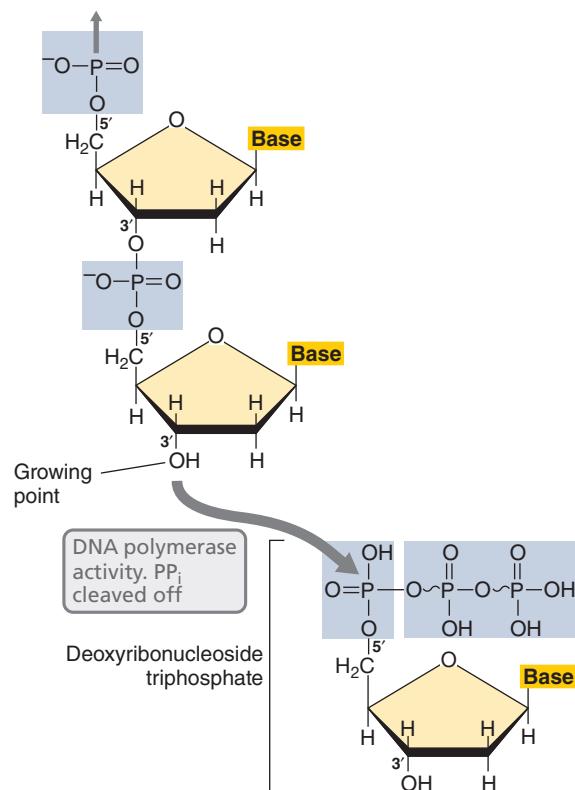

Figure 4.12 Extension of a DNA chain by adding a deoxyribonucleoside triphosphate at the 3' end. Growth proceeds from the 5'-phosphate to the 3'-hydroxyl end. DNA polymerase catalyzes the reaction. The four precursors are deoxythymidine triphosphate (dTTP), deoxyadenosine triphosphate (dATP), deoxyguanosine triphosphate (dGTP), and deoxycytidine triphosphate (dCTP). Upon nucleotide insertion, the two terminal phosphates of the triphosphate are split off as pyrophosphate (PP_i). Thus, two energy-rich phosphate bonds are consumed when adding each nucleotide.

Enzymes that catalyze the addition of deoxynucleotides are called **DNA polymerases**. Several such enzymes play a role in replication, each with a specific function. There are five different DNA polymerases in *Escherichia coli*, DNA polymerases I, II, III, IV, and V. DNA polymerase III (DNA Pol III) is the primary enzyme for replicating chromosomal DNA. DNA polymerase I (DNA Pol I) also participates in chromosomal replication, though to a lesser extent (see below). The other DNA polymerases help repair damaged DNA (Section 10.4).

All known DNA polymerases synthesize DNA in the $5' \rightarrow 3'$ direction. However, no known DNA polymerase can initiate a new chain; all of these enzymes can only add a nucleotide onto a preexisting 3'-OH group. Thus, in order to start a new chain, a **primer**, a nucleic acid molecule to which DNA polymerase can attach the first nucleotide, is required. In most cases this primer is a short stretch of RNA rather than DNA (Figure 4.13).

When the double helix is opened at the beginning of replication, an RNA-polymerizing enzyme makes the RNA primer. This enzyme, called **primase**, synthesizes a short stretch (11–12 nucleotides) of RNA that is complementary in base pairing to the template strand DNA. At the growing end of this RNA primer is a 3'-OH group to which DNA polymerase adds the first deoxyribonucleotide. Continued extension of the molecule thus

Figure 4.13 The RNA primer. Structure of the RNA-DNA hybrid formed during initiation of DNA synthesis. Orange depicts the RNA primer.

occurs as DNA rather than RNA. The newly synthesized molecule has a structure like that shown in Figure 4.13. The primer is eventually removed and replaced with DNA, as described in the next section.

MINIQUIZ

- To which end (5' end or 3' end) of a newly synthesized strand of DNA does DNA polymerase add a base?
- Why is a primer required for DNA replication? What is the primer made of?

4.5 The Replication Fork

Much of our understanding of the details of DNA replication has been obtained from studying the bacterium *Escherichia coli*; however, DNA replication is probably quite similar in all *Bacteria*. By contrast, although most species of *Archaea* have circular chromosomes, many events in DNA replication resemble those in eukaryotic cells more than those in *Bacteria*, a reflection of the phylogenetic affiliation between *Archaea* and *Eukarya* (Figure 1.6b).

Initiation of DNA Synthesis

Before DNA polymerase can synthesize new DNA, the double helix must be unwound to expose the template strands. The zone of unwound DNA where replication occurs is called the **replication fork**. The enzyme **DNA helicase** unwinds the double helix, using energy from ATP, and exposes a short single-stranded region (Figure 4.14). Helicase moves along the DNA and separates the strands just in advance of the replication fork. The single-stranded region is immediately covered with copies of single-strand binding protein to stabilize the single-stranded DNA and prevent the double helix from re-forming. Unwinding of the double helix by helicase generates positive supercoils ahead of the advancing replication fork. To counteract this, DNA gyrase travels along the DNA ahead of the replication fork and inserts negative supercoils to cancel out the positive supercoiling.

Bacteria possess a single location on the chromosome where DNA synthesis is initiated, the origin of replication (*oriC*). This is a specific DNA sequence of about 250 bases that is recognized by initiation proteins, in particular a protein called DnaA (Table 4.3), which binds to this region and opens up the double helix. Next to assemble is the helicase (known as DnaB), which is helped onto the DNA by the helicase loader protein (DnaC). Two helicases are loaded, one onto each strand, facing in opposite directions. Next, two primase and then two DNA polymerase enzymes are loaded onto the DNA behind the helicases. Initiation of DNA

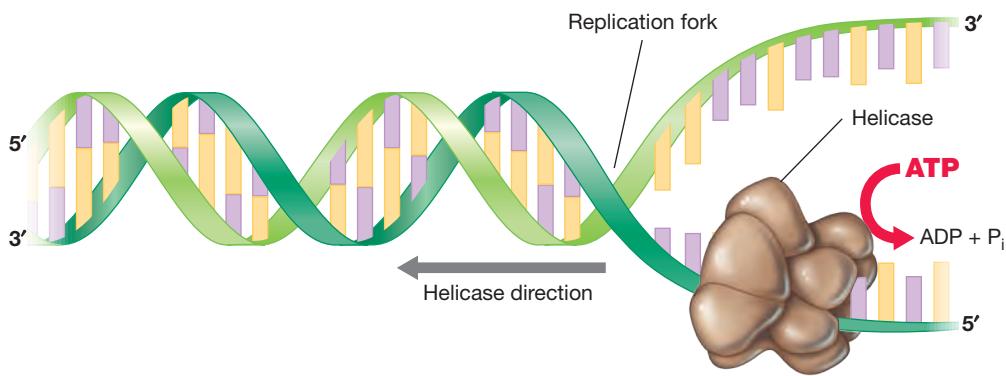

Figure 4.14 DNA helicase unwinding a double helix. In this figure, the helicase is denaturing or pulling the two antiparallel strands of DNA apart beginning from the right and moving to the left.

replication then begins on the two single strands. As replication proceeds, the replication fork appears to move along the DNA (Figure 4.14).

Leading and Lagging Strands

Figure 4.15 shows details of DNA replication at the replication fork. An important distinction in replication between the two DNA strands can be made due to the fact that replication always proceeds from 5' to 3' (5' → 3', always adding a new nucleotide to the 3'-OH of the growing chain). On the strand growing from the 5'-PO₄²⁻ to the 3'-OH, called the **leading strand**, DNA synthesis occurs *continuously* because there is always a free 3'-OH at the

replication fork to which a new nucleotide can be added. But on the opposite strand, called the **lagging strand**, DNA synthesis occurs *discontinuously* because there is no 3'-OH at the replication fork to which a new nucleotide can attach (Figure 4.15). The 3'-OH on this strand is located at the opposite end, away from the replication fork. Therefore, on the lagging strand, RNA primers must be synthesized by primase multiple times to provide free 3'-OH groups for DNA Pol III. By contrast, the leading strand is primed only once, at the origin. As a result, the lagging strand is made in short segments, called *Okazaki fragments*, named after their discoverer, Reiji Okazaki. These lagging strand fragments are joined together later to yield a continuous strand of DNA.

Synthesis of the New DNA Strands

After synthesizing the RNA primer, primase is replaced by DNA Pol III. This enzyme is actually a complex of several proteins (Table 4.3), including the polymerase core enzyme itself. Each molecule of polymerase is held on the DNA by a sliding clamp, which encircles and slides along the single template strands of DNA. Consequently, the replication fork contains two polymerase core

Table 4.3 Major enzymes involved in DNA replication in *Bacteria*

Enzyme	Encoding genes	Function
DNA gyrase	<i>gyrAB</i>	Replaces supercoils ahead of replisome
Origin-binding protein	<i>dnaA</i>	Binds origin of replication to open double helix
Helicase loader	<i>dnaC</i>	Loads helicase at origin
Helicase	<i>dnaB</i>	Unwinds double helix at replication fork
Single-strand binding protein	<i>ssb</i>	Prevents single strands from annealing
Primase	<i>dnaG</i>	Primes new strands of DNA
DNA polymerase III		Main polymerizing enzyme
Sliding clamp	<i>dnaN</i>	Holds Pol III on DNA
Clamp loader	<i>holA-E</i>	Loads Pol III onto sliding clamp
Dimerization subunit (Tau)	<i>dnaX</i>	Holds together the two core enzymes for the leading and lagging strands
Polymerase subunit	<i>dnaE</i>	Strand elongation
Proofreading subunit	<i>dnaQ</i>	Proofreading
DNA polymerase I	<i>polA</i>	Excises RNA primer and fills in gaps
DNA ligase	<i>ligA, ligB</i>	Seals nicks in DNA
Tus protein	<i>tus</i>	Binds terminus and blocks progress of the replication fork
Topoisomerase IV	<i>parCE</i>	Unlinking of interlocked circles

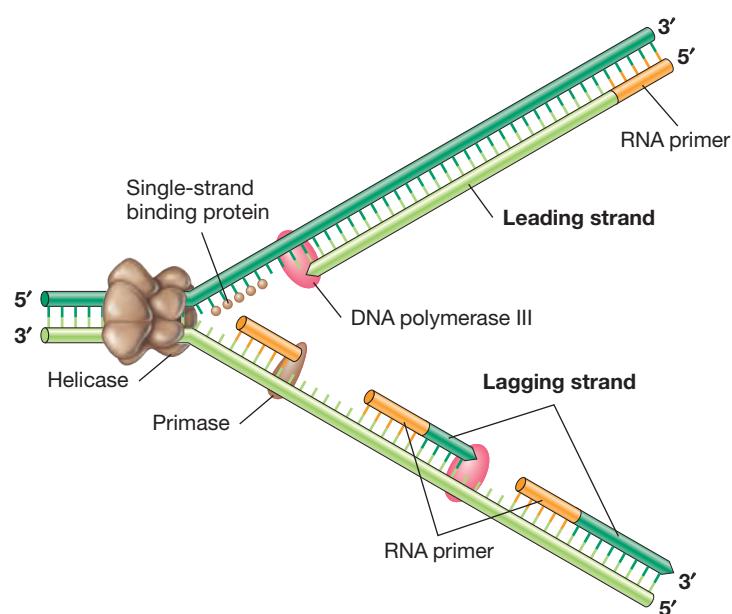

Figure 4.15 Events at the DNA replication fork. Note the polarity and antiparallel nature of the DNA strands.

enzymes and two sliding clamps, one set for each strand. However, there is only a single clamp-loader complex, which functions to assemble the two sliding clamps onto the DNA. After assembly on the lagging strand, the elongation activity of DNA Pol III, catalyzed by DnaE, then adds deoxyribonucleotides sequentially until it reaches previously synthesized DNA (Figure 4.16). At this point, DNA Pol III stops.

The next enzyme to take part, DNA Pol I, has more than one enzymatic activity. Besides synthesizing DNA, Pol I has a $5' \rightarrow 3'$ exonuclease activity that removes the RNA primer preceding it (Figure 4.16). When the primer has been removed and replaced with DNA, DNA Pol I is released. The very last phosphodiester bond is made by an enzyme called **DNA ligase**. This enzyme seals nicks in DNAs that have an adjacent $5'-PO_4^{2-}$ and $3'-OH$ (something that DNA Pol III is unable to do), and along with DNA Pol I, it also participates in DNA repair. DNA ligase is also important for sealing genetically manipulated DNA during molecular cloning (Section 11.4).

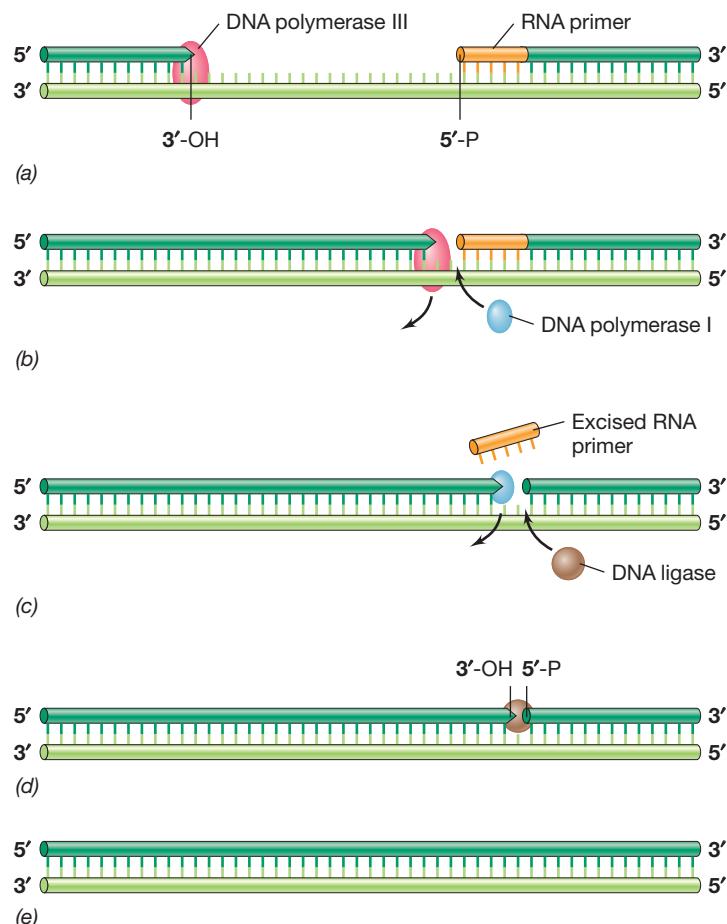

Figure 4.16 Sealing two fragments on the lagging strand. (a) DNA polymerase III is synthesizing DNA in the $5' \rightarrow 3'$ direction toward the RNA primer of a previously synthesized fragment on the lagging strand. (b) On reaching the fragment, DNA polymerase III leaves and is replaced by DNA polymerase I. (c) DNA polymerase I continues synthesizing DNA while removing the RNA primer from the previous fragment, and DNA ligase replaces DNA polymerase I after the primer has been removed. (d) DNA ligase seals the two fragments together. (e) The final product, complementary and antiparallel double-stranded DNA.

MINIQUIZ

- Why are there leading and lagging strands?
- How is the origin of replication recognized?
- Which enzymes take part in joining the fragments of the lagging strand?

4.6 Bidirectional Replication and the Replisome

The circular nature of the prokaryotic chromosome creates an opportunity for speeding up the replication process. In *Escherichia coli*, and probably in all prokaryotes with circular chromosomes, DNA replication is *bidirectional* from the origin of replication, as shown in Figure 4.17. There are thus *two* replication forks on each chromosome, each moving in opposite directions. These are held together by the two Tau protein subunits. In circular DNA, bidirectional replication leads to the formation of characteristic shapes called theta structures (Figure 4.17).

During bidirectional replication, synthesis occurs in both a leading and lagging fashion on each template strand, allowing DNA to replicate as rapidly as possible (Figure 4.17). While DNA Pol III can add nucleotides to a growing DNA strand at the rate of about 1000 per second, chromosome replication in *E. coli* still takes about 40 min. Interestingly, under the best growth conditions, *E. coli* can grow with a doubling time of about 20 min. The solution to this conundrum is that cells of *E. coli* growing at doubling times shorter than 40 min contain multiple DNA replication forks. That is, a new round of DNA replication begins before the last round has been completed. We consider this problem in more detail in Chapter 5 (Figure 5.4).

The Replisome

Figure 4.15 shows the differences in replication of the leading and the lagging strands and the enzymes that participate in the process. From such a schematic drawing it might appear that each replication fork contains several different proteins all working independently. Actually, this is not the case. Instead, replication proteins aggregate to form a large replication complex called the **replisome** (Figure 4.18). The lagging strand of DNA actually loops out to allow the replisome to move smoothly along both strands, and the replisome literally pulls the DNA template through it as replication occurs. Therefore, it is the DNA, rather than DNA polymerase, that moves during replication. Note also how helicase and primase form a subcomplex, called the *primosome*, which aids their working in close association during the replication process.

In summary, in addition to DNA Pol III, the replisome contains several key replication proteins: (1) DNA gyrase, which removes supercoils; (2) DNA helicase and primase (the primosome), which unwind and prime the DNA; and (3) single-strand binding protein, which prevents the separated template strands from re-forming a double helix (Figure 4.18). Table 4.3 summarizes the properties of proteins essential for DNA replication in *Bacteria*.

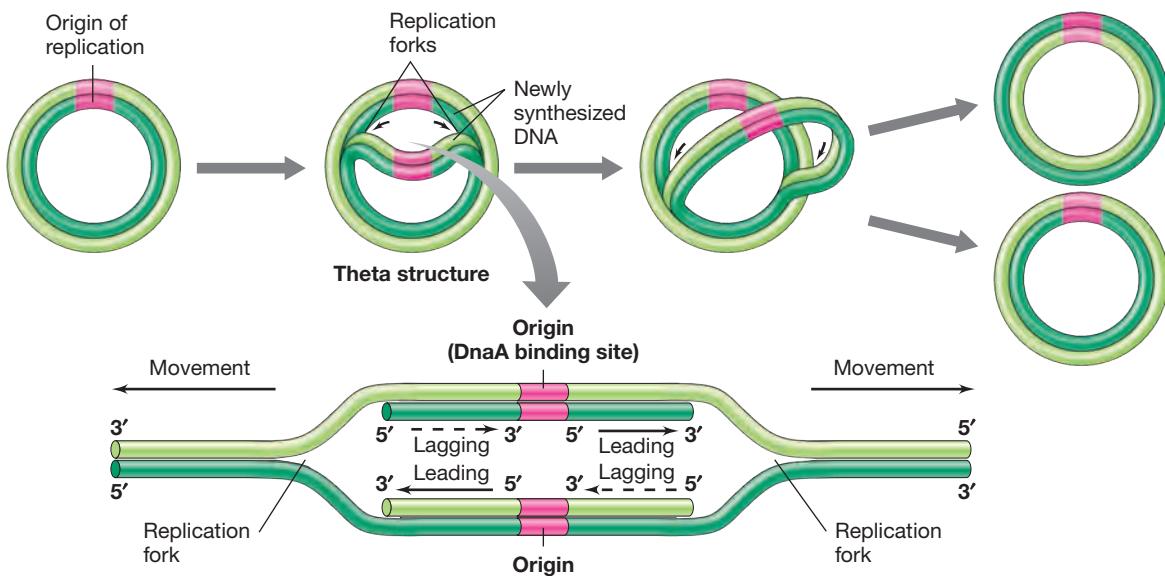

Figure 4.17 Replication of circular DNA: the theta structure. In circular DNA, bidirectional replication from an origin forms an intermediate structure resembling the Greek letter theta (θ). Inset shows dual replication forks in the circular chromosome. In *Escherichia coli*, the origin of replication is recognized by a specific protein, DnaA. Note that DNA synthesis is occurring in both a leading and a lagging manner on each of the new daughter strands. Compare this figure with the description of the replisome shown in Figure 4.18.

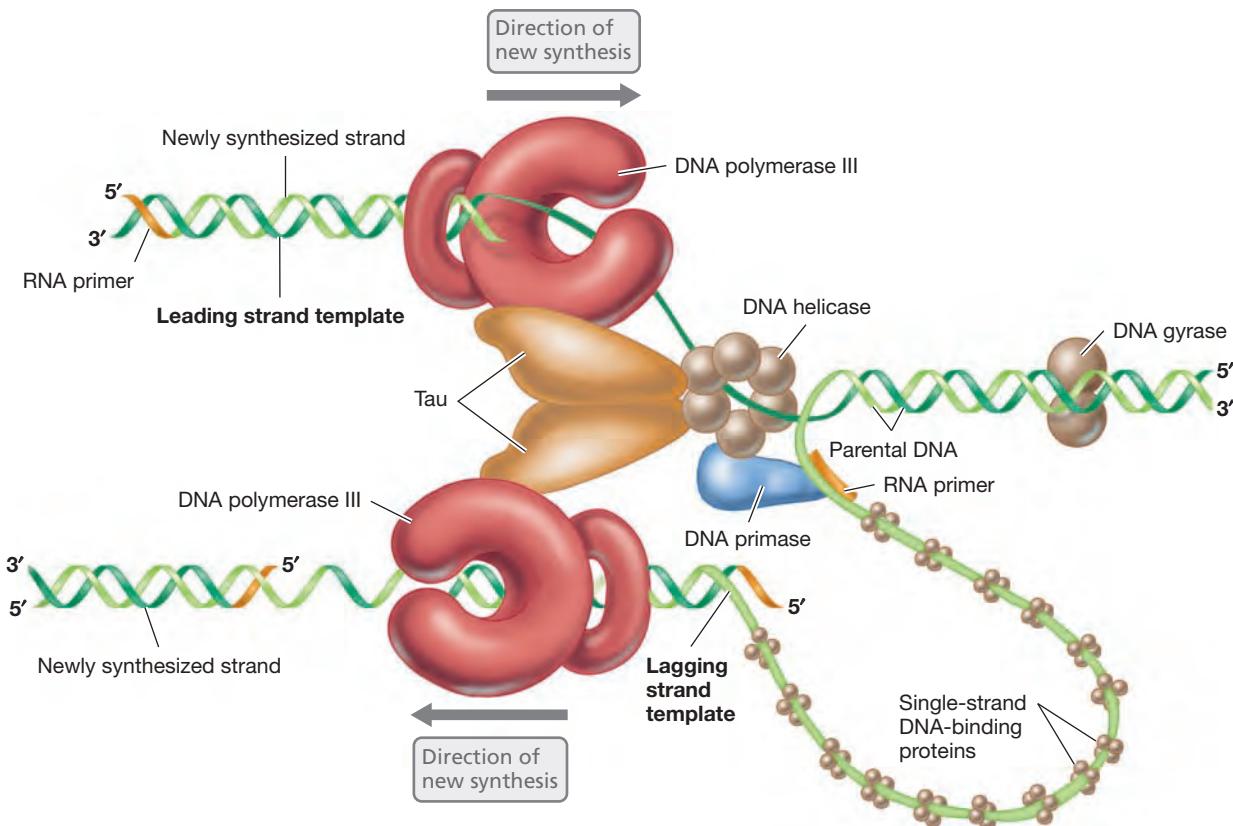

Figure 4.18 The replisome. The replisome consists of two copies of DNA polymerase III and DNA gyrase, plus helicase and primase (together forming the primosome), and many copies of single-strand DNA-binding protein. The Tau subunits hold the two DNA polymerase assemblies and helicase together. Just upstream of the rest of the replisome, DNA gyrase removes supercoils in the DNA to be replicated. Note that the two polymerases are replicating the two individual strands of DNA in opposite directions. Consequently, the lagging-strand template loops around so that the whole replisome moves in the same direction along the chromosome.

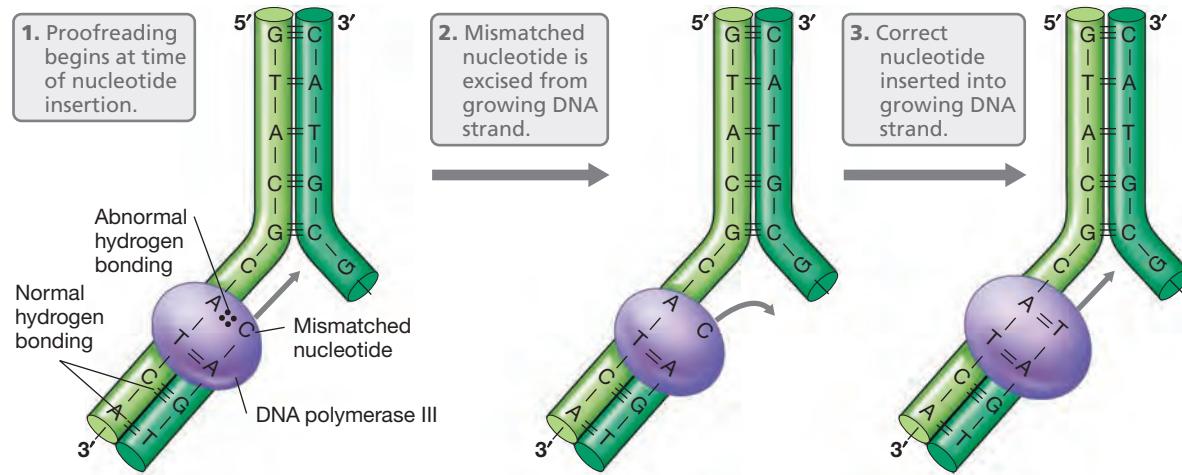

Figure 4.19 Proofreading by the $3' \rightarrow 5'$ exonuclease activity of DNA polymerase III. A mismatch in base pairing at the terminal base pair causes the polymerase to pause briefly. This signals the proofreading activity to cut out the mismatched nucleotide, after which the correct base is inserted by the polymerase activity.

Fidelity of DNA Replication: Proofreading

DNA replicates with a remarkably low error rate. Nevertheless, when errors do occur, a mechanism exists to detect and correct them. Errors in DNA replication introduce *mutations*, changes in DNA sequence. Mutation rates in cells are remarkably low, between 10^{-8} and 10^{-11} errors per base pair inserted. This accuracy is possible partly because DNA polymerases get two chances to incorporate the correct base at a given site. The first chance comes when complementary bases are inserted opposite the bases on the template strand by DNA Pol III according to the base-pairing rules, A with T and G with C. The second chance depends upon a second enzymatic activity of both DNA Pol I and Pol III, called *proofreading* (Figure 4.19). In DNA Pol III, a separate protein subunit, DnaQ, performs the proofreading function, whereas in DNA Pol I, a single protein performs both polymerization and proofreading.

Proofreading activity occurs if an incorrect base has been inserted because this creates a mismatch in base pairing. Both DNA Pol I and Pol III possess a $3' \rightarrow 5'$ exonuclease activity that can remove such wrongly inserted nucleotides. The polymerase senses the error because incorrect base pairing causes a slight distortion in the double helix. After the removal of a mismatched nucleotide, the polymerase then gets a second chance to insert the correct nucleotide (Figure 4.19). The proofreading exonuclease activity is distinct from the $5' \rightarrow 3'$ exonuclease activity of DNA Pol I that removes the RNA primer from both the leading and lagging strands. Only DNA Pol I has this latter activity. Exonuclease proofreading occurs in prokaryotes, eukaryotes, and

viral DNA replication systems. However, many organisms have additional mechanisms for reducing errors made during DNA replication that operate after the replication fork has passed by. We will discuss some of these in Chapter 10.

Termination of Replication

Eventually the process of DNA replication is finished. How does the replisome know when to stop? On the opposite side of the circular chromosome from the origin is a site called the *terminus of replication*. Here the two replication forks collide as the new circles of DNA are completed. In the terminus region are several DNA sequences called *Ter* sites that are recognized by a protein called Tus, whose function is to block progress of the replication forks. When replication of the circular chromosome is complete, the two circular molecules are linked together, much like the links of a chain. They are unlinked by another enzyme, topoisomerase IV. Obviously, it is critical that, after DNA replication, the DNA is partitioned so that each daughter cell receives a copy of the chromosome. This process may be assisted by the important cell division protein FtsZ, which helps orchestrate several key events of cell division (see Section 5.2).

III • RNA Synthesis: Transcription

Transcription is the synthesis of ribonucleic acid (RNA) using DNA as a template. There are three key differences in the chemistry of RNA and DNA: (1) RNA contains ribose

instead of deoxyribose; (2) RNA contains uracil instead of thymine; and (3) except in certain viruses, RNA is not double-stranded. The change from deoxyribose to ribose affects the

chemistry of a nucleic acid; enzymes that act on DNA usually have no effect on RNA, and vice versa. However, the change from thymine to uracil does not affect base pairing, as these two bases pair with adenine equally well.

While RNA predominantly exists in single strands, molecules typically fold back upon themselves in regions where complementary base pairing is possible. The term **secondary structure** refers to this folding, and the term *primary structure* refers to the nucleotide sequence, as it does for DNA. Secondary structure leads to highly folded and twisted RNA molecules whose biological function depends critically on their final three-dimensional shape.

RNA plays several important roles in the cell. As we have seen (Figure 4.3), three major types of RNA participate in protein synthesis: *messenger RNA* (mRNA), *transfer RNA* (tRNA), and *ribosomal RNA* (rRNA). Several other types of RNA are also known but mostly function in regulation (Chapter 7). All RNA molecules result from the transcription of DNA. It should be emphasized that RNA operates at two levels, genetic and functional. At the genetic level, mRNA carries genetic information from the genome to the ribosome. In contrast, rRNA has both a functional and a structural role in ribosomes, and tRNA has an active role in carrying amino acids for protein synthesis. Indeed, some RNA molecules including rRNA have enzymatic activity. Here we focus on how RNA is synthesized in *Bacteria*, once again using *Escherichia coli* as our model organism.

4.7 Transcription

Transcription is catalyzed by the enzyme **RNA polymerase**. Like DNA polymerase, RNA polymerase forms phosphodiester bonds but in this case between the ribonucleotides rATP, rGTP, rCTP, and rUTP rather than deoxyribonucleotides. Polymerization is driven by energy released from the hydrolysis of two energy-rich phosphate bonds of the incoming ribonucleoside triphosphates. The mechanism of RNA synthesis is much like that of DNA synthesis (Figure 4.12): During elongation of an RNA chain, ribonucleoside triphosphates are added to the 3'-OH of the ribose of the preceding nucleotide. Thus chain growth is 5' to 3' and the newly synthesized strand of RNA is antiparallel to the DNA template strand it was transcribed from. The overall process of RNA synthesis is illustrated in Figure 4.20.

RNA polymerase uses DNA as a template, but only one of the two strands is transcribed for any given gene. Nevertheless, genes are present on both strands of DNA and thus DNA sequences on both strands are transcribed, although at different locations. Unlike DNA polymerase, RNA polymerase can initiate new strands of RNA on its own; no primer sequence is necessary. As the newly made RNA dissociates from the DNA, the opened DNA closes back into the original double helix. Transcription stops at specific sites called *transcription terminators*. Unlike DNA replication, which copies entire genomes, transcription copies much smaller units of DNA, often as little as a single gene. This system allows the cell to transcribe different genes at different frequencies, depending on the needs of the cell for different proteins. In other words, gene expression is regulated. As we shall see in Chapter 7,

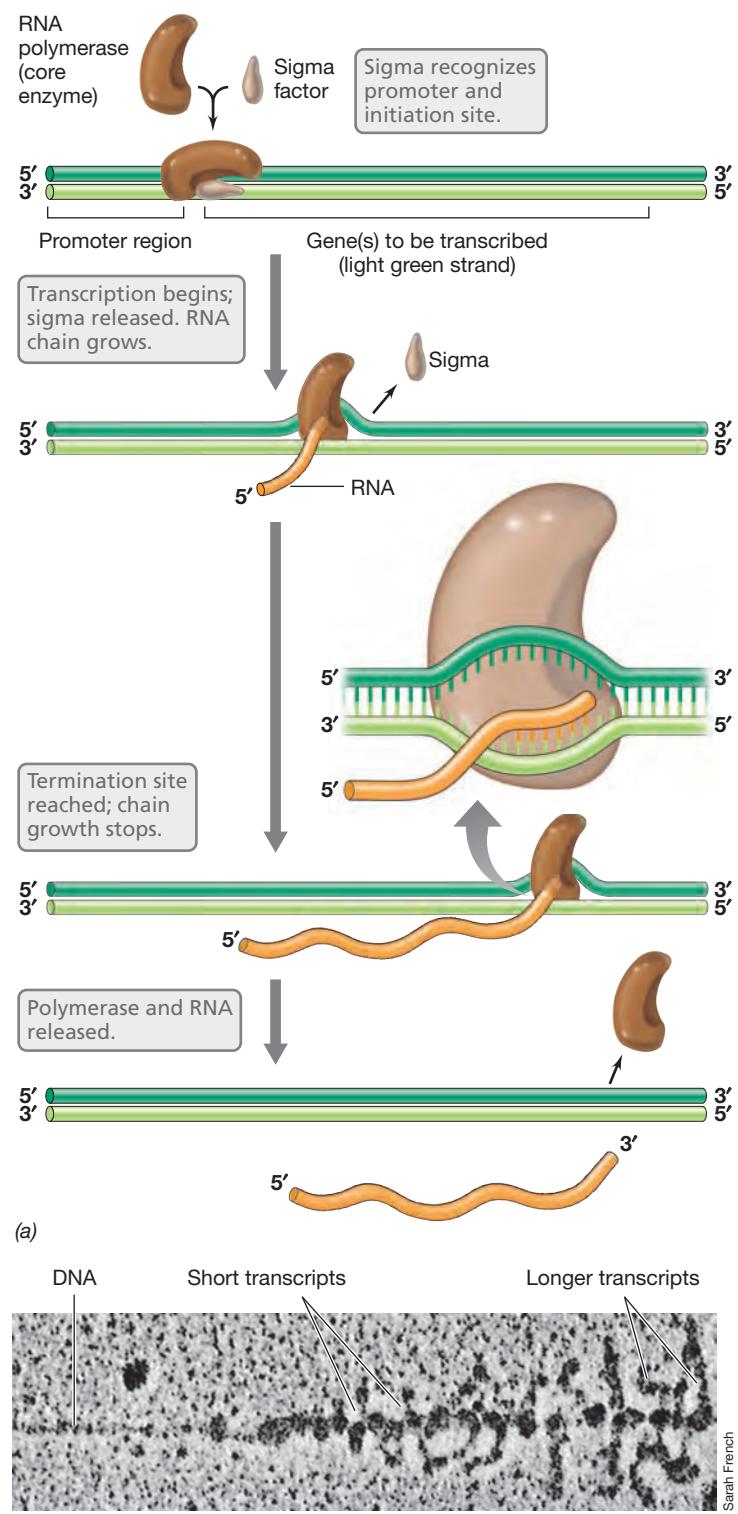

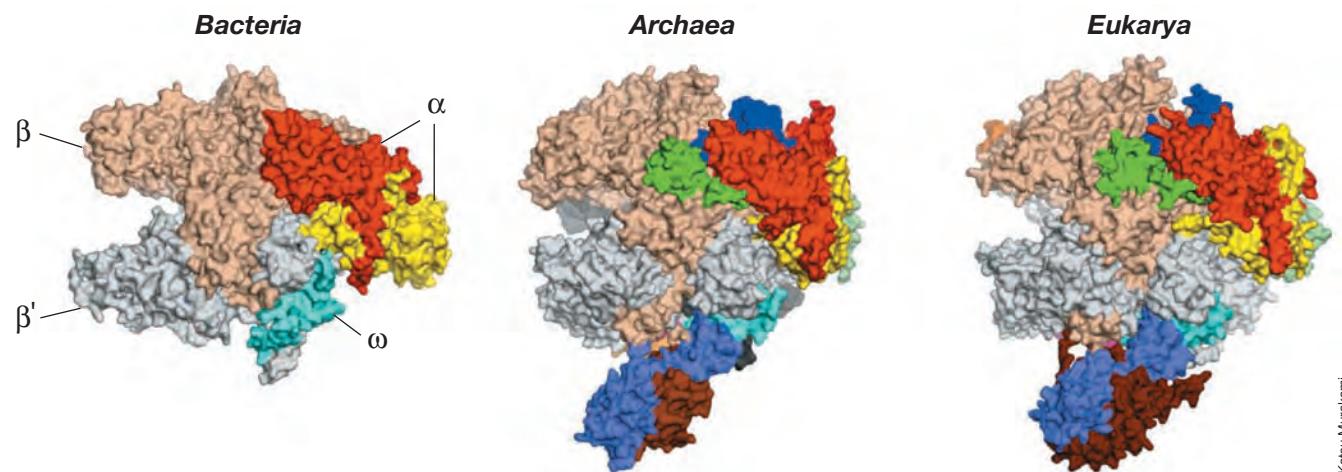

Figure 4.20 Transcription. (a) Steps in RNA synthesis. The initiation site (promoter) and termination site are specific nucleotide sequences on the DNA. RNA polymerase moves down the DNA chain, temporarily opening the double helix and transcribing one of the DNA strands. (b) Electron micrograph illustrates transcription along a gene on the *Escherichia coli* chromosome. Transcription is proceeding from left to right, with the shorter transcripts on the left becoming longer as transcription proceeds.

regulation of transcription is an important and elaborate process that uses many different mechanisms and is very efficient at controlling gene expression and conserving cell resources.

RNA Polymerases

The RNA polymerase from *Bacteria*, which has the simplest structure and about which most is known, has five different subunits, designated β , β' , α , ω (omega), and σ (sigma), with α present in two copies. The β and β' (beta prime) subunits are similar but not identical (Figure 4.21). The subunits interact to form the active enzyme, called the RNA polymerase holoenzyme, but the sigma factor is not as tightly bound as the others and easily dissociates, leading to the formation of the RNA polymerase core enzyme, $\alpha_2\beta\beta'\omega$. The core enzyme alone synthesizes RNA while the sigma factor functions to recognize the appropriate site on the DNA for RNA synthesis to begin. The omega subunit is needed for assembly of the core enzyme but not for RNA synthesis. In *Bacteria*, the sigma factor dissociates from the bacterial RNA polymerase holoenzyme once a short stretch of RNA has been formed (Figure 4.20). Elongation of the RNA molecule is then catalyzed by the core enzyme alone (Figure 4.20). Sigma is only needed to form the initial RNA polymerase–DNA complex at the promoter.

Promoters

To initiate RNA synthesis correctly, RNA polymerase must first recognize the initiation sites on the DNA called **promoters** (Figure 4.20). In *Bacteria*, promoters are recognized by the sigma subunit of RNA polymerase. Once RNA polymerase has bound to a promoter, transcription can proceed (Figure 4.20). In this process, the DNA double helix at the promoter is opened up by the RNA polymerase to form a transcription bubble. As the polymerase moves, it unwinds the DNA in short segments. This transient unwinding exposes the template strand and allows it to be copied into the RNA complement. Thus, promoters can

be thought of as structures that effectively “point” RNA polymerase in one direction or the other along the DNA. If a region of DNA has two nearby promoters pointing in opposite directions, then transcription from one will proceed in one direction (on one of the DNA strands) while transcription from the other promoter will proceed in the opposite direction (on the other strand).

Sigma Factors and Consensus Sequences

Promoters are specific DNA sequences that bind RNA polymerase, and Figure 4.22 shows the sequence of several promoters from *Escherichia coli*. All these sequences are recognized by the same major sigma factor in *E. coli* called σ^{70} (the superscript 70 indicates the size of this protein, 70 kilodaltons); although these sequences are not identical, sigma recognizes two highly conserved shorter sequences within the promoter. These conserved sequences are upstream of the transcription start site. One is 10 bases before the transcription start, the -10 region, or *Pribnow box*. Although promoters differ slightly, comparison of many -10 regions gives the consensus sequence: TATAAT. The second conserved region is about 35 bases upstream from the start of transcription. The consensus sequence in the -35 region is TTGACA (Figure 4.22). Again, most promoters differ slightly, but are very close to consensus.

In *E. coli*, promoters that are most like the consensus sequence are usually more effective in binding RNA polymerase. Such promoters are called *strong promoters* and are very useful in genetic engineering, as discussed in Chapter 11. While most genes in *E. coli* require the standard sigma factor, σ^{70} (RpoD), for transcription, several alternative sigma factors exist that recognize different consensus sequences (Table 4.4). Each alternative sigma factor is specific for a group of genes required under special circumstances and thus essential for regulating gene expression. Consequently, it is possible to control the expression of different gene families by regulating the presence or absence of the

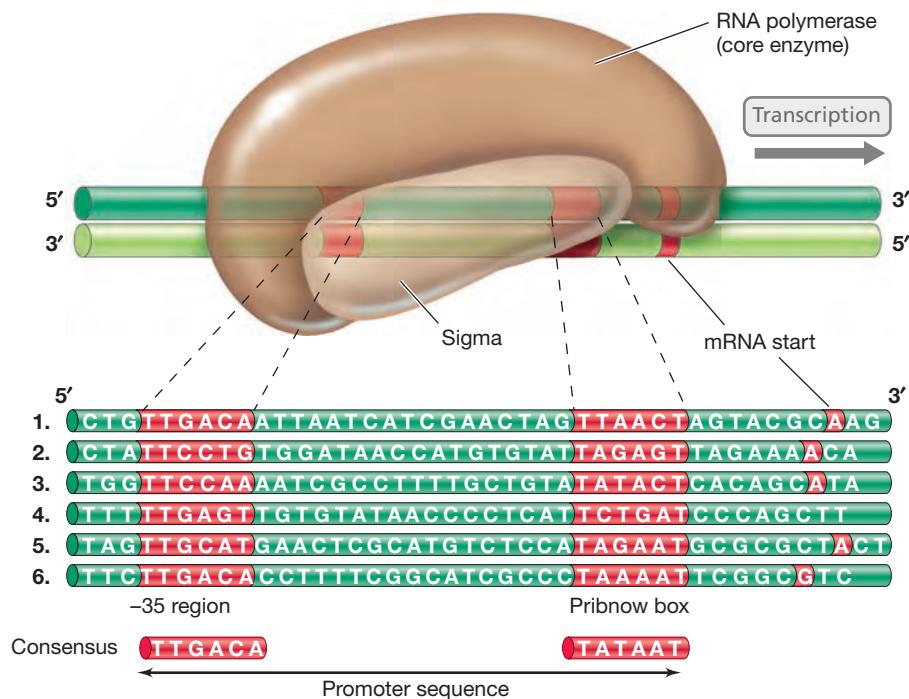

Figure 4.22 The interaction of RNA polymerase with a bacterial promoter. Shown below the RNA polymerase and DNA are six different promoter sequences identified in *Escherichia coli*. The contacts of the RNA polymerase with the –35 region and the Pribnow box (–10 sequence) are shown. Transcription begins at a unique base just downstream from the Pribnow box. Below the actual sequences at the –35 and Pribnow box regions are consensus sequences derived from comparing many promoters. Note that although sigma recognizes the promoter sequences on the 5' → 3' (dark green) strand of DNA, the RNA polymerase core enzyme will actually transcribe the light green strand (that runs 3' → 5') because core enzyme works only in a 5' → 3' direction.

corresponding sigma factor, and this occurs by changing the rate of either synthesis or degradation of the sigma factor.

Termination of Transcription

In a growing bacterial cell, only those genes that need to be expressed are usually transcribed. Therefore, it is important to

Table 4.4 Sigma factors in *Escherichia coli*

Name ^a	Upstream recognition sequence ^b	Function
σ^{70} RpoD	TTGACA	For most genes, major sigma factor for normal growth
σ^{54} RpoN	TTGGCACA	Nitrogen assimilation
σ^{38} RpoS	CCGGCG	Stationary phase, plus oxidative and osmotic stress
σ^{32} RpoH	TNTNCNCCTTGAA	Heat shock response
σ^{28} FliA	TAAA	For genes involved in flagella synthesis
σ^{24} RpoE	GAACTT	Response to misfolded proteins in periplasm
σ^{19} Fecl	AAGGAAAAT	For certain genes in iron transport

^aSuperscript number indicates size of protein in kilodaltons. Many factors also have other names, for example, σ^{70} is also called σ^D
^bN = any nucleotide.

terminate transcription at the correct position. **Termination** of RNA synthesis is governed by specific base sequences on the DNA. In *Bacteria* a common termination signal on the DNA is a GC-rich sequence containing an inverted repeat with a central nonrepeating segment. When such a DNA sequence is transcribed, the RNA forms a stem-loop structure by intra-strand base pairing (Figure 4.23). Stem-loops followed by a run of adenines in the DNA template (and therefore a run of uridines in the mRNA) are effective transcription terminators. This is due to the formation of a stretch of U:A base pairs that holds the RNA and DNA template together. This structure is very weak as U:A base pairs have only two hydrogen bonds each. The RNA polymerase pauses at the stem-loop, and the DNA and RNA dissociate at the run of uridines, terminating transcription.

The other mechanism for transcription termination in *Bacteria* uses a specific protein factor, known as Rho. Rho does not bind to RNA polymerase or to the DNA, but binds tightly to RNA and moves down the chain toward the RNA polymerase–DNA complex. Once RNA polymerase has paused at a Rho-dependent termination site (a specific sequence on the DNA template), Rho causes both the RNA and RNA polymerase to be released from the DNA, thus terminating transcription.

MINIQUIZ

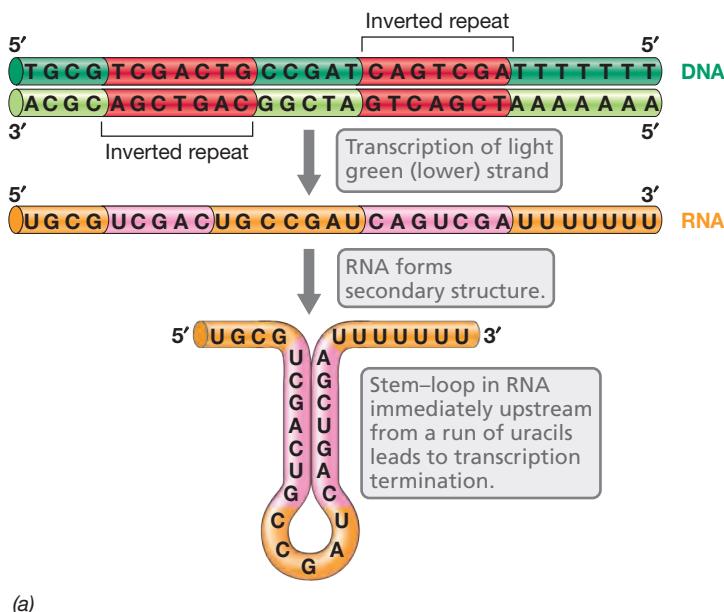

- In which direction along the DNA template strand does transcription proceed, and what enzyme catalyzes the reaction?
- What is a promoter? What protein recognizes the promoters in *Escherichia coli*?
- How can the expression of gene families be controlled as a group?
- What type of structures can lead to transcription termination?

4.8 The Unit of Transcription

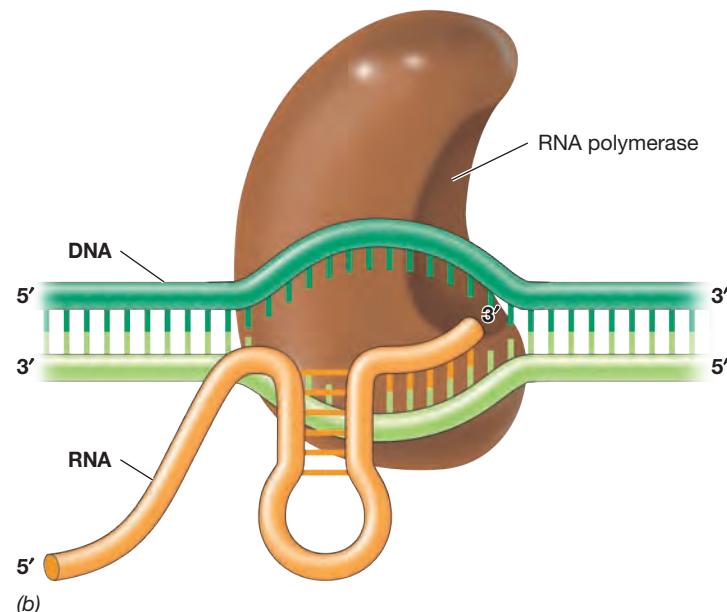

Genetic information is organized into transcriptional units. These are segments of DNA that are transcribed into a single RNA molecule. Each transcription unit is bound by sites where transcription is initiated and terminated. Some units of transcription include only a single gene. Others contain two or more genes. The latter are said to be *cotranscribed*, yielding a single RNA molecule.

Ribosomal and Transfer RNAs and RNA Longevity

Most genes encode proteins, but others encode nontranslated RNAs, such as ribosomal RNA or transfer RNA. There are several different types of rRNA in an organism. *Bacteria* and *Archaea* produce three types: 16S rRNA, 23S rRNA, and 5S rRNA (with a ribosome having one copy of each; Section 4.14). As shown

(a)

(b)

Figure 4.23 Inverted repeats and transcription termination. (a) Inverted repeats in transcribed DNA form a stem-loop structure in the RNA that terminates transcription when followed by a run of uracils. (b) Diagram indicating the formation of the terminator stem-loop in the RNA within the RNA polymerase.

In Figure 4.24, transcription units exist that contain one gene for each of these rRNAs, and these genes are cotranscribed. Therefore, the unit of transcription for most rRNAs is longer than a single gene. In prokaryotes tRNA genes are often cotranscribed with each other or even, as shown in Figure 4.24, with genes for rRNA. These cotranscribed transcripts are processed by specific proteins in the cell that cut them into individual units, yielding mature (functional) rRNAs or tRNAs.

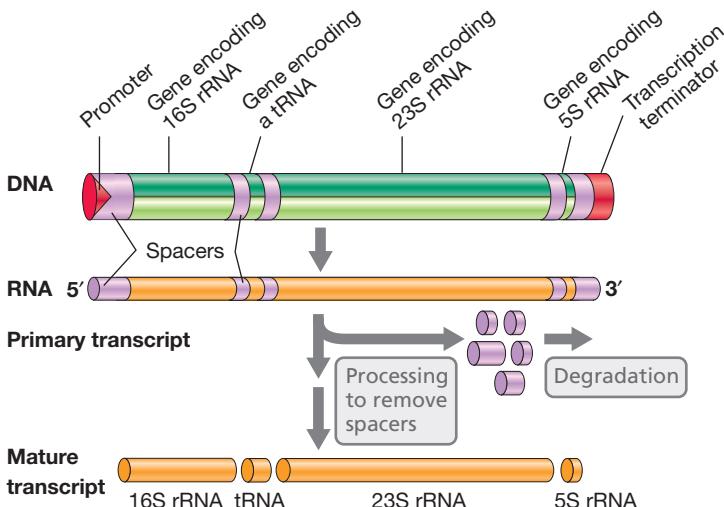

Figure 4.24 A ribosomal rRNA transcription unit from *Bacteria* and its subsequent processing. In *Bacteria*, all rRNA transcription units have the genes in the order 16S rRNA, 23S rRNA, and 5S rRNA (shown approximately to scale). Note that in this particular transcription unit the spacer between the 16S and 23S rRNA genes contains a tRNA gene. In other transcription units this region may contain more than one tRNA gene. Often one or more tRNA genes also follow the 5S rRNA gene and are cotranscribed. *Escherichia coli* contains seven rRNA transcription units.

In prokaryotes, most messenger RNAs have a short half-life (on the order of a few minutes), after which they are degraded by enzymes called *ribonucleases*. This is in contrast to rRNA and tRNA, which are stable RNAs. This stability can be ascribed to the highly folded secondary structures of tRNAs and rRNAs that prevent them from being degraded by ribonucleases. By contrast, mRNA does not form such structures and is susceptible to ribonuclease attack. The rapid turnover of prokaryotic mRNAs permits the cell to quickly adapt to new environmental conditions and halt the translation of mRNAs whose products are no longer needed.

Polycistronic mRNA and the Operon

In prokaryotes, genes that encode several enzymes of a particular metabolic pathway, for example, the biosynthesis of a particular amino acid, are often clustered together. RNA polymerase proceeds through such clusters and transcribes the entire group of genes into a single, long mRNA molecule. An mRNA encoding such a group of cotranscribed genes is called a *polycistronic mRNA* (Figure 4.25). Polycistronic mRNAs contain multiple *open-reading frames*, portions of the mRNA that actually encode amino acids (Section 4.11). When this mRNA is translated, several polypeptides are synthesized sequentially by the same ribosome.

A group of related genes that are transcribed together to give a single polycistronic mRNA is known as an *operon*. Assembling genes for the same biochemical pathway or genes needed under the same conditions into an operon allows their expression to be coordinated. Often, transcription of an operon is controlled by a specific region of the DNA just upstream of the protein-coding region of the operon. This is considered in more detail in Chapter 7.

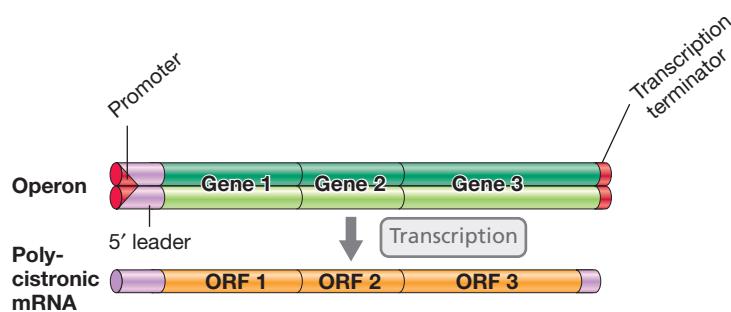

Figure 4.25 Operon and polycistronic mRNA structure in prokaryotes. Note that a single promoter controls the three genes within the operon and that the polycistronic mRNA molecule contains an open-reading frame (ORF) corresponding to each gene.

4.9 Transcription in Archaea and Eukarya

So far we have focused on transcription in *Bacteria* using *Escherichia coli* as a model system. Although in both *Archaea* and *Eukarya* the overall flow of genetic information from DNA to RNA is the same as in *Bacteria*, some details differ, and in eukaryotic cells the presence of a nucleus complicates the routing of genetic information. While *Archaea* lack a nucleus, many of their molecular properties resemble *Eukarya* more closely than *Bacteria*. These shared central dogma features confirm that these two domains are more closely related to each other than either is to *Bacteria* (☞ Section 1.3). However, *Archaea* also share transcriptional similarities to *Bacteria*, such as operons. Units of transcription in eukaryotes include only one gene. Here we discuss key elements of transcription in *Archaea* and *Eukarya* that differ from those of *Bacteria*.

Archaeal and Eukaryotic RNA Polymerases

Archaeal and eukaryotic RNA polymerases are more similar and structurally more complex than those of *Bacteria*. *Archaea* contain only a single RNA polymerase that most closely resembles eukaryotic RNA polymerase II. The archaeal RNA polymerase typically has 11 or 12 subunits, while eukaryotic RNA polymerase II has 12 or more subunits. This is in sharp contrast to the RNA polymerase from *Bacteria* that is made up of only four different subunits plus the sigma (recognition) subunit (Figure 4.21).

We learned in Section 4.7 the importance of the promoter to transcription. The structure of archaeal promoters resembles those of eukaryotic promoters recognized by eukaryotic RNA polymerase II more than the promoters of *Bacteria*. *Eukarya* differ from both *Archaea* and *Bacteria* by having multiple RNA polymerases. Within the nucleus three separate RNA polymerases exist and transcribe different categories of genes. Mitochondria and chloroplasts also possess specific RNA polymerases, but, not surprisingly, considering the phylogenetic connections between *Bacteria* and eukaryotic cell organelles (☞ Figure 1.6b), these are more closely related to the RNA polymerase of *Bacteria*.

Promoters and Terminators in Archaea and Eukarya

Three main recognition sequences are part of the promoters in both prokaryotic domains, and these sequences are recognized by a series of proteins called *transcription factors* that are similar in *Eukarya* and *Archaea*. The most important recognition sequence in archaeal and eukaryotic promoters is the 6- to 8-base-pair “TATA” box, located 18–27 nucleotides upstream of the transcriptional start site (Figure 4.26). This is recognized by the *TATA-binding protein* (TBP). Upstream of the TATA box is the *B recognition element* (BRE) sequence that is recognized by transcription factor B (TFB). In addition, an initiator element sequence is located at the start of transcription. Once TBP has bound to the TATA box and TFB has bound to the BRE, then archaeal RNA polymerase can bind and initiate transcription. This process is similar in eukaryotes except that several additional transcription factors are required.

Less is known about transcription termination in *Archaea* and *Eukarya* than in *Bacteria* (Section 4.7). Some archaeal genes have inverted repeats followed by an AT-rich sequence similar to those found in many bacterial transcription terminators. However, such termination sequences are not found in all archaeal genes. One other type of suspected transcription terminator lacks inverted repeats but contains repeated runs of thymines. In some way, this signals the archaeal termination machinery to terminate transcription. In eukaryotes, termination differs depending on the RNA polymerase and often requires a specific termination factor protein. No Rho-like proteins (Section 4.7) have been found in either *Archaea* or *Eukarya*.

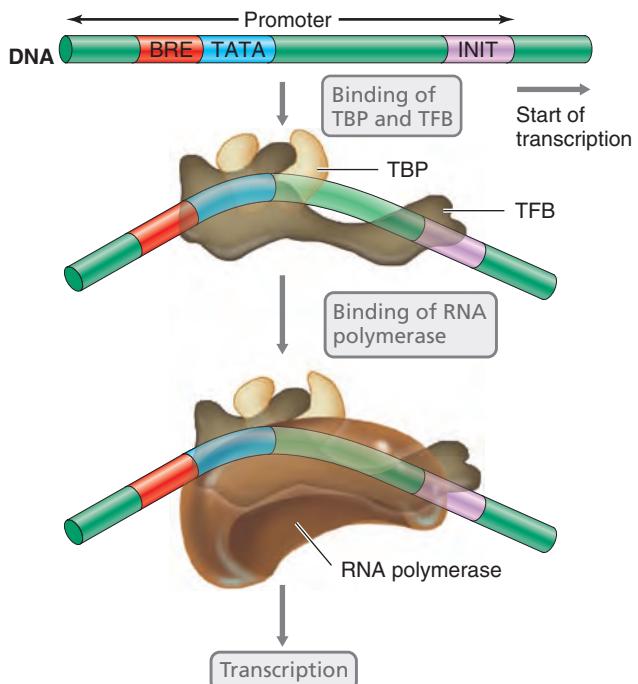

Figure 4.26 Promoter architecture and transcription in *Archaea*. Three promoter elements are critical for promoter recognition in *Archaea*: the initiator element (INIT), the TATA box, and the B recognition element (BRE). The TATA-binding protein (TBP) binds the TATA box; transcription factor B (TFB) binds to both BRE and INIT. Once both TBP and TFB are in place, RNA polymerase binds.

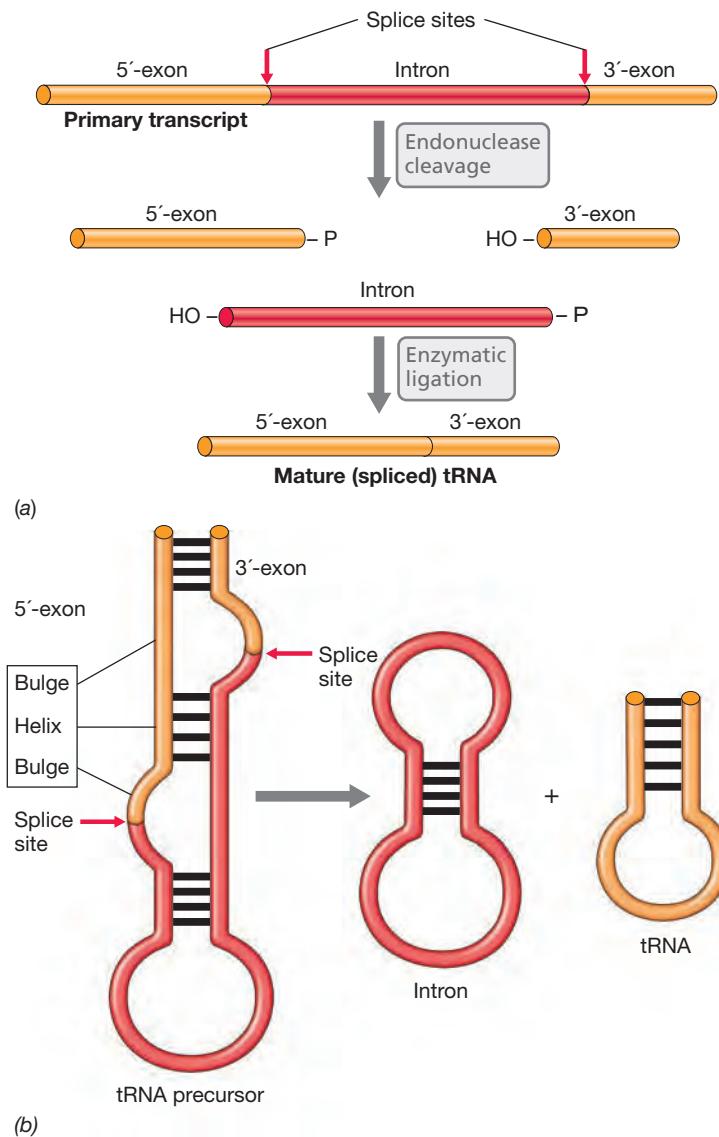

Figure 4.27 Splicing of archaeal introns. **(a)** Reaction scheme. Removal of archaeal introns is a two-step reaction. In the first step a specific endonuclease excises the intron. In the second step a ligase joins the 5'-exon to the 3'-exon, generating the mature, spliced tRNA. **(b)** Folding of the tRNA precursor. The two splice sites (red arrows) are recognized by their characteristic “bulge-helix-bulge” motifs. The products of the reaction are the tRNA and a circular intron.

Intervening Sequences in Archaea

As is the case in *Bacteria*, intervening sequences in genes that encode proteins are extremely rare in *Archaea*. This is in contrast to *Eukarya*, in which many such genes are split into two or more coding regions separated by noncoding regions. These RNA molecules require alterations—known as **RNA processing**—before they are *mature*; that is, ready to carry out their role in the cell. The segments of coding sequence are called **exons**, while **introns** are the intervening noncoding regions. The term **primary transcript** refers to the RNA molecule that is originally transcribed before the introns are removed to generate the final mRNA, consisting solely of the exons. Several tRNA- and rRNA-encoding genes of *Archaea* possess introns that must be removed after transcription to generate the mature tRNA or rRNA. These introns were

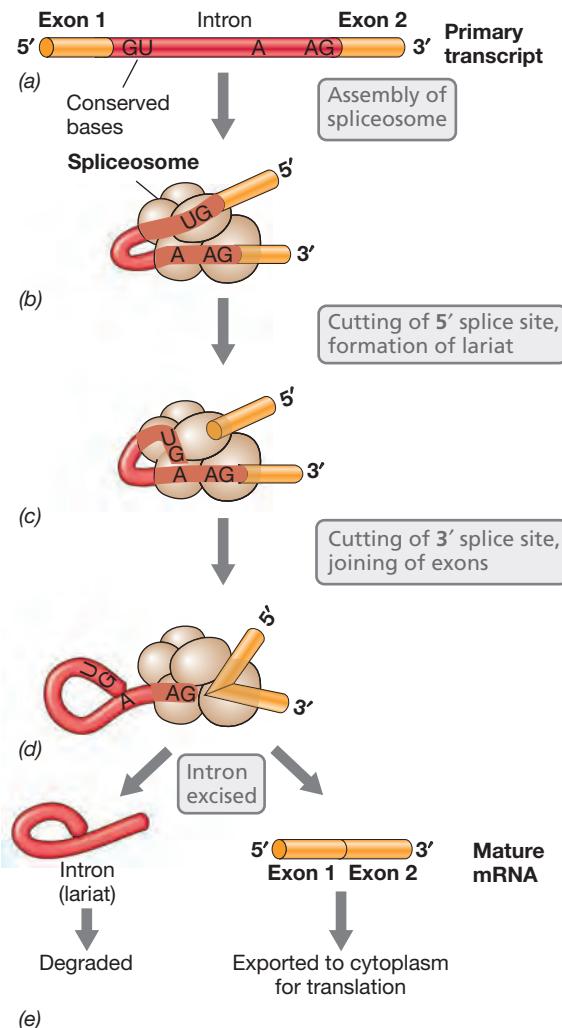

Figure 4.28 Activity of the spliceosome. Removal of an intron from the primary transcript of a protein-coding gene in a eukaryote. **(a)** A primary transcript containing a single intron. The sequence GU is conserved at the 5' splice site, and AG is conserved at the 3' splice site. There is also an interior A that serves as a branch point. **(b)** Several small ribonucleoprotein particles (shown in brown) assemble on the RNA to form a spliceosome. Each of these particles contains distinct small RNA molecules that take part in the splicing mechanism. **(c)** The 5' splice site has been cut with the simultaneous formation of a branch point. **(d)** The 3' splice site has been cut and the two exons have been joined. Note that overall, two phosphodiester bonds were broken, but two others were formed. **(e)** The final products are the joined exons (the mRNA) and the released intron.

named archaeal introns because they are processed by a different mechanism than are typical eukaryotic introns. Archaeal introns are excised by a specific ribonuclease that recognizes exon-intron junctions (Figure 4.27). In a few cases, tRNAs in *Archaea* are assembled by splicing together segments from two or three different primary transcripts.

RNA Processing in Eukaryotes

Most primary transcripts in eukaryotes contain introns and thus require RNA processing before they can function in the cell. The process by which introns are removed and exons are joined in eukaryotes is called *splicing* (Figure 4.28). RNA splicing occurs in the nucleus and is done by a large macromolecular complex

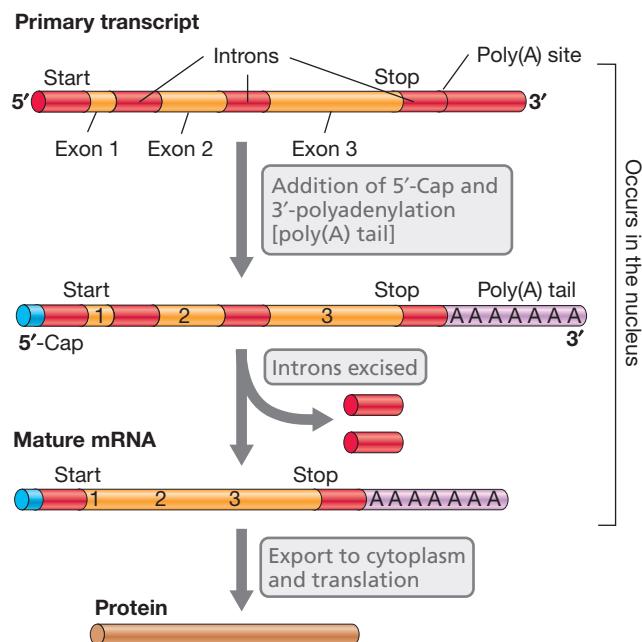

Figure 4.29 Processing of the primary transcript into mature mRNA in eukaryotes. The processing steps include adding a cap at the 5' end, removing the introns, and clipping the 3' end of the transcript while adding a poly(A) tail. All these steps are carried out in the nucleus. The location of the start and stop codons to be used during translation are indicated.

called the **spliceosome**. The proteins of the spliceosome cut out the intron and join the flanking exons together to form a contiguous protein-coding sequence in the mature mRNA. Many genes, especially in higher animals and plants, have multiple introns, so it is clearly important that they should all be recognized and removed by the spliceosome to generate the final mature mRNA (Figure 4.29).

There are two other steps in the processing of mRNA in *Eukarya* that are unique to this domain. Both steps take place in the nucleus prior to splicing. The first, called *capping*, occurs before transcription is complete. Capping is the addition of a methylated guanine nucleotide at the 5' -phosphate end of the mRNA (Figure 4.29). The cap nucleotide is added in reverse orientation relative to the rest of the mRNA molecule and is needed to initiate translation. The second consists of trimming the 3' end of the primary transcript and adding 100–200 adenylate residues, called the *poly(A) tail* (Figure 4.29). The tail recognition sequence, AAUAAA, is located close to the 3' end of the primary transcript. The poly(A) tail stabilizes mRNA and must be removed before the mRNA can be degraded.

IV • Protein Synthesis

Once transcription has occurred and mRNAs are made, the transcripts are translated into protein. This requires many proteins, other RNAs, and a key cellular structure, the ribosome. How these interact to produce a cell's array of proteins is what we consider now.

4.10 Polypeptides, Amino Acids, and the Peptide Bond

Proteins play major roles in cell function. Two major classes of proteins are *catalytic proteins* (enzymes) and *structural proteins*. **Enzymes** are the catalysts for chemical reactions that occur in cells. Structural proteins are integral parts of the major structures of the cell: membranes, walls, ribosomes, and so on. Regulatory proteins control most cell processes by a variety of mechanisms, including binding to DNA and affecting transcription. However, all proteins show certain basic features in common.

Proteins are polymers of **amino acids**. All amino acids contain an amino group ($-NH_2$) and a carboxylic acid group ($-COOH$) that are attached to the α -carbon (Figure 4.30a). Linkages between the carboxyl carbon of one amino acid and the amino nitrogen of a second (with elimination of water) are known as **peptide bonds** (Figure 4.31). Two amino acids bonded by peptide linkage constitute a *dipeptide*; three amino acids, a *tripeptide*; and so on. When many amino acids are linked, they form a **polypeptide**. A protein consists of one or more polypeptides. The number of amino acids

differs greatly from one protein to another, from as few as 15 to as many as 10,000.

Each amino acid has a unique side chain (abbreviated R). These vary considerably, from as simple as a hydrogen atom in the amino acid glycine to aromatic rings in phenylalanine, tyrosine, and tryptophan (Figure 4.30b). Amino acids exist as pairs of **enantiomers**. These are optical isomers that have the same molecular and structural formulas, except that they are mirror images and are designated as either D or L, depending on whether a pure solution rotates light to the right or left, respectively. Cellular proteins are composed of only L-amino acids. Nevertheless, D-amino acids are occasionally found in cells, most notably in the cell wall polymer peptidoglycan (Section 2.10) and in certain peptide antibiotics (Section 27.14). Cells can interconvert enantiomers by enzymes called *racemases*.

The chemical properties of an amino acid are governed by its side chain. Amino acids with similar chemical properties are grouped into related "families" (Figure 4.30b). For example, the side chain may contain a carboxylic acid group, as in aspartic acid or glutamic acid, rendering the amino acid acidic. Others contain additional amino groups, making them positively charged and basic. Several amino acids contain hydrophobic side chains and are called nonpolar amino acids. Cysteine contains a sulphydryl group ($-SH$). Using their sulphydryl groups, two cysteines can form a disulfide linkage ($R-S-S-R$) that connects two polypeptide chains.

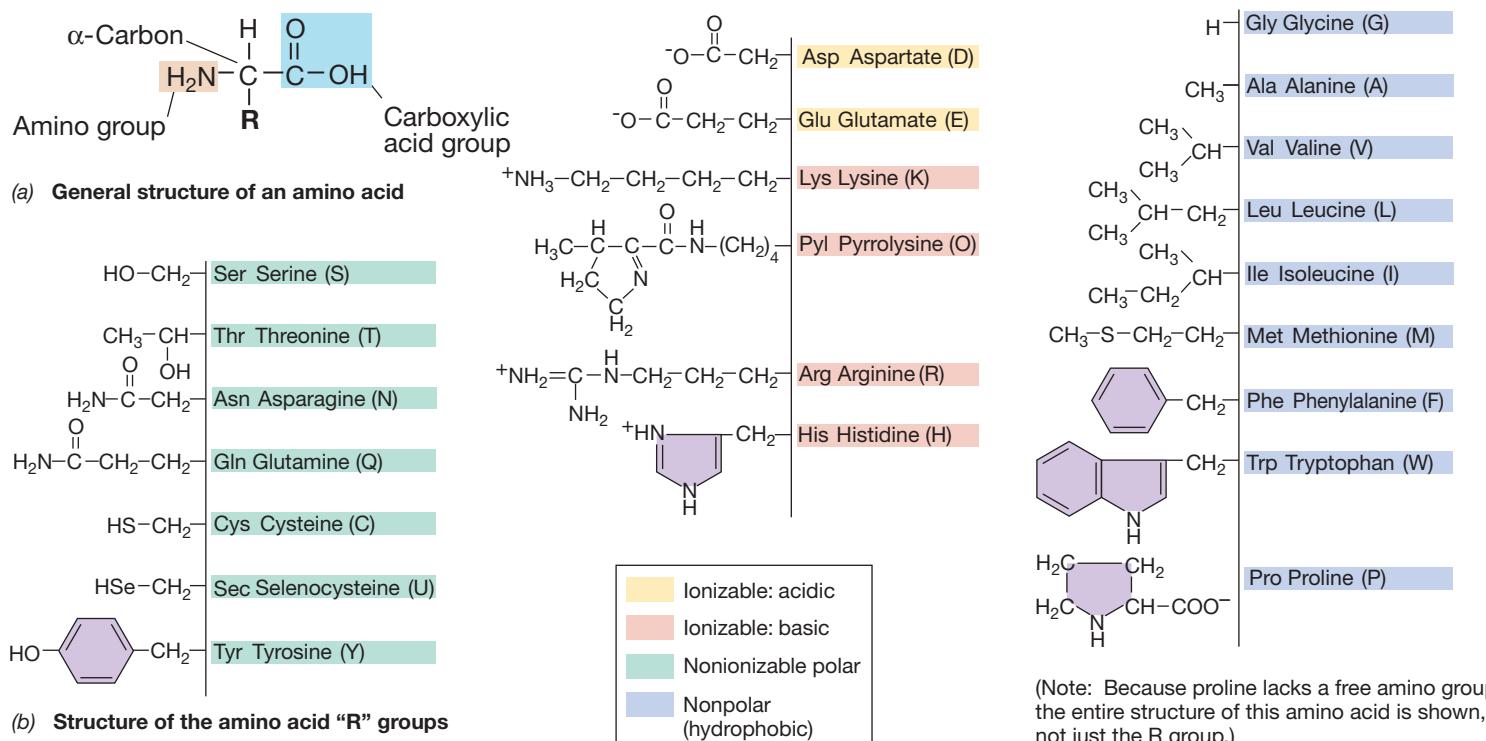

Figure 4.30 Structure of the 22 genetically encoded amino acids. (a) General structure. (b) R group structure. The three-letter codes for the amino acids are to the left of the names, and the one-letter codes are in parentheses to the right of the names. Pyrrolysine has thus far been found only in certain methanogenic Archaea (Section 16.2).

The diversity of chemically distinct amino acids makes possible an enormous number of unique proteins with widely different biochemical properties. If one assumes that an average polypeptide contains 300 amino acids, then 22^{300} different polypeptide sequences are theoretically possible. No cell has anywhere near this many different proteins. A cell of *Escherichia coli* contains around 2000 different kinds of proteins, with the exact number being highly dependent on the resources (nutrients) and growth conditions employed.

The linear sequence of amino acids in a polypeptide is its *primary structure*. This ultimately determines the further folding of the polypeptide, which in turn determines its biological activity (Section 4.14). The two ends of a polypeptide are designated as the “C-terminus” and “N-terminus” depending on whether a free carboxylic acid group or a free amino group is found (Figure 4.31).

activity (Section 4.14). The two ends of a polypeptide are designated as the “C-terminus” and “N-terminus” depending on whether a free carboxylic acid group or a free amino group is found (Figure 4.31).

- Which enantiomeric form of amino acids is found in proteins?
- Glycine does not have two different enantiomers; why?

4.11 Translation and the Genetic Code

As we have seen, in the first two steps of biological information transfer—replication and transcription—nucleic acids are synthesized on nucleic acid templates. The last step, *translation*, also uses a nucleic acid as template, but in this case the product is a polypeptide rather than a nucleic acid. The heart of biological information transfer is the correspondence between the nucleic acid template and the amino acid sequence of the polypeptide formed. This correspondence is rooted in the **genetic code**. An RNA triplet of three bases, called a *codon*, encodes each specific amino acid. The 64 possible codons (four bases taken three at a time = 4^3) of mRNA are shown in Table 4.5. The genetic code is written as RNA rather than as DNA because it is mRNA that is actually translated. Note that in addition to the codons for amino acids, there are also specific codons for starting and stopping translation. Here we focus on translation in *Bacteria*, but it

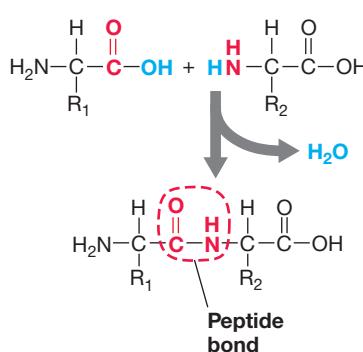

Figure 4.31 Peptide bond formation. R₁ and R₂ refer to the side chains of the amino acids. Note that following peptide bond formation, a free OH group is present at the C-terminus for formation of the next peptide bond.

^aAUG encodes N-formylmethionine at the beginning of polypeptide chains of *Bacteria*.

is important to note that the translation machinery of *Archaea* and *Eukarya* are more closely related to each other than to that of *Bacteria*.

Properties of the Genetic Code

There are 22 amino acids that are encoded by the genetic information carried on mRNA (some other amino acids are formed by modification of these after translation). Consequently, because there are 64 codons, many amino acids can be encoded by more than 1 codon. Although knowing the codon at a given location unambiguously identifies the corresponding amino acid, the reverse is not true. Knowing the amino acid does not mean that the codon at that location is known. A code such as this that lacks one-to-one correspondence between “word” (that is, the amino acid) and code (codon) is called a *degenerate code*. However, knowing the DNA sequence and the correct reading frame, one can specify the amino acid sequence of a protein. This permits the determination of amino acid sequences from DNA base sequences and is at the heart of genomics (Chapter 6).

A codon is recognized by specific base pairing with a complementary sequence of three bases called the **anticodon**, which is part of tRNAs. If this base pairing were always the standard pairing of A with U and G with C, then at least one specific tRNA would be needed to recognize each codon. In some cases, this is true. For instance, there are six different tRNAs in *Escherichia coli* for the amino acid leucine, one for each codon (Table 4.5). By contrast, some tRNAs can recognize more than one codon. Thus, although there are two lysine codons in *E. coli*, there is only one lysyl tRNA, whose anticodon can base-pair with either AAA or AAG. In these special cases, tRNA molecules form standard base pairs at only the first two positions of the codon while tolerating irregular base pairing at the third position. This phenomenon

is called **wobble** and is illustrated in Figure 4.32, where a pairing between G and U (rather than G with C) is illustrated at the wobble position.

Several amino acids are encoded by multiple codons, and in most cases, the multiple codons are closely related in base sequence (Table 4.5). One might assume that such multiple codons would be used at equal frequencies. However, this is not so, and genomic sequence data have revealed organism-specific **codon bias**. In other words, some codons are greatly preferred over others even though they encode the same amino acid. Codon bias is correlated with a corresponding bias in the concentration of different tRNA molecules. Thus a tRNA corresponding to a rarely used codon will be in relatively short supply. Codon bias must be taken into consideration during genetic engineering. For example, a gene from one organism whose codon usage differs

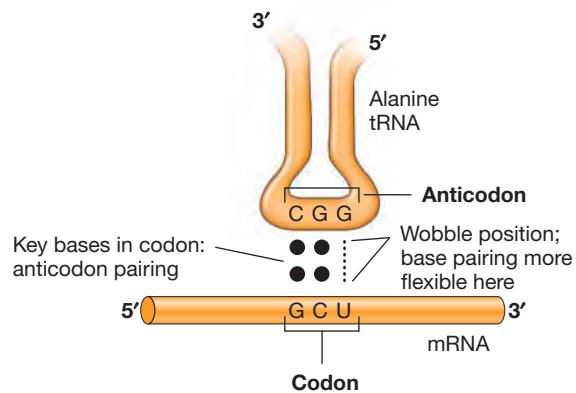

Figure 4.32 The wobble concept. Base pairing is more flexible for the third base of the codon than for the first two. Only a portion of the tRNA is shown here.

dramatically from that of another may not be translated efficiently if the gene is cloned into the latter using genetic engineering techniques (Chapter 11).

Open Reading Frames

One common method of identifying protein-encoding genes is to examine each strand of the DNA sequence for **open reading frames (ORFs)**. If an mRNA can be translated, it contains an open reading frame: a start codon (typically AUG) followed by a number of codons and then a stop codon in the same reading frame as the start codon. In practice, only ORFs long enough to encode a functional polypeptide are accepted as true coding sequences. Although most functional proteins are at least 100 amino acids in length, a few protein hormones and regulatory peptides are much shorter. Consequently, it is not always possible to tell from sequence data alone whether a relatively short ORF is merely due to chance or encodes a genuine, albeit short, polypeptide.

Using computational methods, a long DNA base sequence can be scanned to look for open reading frames. In addition to looking for start and stop codons, the search may include promoters and ribosome-binding sequences as well. The search for ORFs is very important in genomics (Chapter 6). If an unknown piece of DNA has been sequenced, the presence of an ORF implies that it can encode protein.

Start and Stop Codons and Reading Frame

Messenger RNA is translated beginning with its **start codon** (AUG, Table 4.5), which encodes a chemically modified methionine in *Bacteria* called *N-formylmethionine*. Although AUG at the *beginning* of a coding region encodes *N*-formylmethionine, AUG *within* the coding region encodes methionine. Two different tRNAs are involved in this process (Section 4.13). Conversely, *Archaea* and *Eukarya* insert a regular methionine as the first amino acid in a polypeptide.

With a triplet code it is critical for translation to begin at the correct nucleotide. If it does not, the whole reading frame of the mRNA will be shifted and thus an entirely different protein will be made. Alternatively, if the shift introduces a stop codon into the reading frame, the polypeptide will terminate prematurely. By convention, the reading frame that when translated yields the polypeptide encoded by the gene is called the *0 frame* (zero frame). As can be seen in Figure 4.33, the other two possible reading frames (*-1* and *+1*) do not encode the same amino acid sequence. Therefore, it is essential that the ribosome finds the correct start codon to begin translation and, once it has, that the mRNA is translocated exactly three bases at a time. How is the correct reading frame ensured?

Reading frame fidelity is governed by interactions between mRNA and rRNA within the ribosome. In prokaryotes, ribosomal RNA recognizes a specific AUG on the mRNA as a start codon with the aid of an upstream sequence in the mRNA called the *ribosome-binding site* (RBS) or Shine–Dalgarno sequence. This alignment requirement explains why some mRNAs from *Bacteria* can use other start codons, such as GUG. However, even these unusual start codons direct the incorporation of *N*-formylmethionine as the initiator amino acid.

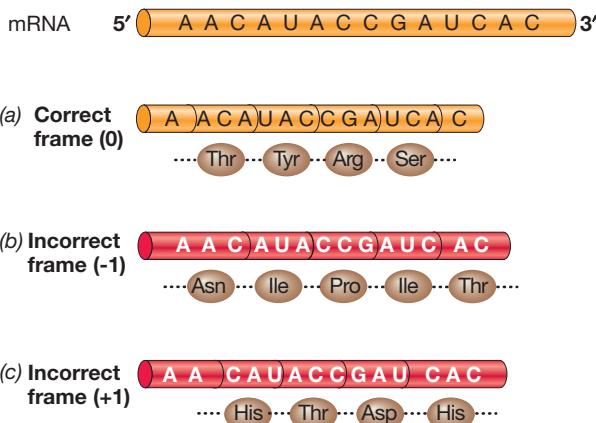

Figure 4.33 Possible reading frames in an mRNA. An interior sequence of an mRNA is shown. (a) The amino acids that would be encoded if the ribosome is in the correct reading frame (designated the “0” frame). (b) The amino acids that would be encoded by this region of the mRNA if the ribosome were in the -1 reading frame. (c) The amino acids that would be encoded if the ribosome were in the $+1$ reading frame.

A few codons do not encode any amino acid. These codons (UAA, UAG, and UGA, Table 4.5) are the **stop codons**, and they signal the termination of translation of a protein-coding sequence on the mRNA. Stop codons are also called **nonsense codons**, because they interrupt the “sense” of the growing polypeptide when they terminate translation. A few exceptions to this rule exist. For example, animal (but not plant) mitochondria use the codon UGA to encode tryptophan instead of using it as a stop codon (Table 4.5), while the genus *Mycoplasma* (*Bacteria*) and the genus *Paramecium* (*Eukarya*) use certain nonsense codons to encode amino acids. These organisms simply have fewer nonsense codons because one or two of them are used as sense codons (► Section 6.5).

In a few rare cases, nonsense codons encode unusual amino acids rather than one of the 20 common amino acids. These exceptions are selenocysteine and pyrrolysine, the 21st and 22nd genetically encoded amino acids (Figure 4.30). Both selenocysteine and pyrrolysine are encoded by stop codons (UGA and UAG, respectively). Both have their own tRNAs that contain anticodons that read these stop codons. Most stop codons in organisms that use selenocysteine and pyrrolysine do indeed indicate stop. However, occasional stop codons are recognized as encoding selenocysteine or pyrrolysine. This switch is controlled by a recognition sequence just downstream of the now coding stop codon. Selenocysteine and pyrrolysine are both relatively rare. Most organisms, including plants and animals, have a few proteins that contain selenocysteine. Pyrrolysine is rarer still. It has been found in certain *Archaea* and *Bacteria* but was first discovered in species of methanogenic *Archaea*.

4.12 Transfer RNA

A transfer RNA carries the anticodon that base-pairs with the codon on mRNA. In addition, each tRNA is specific for the amino acid that corresponds to its own anticodon (that is, its *cognate* amino acid). The tRNA and its specific amino acid are linked by specific enzymes called **aminoacyl-tRNA synthetases**. For each amino acid, a separate aminoacyl-tRNA synthetase exists that specifically binds to both the amino acid and tRNAs possessing corresponding anticodons. These enzymes ensure that each tRNA receives its correct amino acid, so they must recognize both a specific tRNA and its cognate amino acid.

General Structure of tRNA

There are about 60 different tRNAs in bacterial cells and 100–110 in mammalian cells. Transfer RNA molecules are short, single-stranded molecules that contain extensive secondary structure and are 73–93 nucleotides long. Certain bases and secondary structures are constant for all tRNAs, whereas other parts are variable. Transfer RNA molecules also contain some purine and pyrimidine bases that are chemically modified from the standard bases found in RNA. These modifications are made to the bases after transcription. These unusual bases include pseudouridine (ψ), inosine, dihydrouridine (D), ribothymidine, methyl guanosine, dimethyl guanosine, and methyl inosine. The mature and active tRNA also contains extensive double-stranded regions within the molecule. This secondary structure forms by internal base pairing when the single-stranded molecule folds back on itself (Figure 4.34).

The structure of a tRNA can be drawn in a cloverleaf fashion, as shown in Figure 4.34a. Some regions of tRNA secondary structure

are named after the modified bases found there (for example, the T ψ C and D loops) or after their functions (for example, the anticodon loop and acceptor stem). The three-dimensional structure of a tRNA is shown in Figure 4.34b. Note that bases that appear widely separated in the cloverleaf model may actually be much closer together when viewed in three dimensions. This close proximity allows some of the bases in one loop to base-pair with bases in another loop.

The Anticodon and the Amino Acid-Binding Site

One of the key variable parts of the tRNA molecule is the *anticodon*, the group of three bases that recognizes the codon on the mRNA. The anticodon is found in the anticodon loop (Figure 4.34). The three nucleotides of the anticodon recognize the codon by specifically pairing with its three bases. By contrast, other portions of the tRNA interact with both the rRNA and protein components of the ribosome, nonribosomal translation proteins, and the aminoacyl-tRNA synthetase enzyme.

At the 3' end (acceptor stem) of all tRNAs are three unpaired nucleotides. The sequence of these three nucleotides is always cytosine-cytosine-adenine (CCA), and they are absolutely essential for function. Curiously, however, in most organisms the 3' CCA is not encoded in the tRNA gene on the chromosome. Instead, each nucleotide is added one by one by a protein called *CCA-adding enzyme*, using CTP and ATP as substrates. The cognate amino acid is then covalently attached to the terminal adenosine of the CCA end of its corresponding tRNA by an ester linkage to the ribose sugar. As we shall see, from this location on the tRNA, the amino acid is incorporated into the growing polypeptide chain on the ribosome by a mechanism described in the next section.

Recognition, Activation, and Charging of tRNAs

Recognition of the correct tRNA by an aminoacyl-tRNA synthetase involves specific contacts between key regions of the tRNA and the synthetase (Figure 4.35). As might be expected because of its unique sequence, the anticodon of the tRNA is important in recognition by the synthetase. However, other contact sites between the tRNA and the synthetase are also important. Studies of tRNA binding to aminoacyl-tRNA synthetases in which specific tRNA bases have been changed by mutation have shown that only a small number of key nucleotides in tRNA are involved in recognition. These other key recognition nucleotides are often part of the acceptor stem or D loop of the tRNA (Figure 4.34). It should be emphasized that the fidelity of this recognition process is crucial, for if the wrong amino acid is attached to the tRNA, it will be inserted into the growing polypeptide, likely leading to the synthesis of a faulty protein.

The specific reaction between amino acid and tRNA catalyzed by the aminoacyl-tRNA synthetase begins with activation of the amino acid by reaction with ATP:

The aminoacyl-AMP intermediate formed normally remains bound to the tRNA synthetase until collision with the appropriate

tRNA molecule. Then, as shown in Figure 4.35a, the activated amino acid is attached to the tRNA to form a *charged tRNA*:

The pyrophosphate (PP_i) formed in the first reaction is split by a pyrophosphatase, giving two molecules of inorganic phosphate. Because ATP is used and AMP is formed in these reactions, a total of two energy-rich phosphate bonds are expended to charge a tRNA with its cognate amino acid. After activation and charging, the aminoacyl-tRNA leaves the synthetase until it is bound by a ribosome where actual polypeptide synthesis occurs.

4.13 Protein Synthesis

It is vital for proper functioning of proteins that the correct amino acids be inserted at their correct locations in the polypeptide chain. This is the task of the protein-synthesizing machinery, the

ribosome. Although protein synthesis is a continuous process, it can be broken down into a number of steps: *initiation*, *elongation*, and *termination*. In addition to mRNA, tRNA, and ribosomes, the process requires a number of proteins designated initiation, elongation, and termination factors. The energy-rich compound guanosine triphosphate (GTP) provides the necessary energy for the process.

Ribosomes

Ribosomes are the sites of protein synthesis. A cell may have many thousand ribosomes, the number increasing at higher growth rates. Each ribosome consists of two subunits. Prokaryotes have 30S and 50S ribosomal subunits that yield intact 70S ribosomes. The S-values are *Svedberg units*, which refer to the sedimentation coefficients of ribosomal subunits (30S and 50S) or intact ribosomes (70S) when subjected to centrifugal force in an ultracentrifuge. (Although larger particles do have larger S-values, the relationship is not linear and thus S-values cannot simply be summed.)

Each ribosomal subunit contains specific ribosomal RNAs and ribosomal proteins. The 30S subunit contains 16S rRNA and 21 proteins, and the 50S subunit contains 5S and 23S rRNA and 31 proteins. Thus, in *Escherichia coli*, there are 52 distinct ribosomal proteins, most present at one copy per ribosome. The ribosome is a dynamic structure whose subunits alternately associate and dissociate and also interact with many other proteins. Several proteins that are essential for ribosome function interact with the ribosome at various stages of translation. These are regarded as “translation factors” rather than “ribosomal proteins” per se.

Initiation of Translation

In *Bacteria*, such as *E. coli*, initiation of protein synthesis begins with a free 30S ribosomal subunit (Figure 4.36). From this, an initiation complex forms consisting of the 30S subunit, mRNA, formylmethionine tRNA, and several initiation proteins called IF1, IF2, and IF3. GTP is also required for this step. Next, a 50S ribosomal subunit is added to the initiation complex to form the active 70S ribosome. At the end of the translation process, the ribosome separates again into 30S and 50S subunits.

Just preceding the start codon on the mRNA is a sequence of three to nine nucleotides called the ribosome-binding site (RBS in Figure 4.36) that helps bind the mRNA to the ribosome. The ribosome-binding site is toward the 5' end of the mRNA and is complementary to base sequences in the 3' end of the 16S rRNA. Base pairing between these two molecules holds the ribosome-mRNA complex securely together in the correct reading frame. Polycistronic mRNA has multiple RBS sequences, one upstream of each coding sequence. This allows bacterial ribosomes to translate several genes on the same mRNA because the ribosome can find each initiation site within a message by binding to its RBS.

Translational initiation always begins with a special initiator aminoacyl-tRNA binding to the start codon, AUG. In *Bacteria* this is formylmethionyl-tRNA. After polypeptide completion, the formyl group is removed. Consequently, the N-terminal amino acid of the completed protein will be

methionine. However, in many proteins this methionine is removed by a specific protease.

Elongation, Translocation, and Termination

The mRNA threads through the ribosome primarily bound to the 30S subunit. The ribosome contains other sites where the tRNAs interact. Two of these sites are located primarily on the 50S subunit, and they are termed the A site and the P site (Figure 4.36). The A site, the acceptor site, is the site on the ribosome where the incoming charged tRNA first attaches. Loading of a tRNA into the A site is assisted by the elongation factor EF-Tu.

The P site, or peptide site, is the site where the growing polypeptide chain is held by the previous tRNA. During peptide bond formation, the growing polypeptide chain moves to the tRNA at the A site as a new peptide bond is formed. Several nonribosomal proteins are required for elongation, especially the elongation factors, EF-Tu and EF-Ts, as well as more GTP (to simplify Figure 4.36, the elongation factors are omitted and only part of the ribosome is shown).

Following elongation, the tRNA holding the polypeptide is translocated (moved) from the A site to the P site, thus opening the A site for another charged tRNA (Figure 4.36). Translocation requires the elongation factor EF-G and one molecule of GTP for each translocation event. At each translocation step the ribosome advances three nucleotides, exposing a new codon at the A site. Translocation pushes the now empty tRNA to a third site, called the E site. It is from this exit site that the tRNA is actually released from the ribosome. As one might expect, the precision of the translocation step is critical to the accuracy of protein synthesis. The ribosome must move *exactly* one codon at each step. Although mRNA appears to be moving through the ribosome complex, in reality, the ribosome is moving along the mRNA. Thus, the three sites on the ribosome shown in Figure 4.36 are not static locations but are moving parts of a biomolecular machine.

Several ribosomes can translate a single mRNA molecule simultaneously, forming a complex called a *polysome* (Figure 4.37). Polysomes increase the speed and efficiency of translation simultaneously because each ribosome in a polysome complex makes a complete polypeptide. Note in Figure 4.37 how ribosomes in the polysome complex that are closest to the 5' end (the beginning) of the mRNA molecule have short polypeptides attached to them because only a few codons have been read, while ribosomes closest to the 3' end of the mRNA have nearly finished polypeptides.

Protein synthesis terminates when the ribosome reaches a stop codon (nonsense codon). No tRNA binds to a stop codon. Instead, specific proteins called *release factors* (RFs) recognize the stop codon and cleave the attached polypeptide from the final tRNA, releasing the finished product. Following this, the ribosomal subunits dissociate, and the 30S and 50S subunits are then free to form new initiation complexes and repeat the process.

Role of Ribosomal RNA in Protein Synthesis

Ribosomal RNA plays vital roles in all stages of protein synthesis, from initiation to termination. By contrast, the role of the many

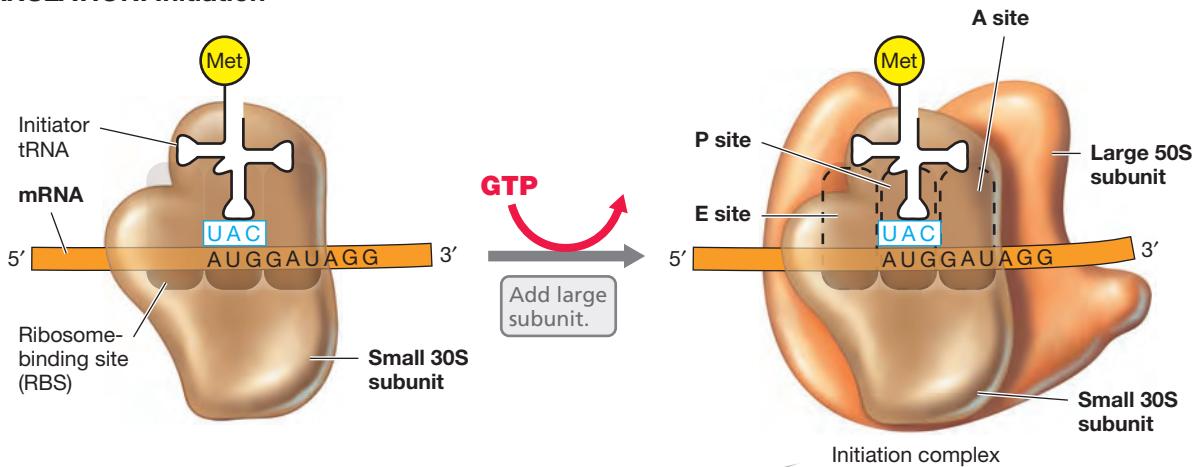

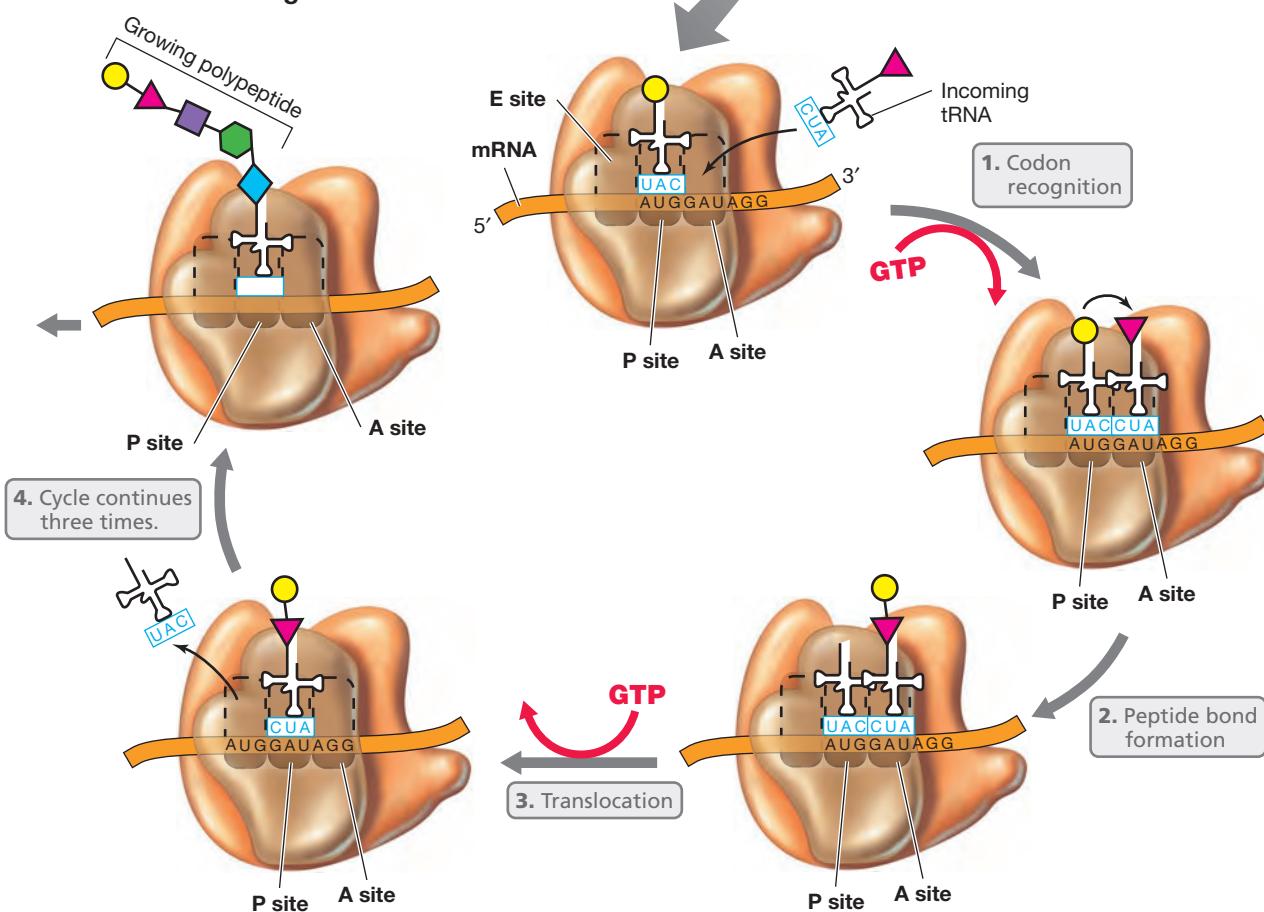

TRANSLATION: Initiation**TRANSLATION: Elongation**

Figure 4.36 The ribosome and protein synthesis. *Initiation* of protein synthesis. The mRNA and initiator tRNA, carrying N-formylmethionine ("Met"), bind first to the small subunit of the ribosome. Initiation factors (not shown) use energy from GTP to promote the addition of the large ribosomal subunit. The initiator tRNA starts out in the P site. *Elongation* cycle of translation. 1. Elongation factors (not shown) use GTP to install the incoming tRNA into the A site. 2. Peptide bond formation is then catalyzed by the 23S rRNA. 3. Translocation of the ribosome along the mRNA from one codon to the next requires hydrolysis of another GTP. The outgoing tRNA is released from the E site. 4. The next charged tRNA binds to the A site and the cycle repeats. The genetic code, expressed in the language of mRNA, is shown in Table 4.5.

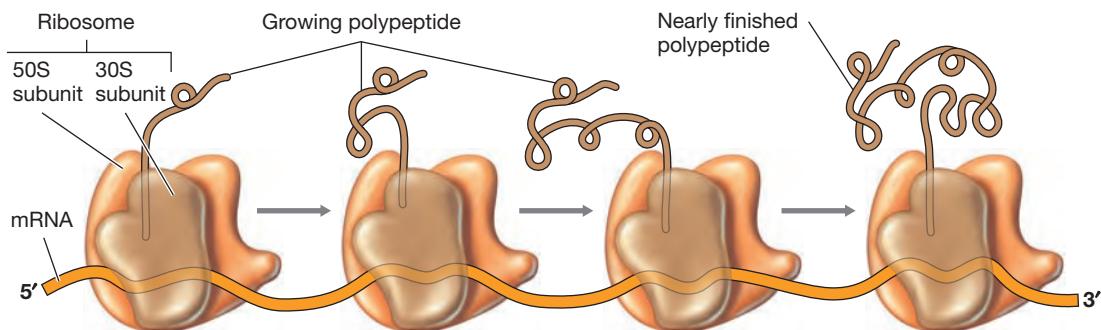

Figure 4.37 Polysomes. Translation by several ribosomes on a single messenger RNA forms the polysome. Note how the ribosomes nearest the 5' end of the message are at an earlier stage in the translation process than ribosomes nearer the 3' end, and thus only a relatively short portion of the final polypeptide has been made.

proteins in the ribosome is to form a scaffold to position key sequences in the ribosomal RNAs.

In *Bacteria* it is clear that 16S rRNA participates in initiation through base pairing with the RBS on the mRNA. Other mRNA–rRNA interactions also occur during elongation. On either side of the codons in the A and P sites, the mRNA is held in position by binding to 16S rRNA and ribosomal proteins. Ribosomal RNA also plays a role in ribosome subunit association, as well as in positioning tRNA in the A and P sites on the ribosome (Figure 4.36). Although charged tRNAs that enter the ribosome recognize the correct codon by codon–anticodon base pairing, they are also bound to the ribosome by interactions of the anticodon stem-loop of the tRNA with specific sequences within 16S rRNA. Moreover, the acceptor end of the tRNA (Figure 4.36) base-pairs with sequences in 23S rRNA.

In addition to all of this, the actual formation of peptide bonds is catalyzed by rRNA. The peptidyl transferase reaction occurs on the 50S subunit of the ribosome and is catalyzed by the 23S rRNA itself, rather than by any of the ribosomal proteins. The 23S rRNA also plays a role in translocation, and the EF proteins interact specifically with 23S rRNA. Thus, besides its role as the structural backbone of the ribosome, ribosomal RNA plays a major catalytic role in the translation process.

Freeing Trapped Ribosomes

A defective mRNA that lacks a stop codon causes a problem in translation. Such a defect may arise, for example, from a mutation that removed the stop codon, defective synthesis of the mRNA, or when partial degradation of an mRNA occurs before it is translated. If a ribosome reaches the end of an mRNA molecule and there is no stop codon, release factor cannot bind and the ribosome cannot be released from the mRNA. The ribosome is effectively “trapped.”

Bacterial cells contain a small RNA molecule, called *tmRNA*, that frees stalled ribosomes (Figure 4.38). The “tm” in its name refers to the fact that tmRNA mimics both a tRNA, in that it carries the amino acid alanine, and mRNA, in that it contains a short stretch of RNA that can be translated. When tmRNA collides with a stalled ribosome, it binds alongside the defective mRNA. Protein synthesis can then proceed, first by adding the alanine on the

tmRNA and then by translating the short tmRNA message. The tmRNA contains a stop codon that allows release factor to bind and disassemble the ribosome. The protein made as a result of this rescue operation is defective and is subsequently degraded. This is accomplished by a short sequence of amino acids encoded by tmRNA and added to the end of the defective protein; the sequence is a signal for a specific protease to degrade the protein. Thus, through the activity of tmRNA, stalled ribosomes are not inactivated but instead are freed up to participate in protein synthesis once again.

MINIQUIZ

- How is a completed polypeptide chain released from the ribosome?
- How does tmRNA free stalled ribosomes?

4.14 Protein Folding and Secretion

For a protein to function properly it must fold correctly after it is synthesized and end up in the correct location in the cell. While many proteins exist inside the cell, some must be transported

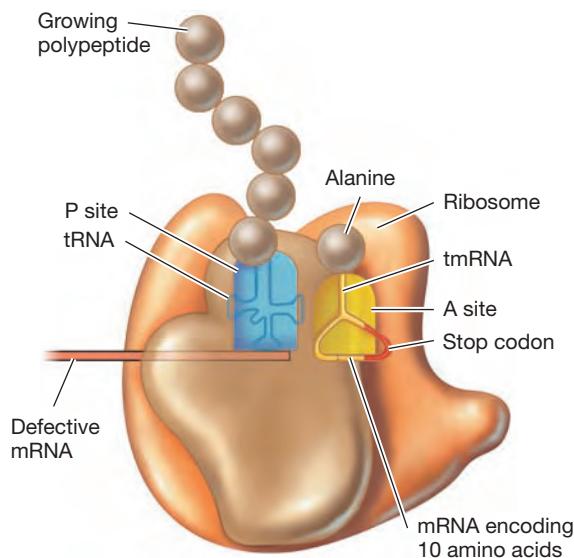

Figure 4.38 Freeing of a stalled ribosome by tmRNA. A defective mRNA lacking a stop codon stalls a ribosome that has a partly synthesized polypeptide attached to a tRNA (blue) in the P site. Binding of tmRNA (yellow) in the A site releases the polypeptide. Translation then continues up to the stop codon provided by the tmRNA.

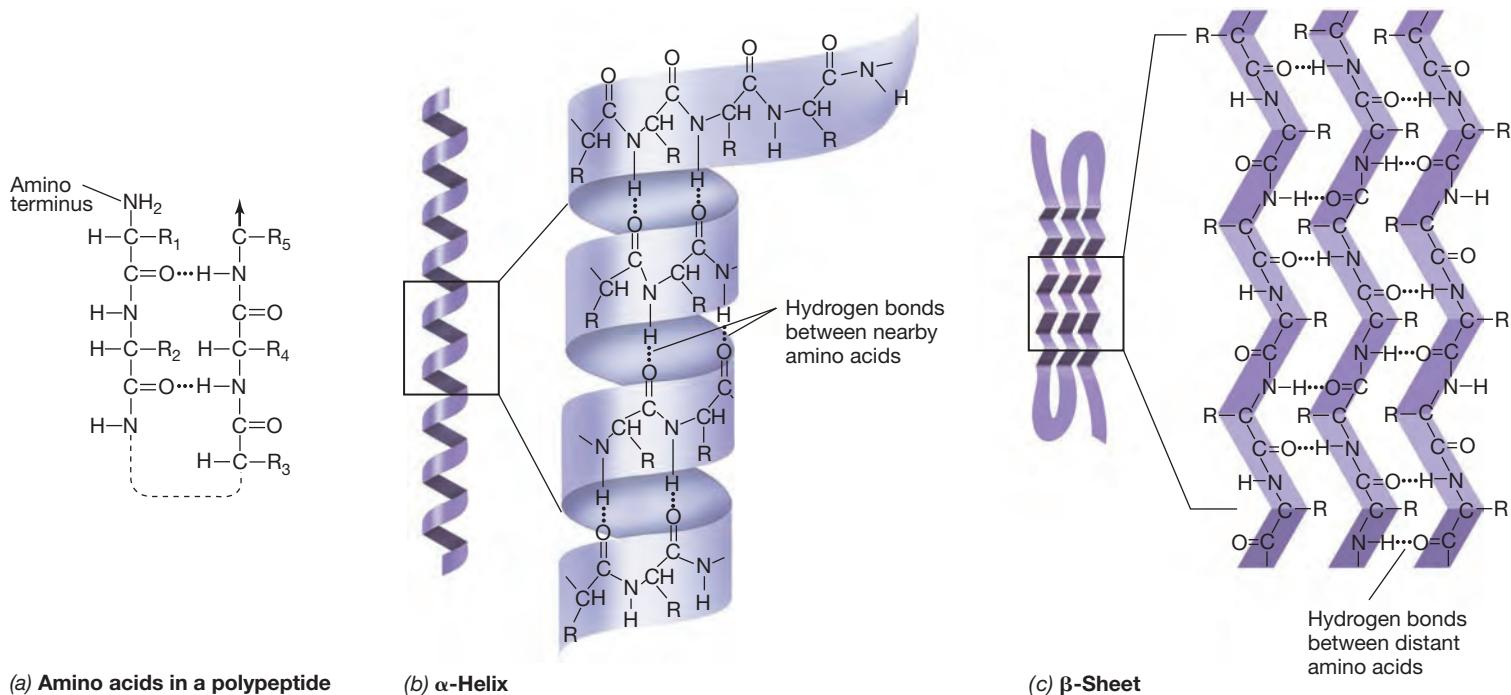

Figure 4.39 Secondary structure of polypeptides. (a) Hydrogen bonding in protein secondary structure. R represents the side chain of the amino acid. (b) α -Helix secondary structure. (c) β -Sheet secondary structure. Note that the hydrogen bonding is between atoms in the peptide bonds and does not involve the R groups.

outside of the cytoplasmic membrane into the periplasm or into the inner or outer membranes to facilitate processes such as ion, sugar, and electron transport. Other proteins such as toxins and extracellular enzymes (exoenzymes) must be secreted from the cell entirely to be active in the environment. How does the cell determine the final conformation and location of proteins? We consider these two related processes now.

Levels of Protein Structure

Once formed, a polypeptide does not remain linear; instead it folds to form a more stable structure. Hydrogen bonding, between the oxygen and nitrogen atoms of two peptide bonds, generates the *secondary structure* (Figure 4.39a). One common type of secondary structure is the α -helix. To envision an α -helix, imagine a linear polypeptide wound around a cylinder (Figure 4.39b). This positions peptide bonds close enough to allow hydrogen bonding. The large number of such hydrogen bonds gives the α -helix its inherent stability. In β -sheet secondary structure, the polypeptide chain folds back and forth upon itself instead of forming a helix. However, as in the α -helix, the folding in a β -sheet positions peptide bonds so that they can undergo hydrogen bonding (Figure 4.39c). Polypeptides can contain regions of both α -helix and β -sheet secondary structure, the type of folding and its location in the molecule being determined by the primary structure and the available opportunities for hydrogen bonding.

Interactions between the R groups of the amino acids in a polypeptide generate two further levels of structure. **Tertiary structure** depends largely on hydrophobic interactions, with lesser contributions from hydrogen bonds, ionic bonds, and disulfide bonds. The tertiary folding generates the overall three-dimensional

shape of each polypeptide chain (Figure 4.40). Many proteins consist of two or more polypeptide chains. **Quaternary structure** refers to the number and type of polypeptides in the final protein. In proteins with quaternary structure, each polypeptide is called a *subunit* and has its own primary, secondary, and tertiary structure. Both tertiary and quaternary structure may be stabilized by disulfide bonds between adjacent sulphydryl groups from cysteine residues (Figure 4.40). If the two cysteine residues are located in different polypeptides, the disulfide bond covalently links the two molecules. Alternatively, a single polypeptide chain can fold and bond to itself if a disulfide bond can form within the molecule.

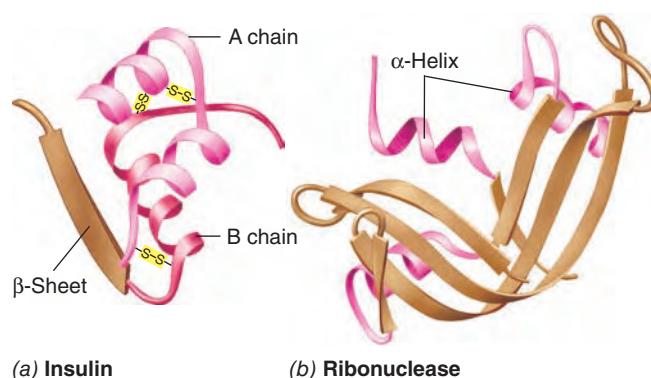

Figure 4.40 Tertiary structure of polypeptides. (a) Insulin, a protein containing two polypeptide chains; note how the B chain contains both α -helix and β -sheet secondary structure and how disulfide linkages (S-S) help in dictating folding patterns (tertiary structure). (b) Ribonuclease, a large protein with several regions of α -helix and β -sheet secondary structure.

When proteins are exposed to extremes of heat or pH or to certain chemicals that affect their folding, they may undergo **denaturation**. This results in the polypeptide chain unfolding. When this occurs, the secondary, tertiary, and quaternary structure of the protein is destroyed along with its biological properties. However, because peptide bonds are not broken, the denatured polypeptide retains its primary structure. Depending on the severity of the denaturing conditions, the polypeptide may properly refold after the denaturant is removed. But if refolding is not correct, the protein cannot function.

Chaperonins Assist Protein Folding

Most polypeptides fold spontaneously into their active form while they are being synthesized. However, some do not and require assistance from other proteins called **chaperonins** (also known as **molecular chaperones**) for proper folding or for assembly into larger complexes. The chaperonins themselves do not become part of the assembly but only assist in folding. Indeed, one important function of chaperonins is to prevent improper aggregation of proteins. Chaperonins are widespread in all domains of life, and their sequences are highly conserved among all organisms.

Four key chaperonins in *Escherichia coli* are the proteins DnaK, DnaJ, GroEL, and GroES. DnaK and DnaJ are ATP-dependent enzymes that bind to newly formed polypeptides and prevent them from folding too quickly, which would increase the risk of improper folding (Figure 4.41). If the DnaKJ complex is unable to fold the protein properly, it may transfer the partially folded protein to the two multi-subunit proteins GroEL and GroES. The protein first enters GroEL, a large barrel-shaped protein that uses the energy of ATP hydrolysis to fold the protein properly. GroES assists in this (Figure 4.41). It is estimated that roughly 100 or so of the several thousand proteins of *E. coli* need help in folding from the GroEL–GroES complex, and of these, approximately a dozen are essential for survival of the bacteria.

In addition to folding newly synthesized proteins, chaperonins can also refold proteins that have partially denatured in the cell. A protein may denature for many reasons, but often it is because the organism has temporarily experienced high temperatures. Chaperonins are thus one type of *heat shock protein*, and their synthesis is greatly accelerated when a cell is stressed by excessive heat (➡ Section 7.10). The heat shock response is an attempt by the cell to refold its partially denatured proteins for reuse before proteases recognize them as improperly folded and destroy them, freeing their amino acids to make new proteins.

Protein Secretion

Many proteins are located in the cytoplasmic membrane, in the periplasm (of gram-negative cells), or even outside the cell proper. Such proteins must get from their site of synthesis on ribosomes into or through the cytoplasmic membrane. Proteins called *translocases* transport specific proteins through and into prokaryotic membranes. For example, the Sec system both exports unfolded proteins and inserts integral membrane proteins into the cytoplasmic membrane, while the Tat system transports proteins folded in the cytoplasm through the membrane. To completely secrete proteins outside of the cell, gram-negative cells must employ additional translocases to transport proteins through the

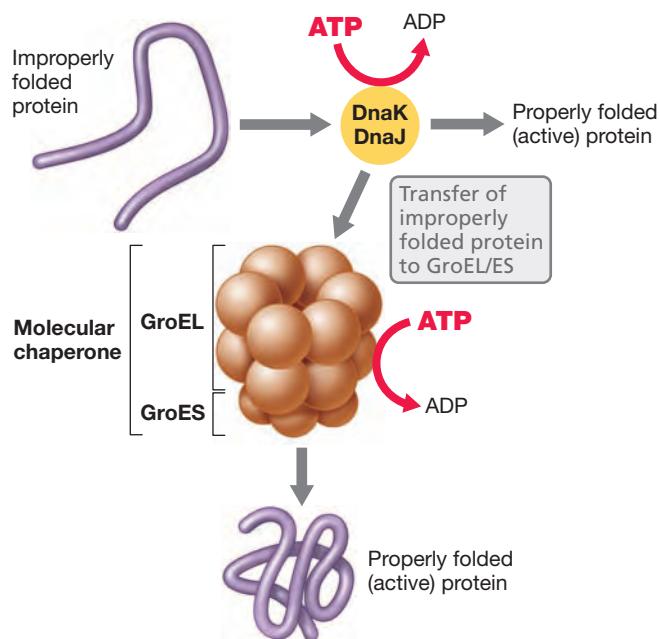

Figure 4.41 The activity of molecular chaperones. An improperly folded protein can be refolded by either the DnaKJ complex or by the GroEL–GroES complex. In both cases, energy for refolding comes from ATP.

outer membrane. At least six different types of secretion systems have been identified, some of which are employed by pathogenic bacteria to excrete toxins or harmful proteins into the host during infection.

Most proteins that must be transported into or through membranes are synthesized with an amino acid sequence of 15–20 residues, called the **signal sequence**, at the beginning (N-terminus, Figure 4.31) of the protein molecule. Signal sequences are variable, but they typically contain a few positively charged amino acids at the beginning, a central region of hydrophobic residues, and then a more polar region at their end. The signal sequence is so called because it “signals” the cell’s secretory system that this particular protein is to be exported and also helps prevent the protein from completely folding, a process that could interfere with its secretion. Because the signal sequence is the first part of the protein to be synthesized, the early steps in export may actually begin before the protein is completely synthesized (Figure 4.42).

Proteins to be exported are recognized by either the *SecA protein* or the *signal recognition particle* (SRP) (Figure 4.42). Typically, SecA binds proteins that are to be exported into the periplasm whereas the SRP binds proteins that are destined to be inserted into the membrane but not released on the other side. SRPs are found in all cells. In *Bacteria*, they contain a single protein and a small noncoding RNA molecule (4.5S RNA). Both SecA and the SRP deliver proteins to the membrane secretion complex, and after crossing the membrane (Sec-mediated) or inserting into the membrane (SRP-mediated), the signal sequence is removed by a protease.

Proteins threaded through the cytoplasmic membrane in an unfolded state by the Sec system fold afterward (Figure 4.42). However, there are a few proteins, such as proteins required for energy metabolism that function in the periplasm, for example,

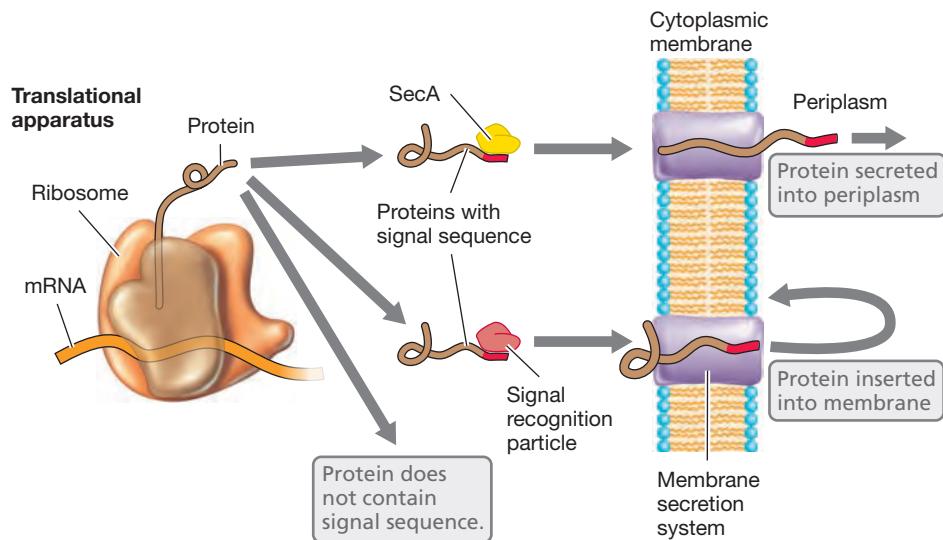

Figure 4.42 Export of proteins via the major secretory system. The signal sequence is recognized either by SecA or by the signal recognition particle, which carries the protein to the membrane secretion system. The signal recognition particle binds proteins that are inserted into the membrane, whereas SecA binds proteins that are secreted across the cytoplasmic membrane.

iron–sulfur proteins and several other redox-coupled proteins (Section 3.10), that must be transported outside the cell after they have already folded. Usually this is because they contain small cofactors that must be inserted into the protein as it folds into its final form. Such proteins fold in the cytoplasm and then are exported by a transport system distinct from Sec, called the *Tat protein export system*. Tat stands for “twin arginine translocase” because the transported proteins have a short signal sequence containing a pair of arginines. This signal sequence on a folded protein is recognized by the TatBC proteins, which carry the protein to TatA, the membrane transporter. Once the protein has been transported to the periplasm using energy supplied by the proton motive force (Section 3.11), the signal sequence is removed by a protease.

Types I through VI Secretion Systems

Several additional systems are used by gram-negative bacteria to deliver proteins into the outer membrane or through the outer membrane to the outside of the cell. These mechanisms are the types I–VI secretion systems. Each of these systems is composed of a large complex of proteins that form a channel through one or more membranes for the secreted molecule to travel through (Figure 4.43).

These diverse systems can be grouped into one- and two-step types. The types II and V systems are considered two-step mechanisms because they depend on the Sec or Tat system to transport either the secreted protein or a portion of the channel through the inner membrane. A second group of transporters move proteins through the outer membrane. Types I, III, IV, and VI are one-step systems because they form channels through both membranes and do not require Sec or Tat.

To inject toxin proteins into host cells, secretion systems of types III, IV, and VI also include structures on the outside of the cell that allow injection or insertion of the secreted protein into another cell. The entire type III structure has been termed the “injectisome” for its similarity to a syringe in both structure and function (Figure 4.43).

MINIQUIZ

- Define the terms primary, secondary, and tertiary structure with respect to proteins. How does a polypeptide differ from a protein?
- What does a molecular chaperone do?
- Why do some proteins have a signal sequence? What is the signal recognition particle?
- Why is it important for gram-negative bacteria to have additional secretion pathways?

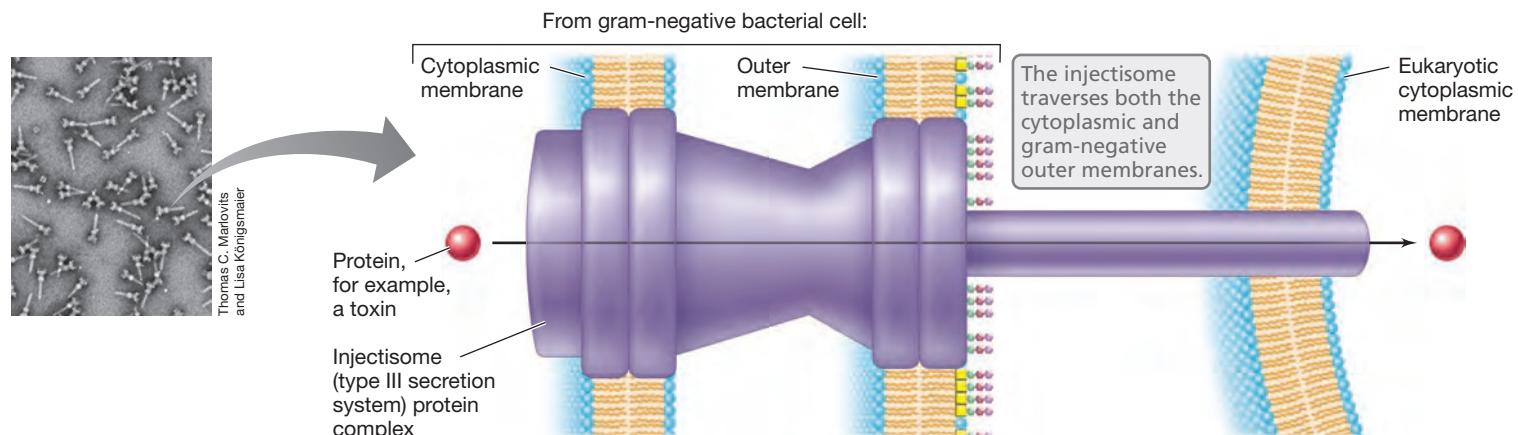

Figure 4.43 Secretion of molecules in gram-negative bacteria using the type III “injectisome” system. The protein complex that makes up the injectisome. Inset: Electron micrograph of purified injectisomes from *Salmonella enterica* serovar *Typhimurium*.

BIG IDEAS

4.1 • The informational content of a nucleic acid is determined by the sequence of nitrogen bases along the polynucleotide chain. Both RNA and DNA are informational macromolecules, as are the proteins they encode. The three key processes of macromolecular synthesis are: (1) DNA replication; (2) transcription (RNA synthesis); and (3) translation (protein synthesis).

4.2 • DNA is a double-stranded molecule that forms into a helix. The two strands in the double helix are complementary and antiparallel. Very long DNA molecules can be packaged into cells because they are supercoiled by enzymes called topoisomerases, such as DNA gyrase.

4.3 • In addition to the chromosome, other genetic elements can exist in cells. Plasmids are DNA molecules that exist separately from the chromosome and may confer a selective growth advantage under certain conditions. Viruses contain an RNA or DNA genome, and transposable elements exist as a part of other genetic elements. *Escherichia coli* is the prime model organism in biology.

4.4 • Both strands of the DNA helix are templates for the synthesis of new strands (semiconservative replication). The new strands are elongated by addition of deoxyribonucleotides to the 3' end. DNA polymerases require a primer made of RNA by the enzyme primase.

4.5 • DNA synthesis begins at a site called the origin of replication. The double helix is unwound by helicase and is stabilized by single-strand binding protein. Extension of the DNA occurs continuously on the leading strand but discontinuously on the lagging strand, resulting in Okazaki fragments on the lagging strand that must be joined together.

4.6 • Starting from a single origin on a circular chromosome, two replication forks synthesize DNA simultaneously in both directions until the forks meet at the terminus region. The proteins at the replication fork form a large complex known as the replisome. Most errors in base pairing that occur during replication are corrected by the proofreading functions of DNA polymerases.

4.7 • In *Bacteria*, promoters are recognized by the sigma subunit of RNA polymerase. Alternative sigma factors allow joint regulation of large families of genes in response to growth conditions. Transcription by RNA polymerase

continues until specific sites called transcription terminators are reached. These terminators function at the level of RNA.

4.8 • The unit of transcription in prokaryotes often contains more than a single gene that is transcribed into a single mRNA molecule that contains information for more than one polypeptide. A cluster of genes that are transcribed together from a single promoter constitute an operon.

4.9 • The transcription apparatus and the promoter architecture of *Archaea* and *Eukarya* have many features in common, although the components are usually relatively more simple in *Archaea*. In contrast, the processing of eukaryotic primary transcripts is unique and has three distinct steps: splicing, capping, and adding a poly(A) tail.

4.10 • Polypeptide chains contain 22 different genetically encoded amino acids that are linked via peptide bonds. The primary structure of a protein is its amino acid sequence, but the higher-order structure (folding) of the polypeptide determines its cellular function.

4.11 • The genetic code is expressed as RNA, and a single amino acid may be encoded by several different but related codons. In addition to the stop (nonsense) codons, there is also a specific start codon that signals the initiation of translation.

4.12 • Enzymes called aminoacyl-tRNA synthetases attach amino acids to their cognate tRNAs. One or more tRNAs exist for each amino acid incorporated into polypeptides by the ribosome.

4.13 • Translation occurs on the ribosome and requires mRNA and aminoacyl-tRNAs. The ribosome has three sites: acceptor, peptide, and exit. During each step of translation, the ribosome advances one codon along the mRNA, and the tRNA in the acceptor site moves to the peptide site. Protein synthesis terminates when a stop codon, which does not have a corresponding tRNA, is reached.

4.14 • Proteins must be properly folded in order to function correctly, and molecular chaperones assist with this process. Many proteins also need to be transported into or through the cytoplasmic membrane. These proteins contain a signal sequence that is recognized by the cellular translocases. Additional secretion systems are employed by gram-negative bacteria to secrete proteins into or through the outer membrane.

REVIEW OF KEY TERMS

Amino acid one of the 22 different monomers that make up proteins; chemically, a two-carbon carboxylic acid containing an amino group and a characteristic substituent on the alpha carbon

Aminocyl-tRNA synthetase an enzyme that catalyzes attachment of an amino acid to its cognate tRNA

Anticodon a sequence of three bases in a tRNA molecule that base-pairs with a codon during protein synthesis

Antiparallel in reference to double-stranded DNA, the two strands run in opposite directions (one runs 5' → 3' and the complementary strand 3' → 5')

Bacteriocin a toxic protein secreted by bacteria that inhibits or kills other, related bacteria

Chaperonin or molecular chaperone a protein that helps other proteins fold or refold from a partly denatured state

Chromosome a genetic element, usually circular in prokaryotes, carrying genes essential to cellular function

Codon a sequence of three bases in mRNA that encodes an amino acid

Codon bias nonrandom usage of multiple codons encoding the same amino acid

Complementary nucleic acid sequences that can base-pair with each other

Denaturation loss of the correct folding of a protein, leading (usually) to protein aggregation and loss of biological activity

DNA (deoxyribonucleic acid) a polymer of deoxyribonucleotides linked by phosphodiester bonds that carries genetic information

DNA helicase an enzyme that uses ATP to unwind the double helix of DNA

DNA gyrase an enzyme found in most prokaryotes that introduces negative supercoils in DNA

DNA ligase an enzyme that seals nicks in the backbone of DNA

DNA polymerase an enzyme that synthesizes a new strand of DNA in the 5' → 3' direction using an antiparallel DNA strand as a template

Enantiomer a form of a molecule that is the mirror image of another form of the same molecule

Enzyme a protein or an RNA that catalyzes a specific chemical reaction in a cell

Exons the coding DNA sequences in a split gene (contrast with intron)

Gene a segment of DNA specifying a protein (via mRNA), a tRNA, an rRNA, or any other noncoding RNA

Genetic code the correspondence between nucleic acid sequence and amino acid sequence of proteins

Genetic element a structure that carries genetic information, such as a chromosome, a plasmid, or a virus genome

Genome the total complement of genes contained in a cell or virus

Informational macromolecule any large polymeric molecule that carries genetic information, including DNA, RNA, and protein

Introns the intervening noncoding DNA sequences in a split gene (contrast with exons)

Lagging strand the new strand of DNA that is synthesized in short pieces and then joined together later

Leading strand the new strand of DNA that is synthesized continuously during DNA replication

Messenger RNA (mRNA) an RNA molecule that contains the genetic information to encode one or more polypeptides

Nonsense codon another name for a stop codon

Nucleic acid DNA or RNA

Nucleoside a nitrogenous base (adenine, guanine, cytosine, thymine, or uracil) plus a sugar (either ribose or deoxyribose) but lacking phosphate

Nucleotide a monomer of a nucleic acid containing a nitrogenous base (adenine, guanine, cytosine, thymine, or uracil), one or more molecules of phosphate, and a sugar, either ribose (in RNA) or deoxyribose (in DNA)

Open reading frame (ORF) a sequence of DNA or RNA that could be translated to give a polypeptide

Operon a cluster of genes that are cotranscribed as a single messenger RNA

Peptide bond a type of covalent bond linking amino acids in a polypeptide

Phosphodiester bond a type of covalent bond linking nucleotides together in a polynucleotide

Plasmid an extrachromosomal genetic element that has no extracellular form

Polynucleotide a polymer of nucleotides bonded to one another by covalent bonds called phosphodiester bonds

Polypeptide a polymer of amino acids bonded to one another by peptide bonds

Primary structure the precise sequence of monomers in a macromolecule such as a polypeptide or a nucleic acid

Primary transcript an unprocessed RNA molecule that is the direct product of transcription

Promase the enzyme that synthesizes the RNA primer used in DNA replication

Primer an oligonucleotide to which DNA polymerase attaches the first deoxyribonucleotide during DNA synthesis

Promoter a site on DNA to which RNA polymerase binds to commence transcription

Protein a polypeptide or group of polypeptides forming a molecule of specific biological function

Purine one of the nitrogenous bases of nucleic acids that contain two fused rings; adenine and guanine

Pyrimidine one of the nitrogenous bases of nucleic acids that contain a single ring; cytosine, thymine, and uracil

Quaternary structure in proteins, the number and types of individual polypeptides in the final protein molecule

Replication synthesis of DNA using DNA as a template

Replication fork the site on the chromosome where DNA replication occurs and where the enzymes replicating the DNA are bound to untwisted, single-stranded DNA

Replisome a DNA replication complex that consists of two copies of DNA polymerase III, DNA gyrase, helicase, primase, and copies of single-strand binding protein

Ribosomal RNA (rRNA) types of RNA found in the ribosome; some participate actively in protein synthesis

Ribosome a cytoplasmic particle composed of ribosomal RNA and protein, whose function is to synthesize proteins

RNA (ribonucleic acid) a polymer of ribonucleotides linked by phosphodiester bonds that plays many roles in cells, in particular, during protein synthesis

RNA polymerase an enzyme that synthesizes RNA in the 5' → 3' direction using a complementary and antiparallel DNA strand as a template

RNA processing the conversion of a primary transcript RNA to its mature form

Secondary structure the initial pattern of folding of a polypeptide or a polynucleotide, usually dictated by opportunities for hydrogen bonding

Semiconservative replication DNA synthesis yielding two new double helices, each consisting of one parental and one progeny strand

Signal sequence a special N-terminal sequence of approximately 20 amino acids that signals that a protein should be exported across the cytoplasmic membrane

Spliceosome a complex of ribonucleoproteins that catalyze the removal of introns from primary RNA transcripts

Start codon a special codon, usually AUG, that signals the start of a protein

Stop codon a codon that signals the end of a protein

Termination stopping the elongation of an RNA molecule at a specific site

Tertiary structure the final folded structure of a polypeptide that has previously attained secondary structure

Transcription the synthesis of RNA using a DNA template

Transfer RNA (tRNA) a small RNA molecule used in translation that possesses an anticodon at one end and has the corresponding amino acid attached to the other end

Translation the synthesis of protein using the genetic information in RNA as a template

Transposable element a genetic element able to move (transpose) from one site to another on host DNA molecules

Wobble a less rigid form of base pairing allowed only in codon–anticodon pairing

REVIEW QUESTIONS

- Describe the central dogma of molecular biology. (Section 4.1)
- Genes were discovered before their chemical nature was known. First, define a gene without mentioning its chemical nature. Then name the chemicals that compose a gene. (Section 4.1)
- DNA molecules that are AT-rich separate into two strands more easily when the temperature rises than do DNA molecules that are GC-rich. Explain this based on the properties of AT and GC base pairing. (Section 4.2)
- Describe how DNA, which is many times the length of a cell when linearized, fits into the cell. (Section 4.2)
- What is the size of the *Escherichia coli* chromosome and about how many proteins can it encode? What other genetic elements might be present in *E. coli*? (Section 4.3)
- What are R plasmids and why are they of medical concern? (Section 4.3)
- With reference to DNA, what is meant by the terms semiconservative, complementary, and antiparallel? (Section 4.4)
- A structure commonly seen in circular DNA during replication is the theta structure. Draw a diagram of the replication process and show how a theta structure could arise. (Sections 4.5 and 4.6)
- Why are errors in DNA replication so rare? What enzymatic activity, in addition to polymerization, is associated with DNA polymerase III and how does it reduce errors? (Section 4.6)
- Do genes for tRNAs have promoters? Do they have start codons? Explain. (Sections 4.7 and 4.11)
- The start and stop sites for mRNA synthesis (on the DNA) are different from the start and stop sites for protein synthesis (on the mRNA). Explain. (Sections 4.7 and 4.11)
- What is an operon and why is it beneficial to link the expression of certain genes? (Section 4.8)
- Why do eukaryotic mRNAs have to be “processed” whereas most prokaryotic RNAs do not? (Section 4.9)
- Why are amino acids so named? Write a general structure for an amino acid. What is the importance of the R group to final protein structure? Why does the amino acid cysteine have special significance for protein structure? (Section 4.10)
- What is “wobble” and what makes it necessary in protein synthesis? (Sections 4.11 and 4.12)
- What are aminoacyl-tRNA synthetases and what types of reactions do they carry out? How does a synthetase recognize its correct substrates? (Section 4.12)
- The enzyme activity that forms peptide bonds on the ribosome is called peptidyl transferase. Which molecule catalyzes this reaction? (Section 4.13)
- Define the types of protein structure: primary, secondary, tertiary, and quaternary. Which of these structures are altered by denaturation? (Section 4.14)
- Sometimes misfolded proteins can be correctly refolded, but sometimes they cannot and are destroyed. What kinds of proteins are involved in refolding misfolded proteins? What kinds of enzymes are involved in destroying misfolded proteins? (Section 4.14)
- How does a cell know which of its proteins are designed to function outside of the cell? (Section 4.14)

APPLICATION QUESTIONS

- The genome of the bacterium *Neisseria gonorrhoeae* consists of one double-stranded DNA molecule that contains 2220 kilobase pairs. Calculate the length of this DNA molecule in centimeters. If 85% of this DNA molecule is made up of the open reading frames

of genes encoding proteins, and the average protein is 300 amino acids long, how many protein-encoding genes does *Neisseria* have? What kind of information do you think might be present in the other 15% of the DNA?

2. Compare and contrast the activity of DNA and RNA polymerases. What is the function of each? What are the substrates of each? What is the main difference in the behavior of the two polymerases?
3. What would be the result (in terms of protein synthesis) if RNA polymerase initiated transcription one base upstream of its normal starting point? Why? What would be the result (in terms of protein synthesis) if translation began one base downstream of its normal starting point? Why?
4. In Chapter 10 we will learn about mutations, inheritable changes in the sequence of nucleotides in the genome. By inspecting Table 4.5, discuss how the genetic code has evolved to help minimize the impact of mutations.

Did the First Cells on Earth Have Cell Walls?

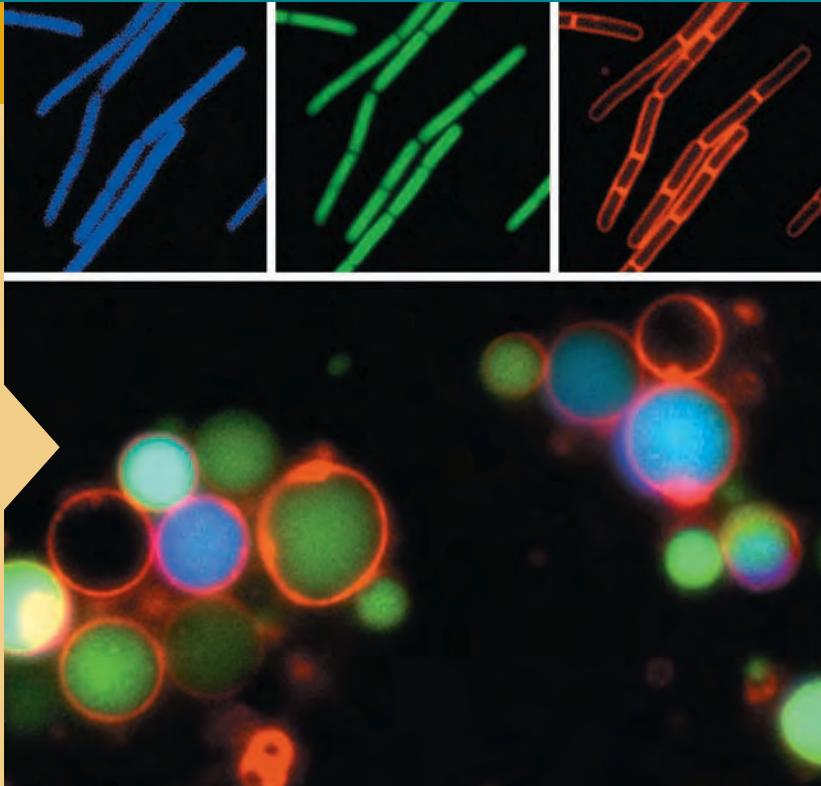

There are many different cell shapes in the bacterial world: rods, cocci, spirilla, and more. What shape were the first cells? The peptidoglycan-containing cell wall is the hallmark of cells of *Bacteria*, as it defines a cell's morphology and prevents its osmotic lysis. But did the first cells on Earth have cell walls?

The rod-shaped bacterium *Bacillus subtilis* has been used as a model for the study of bacterial cell shape, growth, and morphogenesis. Cells of *B. subtilis* are relatively large and easy to visualize by fluorescence microscopy (top photos, L to R: DNA stain, green fluorescent protein, and membrane stain). Moreover, the genetics of this bacterium is well understood; this allows researchers to generate various mutants.

Mutant strains of *B. subtilis* that lack a cell wall, called *L-forms*, can be generated and grown in osmotically protected culture media. Remarkably, conversion of the wild type to the *L-form* requires only two mutations.¹ *L-forms* grow not by the usual binary fission process of rod-shaped bacteria, but instead by releasing small vesicles that slowly enlarge and eventually generate vesicles of their own (bottom photo). And all of this happens independently of the major cell-division and cytoskeletal proteins of bacterial cells, FtsZ and MreB.

Earth's first cells almost certainly did not look like the morphologically diverse *Bacteria* and *Archaea* we know today, but instead more like the *L-forms* of *B. subtilis* shown here. Lacking a cell wall would have allowed early cells to fuse and readily exchange genes. With the emergence of a peptidoglycan cell wall, a barrier to major genetic exchange would have been established, but the wall would have allowed cells to explore osmotically unprotected habitats and evolve diverse cell shapes best suited to exploiting the resources in these habitats.

I • Bacterial Cell Division

In previous chapters we discussed cell structure and function (Chapter 2) and the principles of microbial nutrition and metabolism (Chapter 3). In Chapter 4 we learned the important molecular processes that encode the structures and metabolic processes of cells. Now we will consider how all of these come together to yield new cells during microbial growth.

Growth is the result of cell division and is the ultimate process in the life of a microbial cell. Knowledge of how bacteria grow has given us new insight into cell division in higher organisms and is useful for designing methods to control microbial growth.

5.1 Binary Fission

In microbiology, **growth** is defined as *an increase in the number of cells*. Microbial cells have a finite life span, and a species is maintained only as a result of continued growth of its population. As macromolecules accumulate in the cytoplasm of a cell, they assemble into major cell structures, such as the cell wall, cytoplasmic membrane, flagella, ribosomes, enzyme complexes, and so on, eventually leading to the process of cell division itself. In a growing culture of a rod-shaped bacterium such as *Escherichia coli*, cells elongate to approximately twice their original length and then form a partition that constricts the cell into two daughter cells (Figure 5.1). This process is called **binary fission** (“binary” to express the fact that two cells have arisen from one). This partition is called a *septum* and results from the inward growth of the cytoplasmic membrane and cell wall from opposing directions; septum formation continues until the two daughter cells are pinched off. There are some variations in this general pattern of binary fission. In some bacteria, such as *Bacillus subtilis*, a septum forms without cell wall constriction, while in the budding bacterium *Caulobacter*, constriction occurs but no septum is formed. But in all cases, when one cell eventually separates to form two cells, we say that one *generation* has occurred, and the time required for this process is called the **generation time** (Figure 5.1 and see Figure 5.10).

During one generation, all cellular constituents increase proportionally, and cells are said to be in *balanced growth*. Each daughter cell receives a chromosome and sufficient copies of ribosomes and all other macromolecular complexes, monomers, and inorganic ions to exist as an independent cell. Partitioning of the replicated DNA molecule between the two daughter cells depends on the DNA remaining attached to the cytoplasmic membrane during division, with constriction leading to separation of the chromosomes, one to each daughter cell (see Figure 5.3).

The generation time in a given bacterial species is highly variable and is dependent on nutritional and genetic factors, and temperature. Under the best nutritional conditions, the generation time of a laboratory culture of *E. coli* is about 20 min. A few bacteria can grow even faster than this, with the record holder having an 6-min generation time. Many bacteria grow much slower than this, with generation times of hours or days being more common. In nature, microbial cells probably grow much slower than their

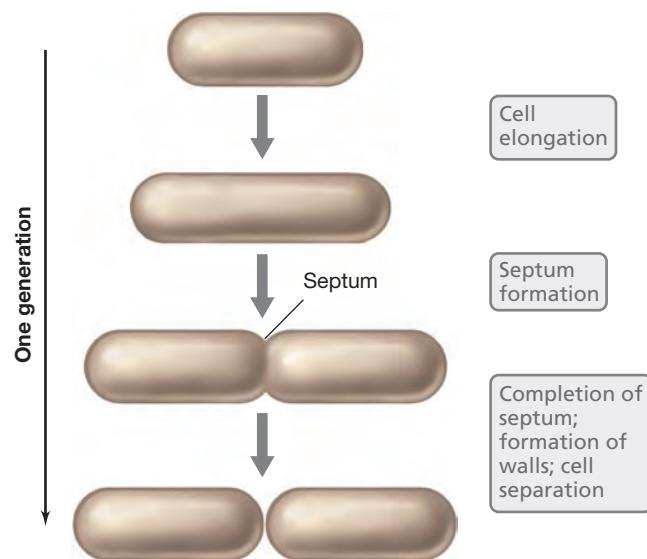

Figure 5.1 Binary fission in a rod-shaped prokaryote. Cell numbers double every generation.

maximum rates observed in the laboratory. This is because the conditions and resources necessary for optimal growth in the laboratory may not be present in a natural habitat, and unlike pure culture growth, microorganisms in nature live with other species in microbial communities and thus must compete with their neighbors for resources and space.

MINIQUIZ

- Summarize the steps that lead up to binary fission in a bacterium like *Escherichia coli*.
- Define the term generation. What is meant by the term generation time?

5.2 Fts Proteins and Cell Division

A series of proteins present in all *Bacteria* are essential for cell division. These proteins are called *Fts proteins* and a key one, **FtsZ**, plays a crucial role in the binary fission process. FtsZ is related to tubulin, the important cell-division protein in eukaryotes (☞ Section 2.22), and is also found in most but not all *Archaea*. Other Fts proteins are found only in *Bacteria* and not in *Archaea*, so our discussion here will be restricted to the *Bacteria*. The gram-negative *Escherichia coli* and the gram-positive *Bacillus subtilis* have been the model bacterial species for the study of cell division events.

The Divisome

Fts proteins interact in the cell to form a division apparatus called the **divisome**. In rod-shaped cells, formation of the divisome begins with the attachment of molecules of FtsZ in a ring precisely around the center of the cell; this ring will become the

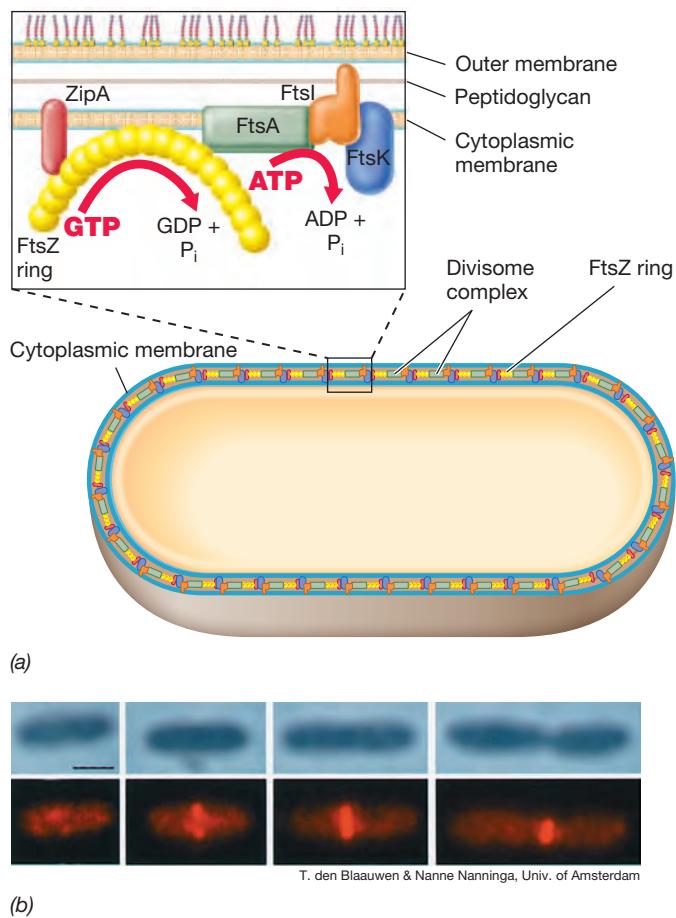

Figure 5.2 The FtsZ ring and cell division. (a) Cutaway view of a rod-shaped cell showing the ring of FtsZ molecules around the division plane. Blowup shows the arrangement of individual divisome proteins. ZipA is an FtsZ anchor, FtsI is a peptidoglycan biosynthesis protein, FtsK assists in chromosome separation, and FtsA is an ATPase. (b) Appearance and breakdown of the FtsZ ring during the cell cycle of *Escherichia coli*. Microscopy: upper row, phase contrast; bottom row, cells stained with a specific reagent against FtsZ. Cell division events: first column, FtsZ ring not yet formed; second column, FtsZ ring appears as nucleoids start to segregate; third column, full FtsZ ring forms as cell elongates; fourth column, breakdown of the FtsZ ring and cell division. Marker bar in upper left photo, 1 μm .

cell-division plane. In a cell of *E. coli* about 10,000 FtsZ molecules polymerize to form the ring, and the ring attracts other divisome proteins, including *FtsA* and *ZipA* (Figure 5.2). *ZipA* is an anchor that connects the FtsZ ring to the cytoplasmic membrane and stabilizes it. *FtsA*, a protein related to actin, an important cytoskeletal protein in eukaryotes (Section 2.22), also helps to connect the FtsZ ring to the cytoplasmic membrane and recruit other divisome proteins. The divisome forms about three-quarters of the way into the cell division cycle. However, before the divisome forms, the cell is already elongating and DNA replication has begun (see Figure 5.3).

The divisome also contains Fts proteins needed for peptidoglycan synthesis, such as *FtsI* (Figure 5.2). *FtsI* is one of several *penicillin-binding proteins* present in the cell. Penicillin-binding proteins are so named because their activities are inhibited by the antibiotic penicillin (Section 5.4). The divisome orchestrates synthesis of new cytoplasmic membrane and cell wall material, called

the *division septum*, at the center of a rod-shaped cell until it reaches twice its original length. The elongated cell then divides, yielding two daughter cells (Figure 5.1).

DNA Replication, Min Proteins, and Cell Division

DNA replicates before the FtsZ ring forms (Figure 5.3) because the ring forms in the space between the duplicated nucleoids; before the nucleoids segregate, they effectively block formation of the FtsZ ring. The proteins MinC, MinD, and MinE interact to help guide FtsZ to the cell midpoint. MinD forms a spiral structure on the inner surface of the cytoplasmic membrane and helps to localize MinC to the cytoplasmic membrane. The MinD spiral oscillates back and forth along the long axis of the growing cell and functions to *inhibit* cell division by preventing the FtsZ ring from forming (Figure 5.3). Simultaneously, however, MinE also oscillates from pole to pole, and as it does, it functions to sweep MinC and MinD aside. Hence, because MinC and MinD dwell longer at the poles than anywhere else during their oscillation cycle, the center of the cell will have, on average, the lowest concentration of these proteins. As a result, the cell center becomes the most permissive site for FtsZ binding and so the FtsZ ring forms there. In this unusual series of events, the Min proteins ensure that the divisome forms only at the *cell center* and not at the cell poles (Figure 5.3).

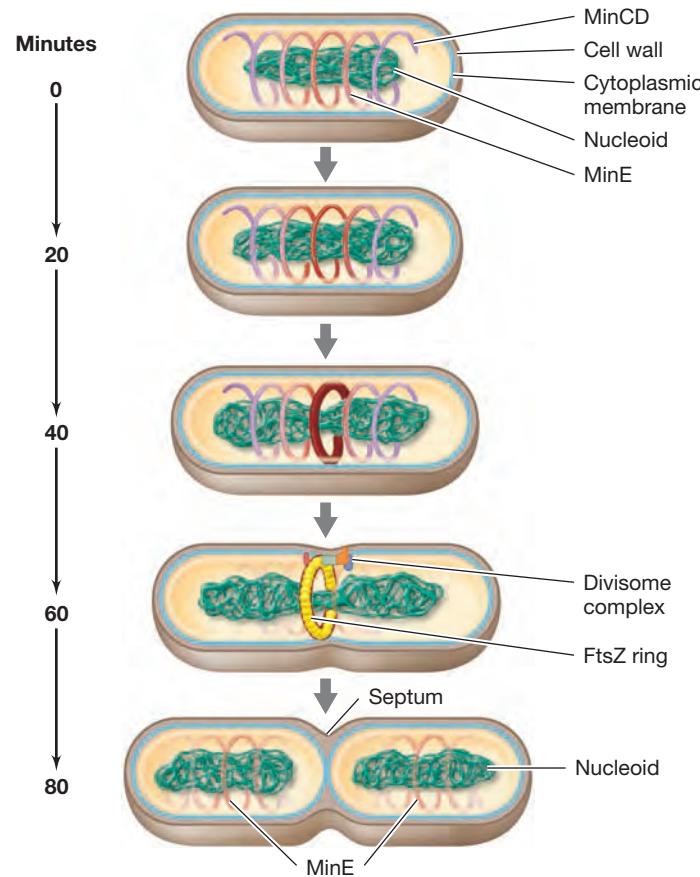

Figure 5.3 DNA replication and cell-division events. The protein MinE directs formation of the FtsZ ring and divisome complex at the cell-division plane. Shown is a schematic for cells of *Escherichia coli* growing with a doubling time of 80 min. MinC and MinD are most abundant at the cell poles.

As cell elongation continues and septum formation begins, the two copies of the chromosome are pulled apart, each to its own daughter cell (Figure 5.3). The Fts protein *FtsK* and several other proteins assist in this process. As the cell constricts, the FtsZ ring begins to depolymerize, triggering the inward growth of wall materials to form the septum and seal off one daughter cell from the other. The enzymatic activity of FtsZ also hydrolyzes guanosine triphosphate (GTP, an energy-rich compound) to yield the energy necessary to fuel the polymerization and depolymerization of the FtsZ ring (Figures 5.2 and 5.3).

There is great practical interest in understanding the details of bacterial cell division because such knowledge could lead to the development of new drugs that target specific steps in the growth of pathogenic bacteria. Like penicillin (a drug that targets bacterial cell wall synthesis), drugs that interfere with the function of specific Fts or other bacterial cell-division proteins could have broad applications in clinical medicine.

Genome Replication in Fast-Growing Cells

As we learned in Chapter 4, the circular nature of the chromosome of *Escherichia coli* and most other prokaryotes creates an

opportunity for speeding up DNA replication. This is because replication of circular genomes is *bidirectional* from the origin of replication. During bidirectional replication, synthesis occurs in both a leading and a lagging fashion on each template strand, and this allows DNA to replicate as rapidly as possible (► Figure 4.17). Studies of chromosome replication in *E. coli* have shown that about 40 min is the minimum time required for genome replication and that this is independent of the generation time (Figure 5.4). However, this creates a conundrum in rapidly growing cultures of *E. coli*, an organism that can divide every 20 min under optimal conditions. At such fast growth rates, how does replication of the genome keep up with that of the cell proper?

The solution to this problem is that cells of *E. coli* growing at doubling times shorter than 40 min contain *multiple DNA replication forks*. That is, a new round of DNA replication begins before the last round has been completed (Figure 5.4), and therefore, some genes are present in more than one copy. This ensures that at generation times shorter than the time required to replicate the genome (a process that occurs at a constant maximal speed), each daughter cell receives a complete copy of the genome at the time of septum formation.

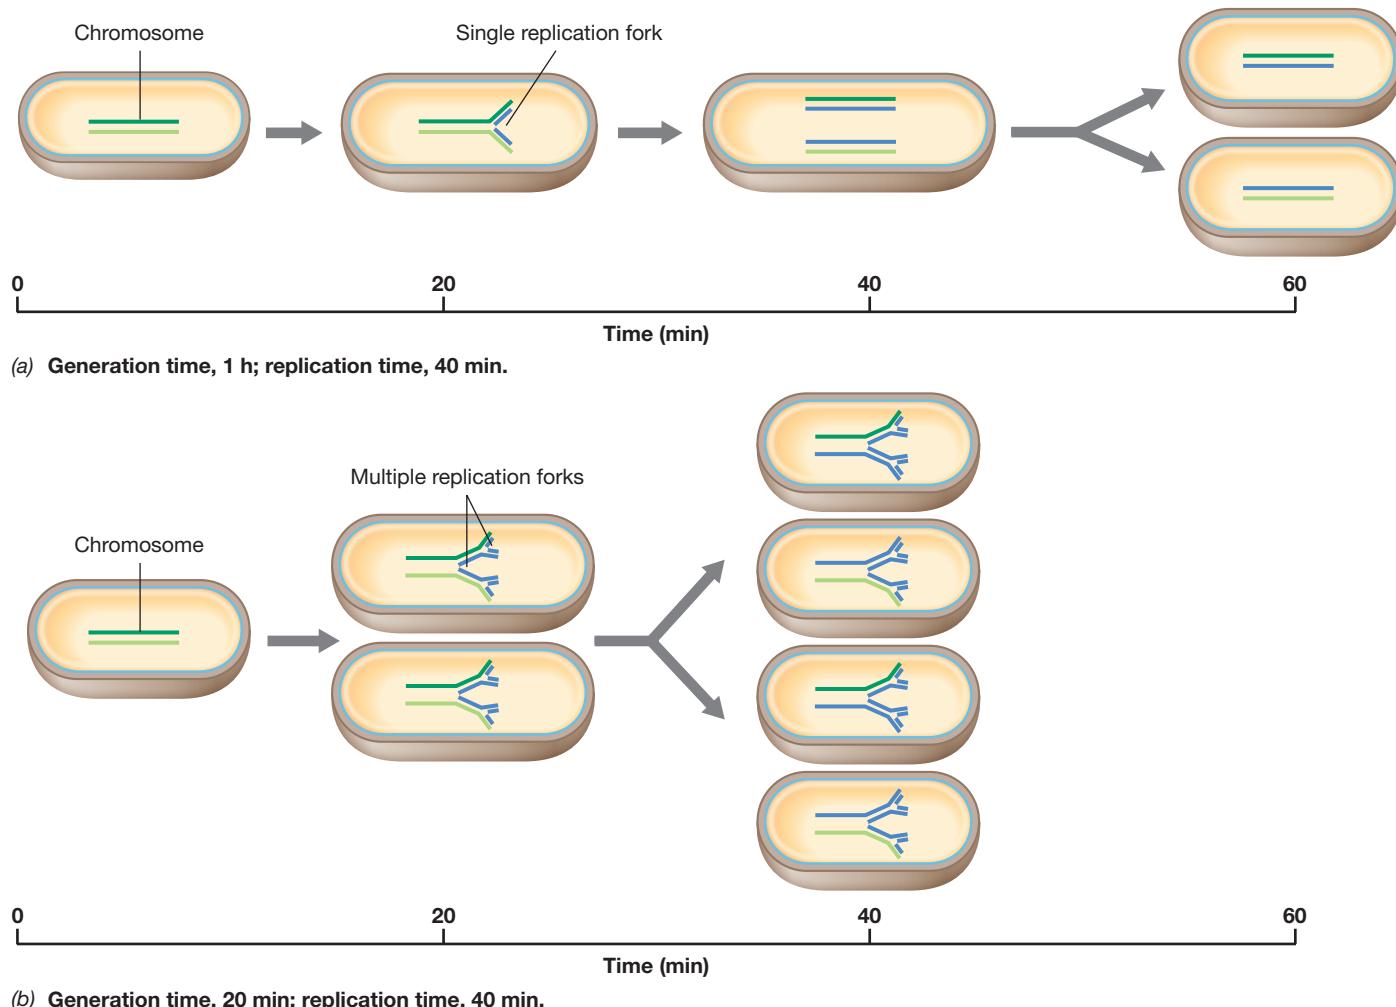

Figure 5.4 Genome replication in cells of *Escherichia coli* growing at 60 min or 20 min generation times. In cells doubling every 20 min, multiple replication forks are needed to ensure that each daughter cell gets a complete copy of the genome, which takes 40 minutes to replicate.

MINIQUIZ

- What is the divisome?
- How does FtsZ find the cell midpoint of a rod-shaped cell?
- Explain how the minimum generation time for the bacterium *Escherichia coli* can be less than the time needed to replicate its chromosome.

5.3 MreB and Cell Morphology

Just as specific proteins direct cell *division* in prokaryotes, other specific proteins direct cell *shape*. Interestingly, these shape-determining proteins show significant homology to key cytoskeletal proteins in eukaryotic cells. Like eukaryotes, prokaryotes also contain a cell cytoskeleton, and one that is both dynamic and multifaceted.

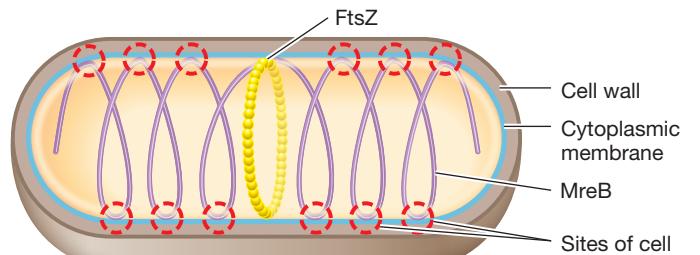

Cell Shape and MreB

The major shape-determining factor in *Bacteria* is a protein called *MreB*. *MreB* forms a simple cytoskeleton in *Bacteria* and in a few species of *Archaea*. *MreB* forms a helix of filaments around the inside of the cell, just below the cytoplasmic membrane (Figure 5.5). The *MreB* cytoskeleton presumably defines cell shape by recruiting other proteins that function in cell wall growth to group into a specific pattern. Inactivation of the gene encoding *MreB* in rod-shaped bacteria causes the cells to become coccus-shaped. Moreover, most naturally coccoid bacteria lack the *MreB* gene and thus do not make *MreB*. This indicates that the “default” morphology for a bacterium is most likely the sphere. Variations in the arrangement of *MreB* filaments in cells of nonspherical bacteria are probably responsible for the different common morphologies of prokaryotic cells (Figure 2.11).

How does *MreB* define a cell’s shape? The helical structures formed by *MreB* (Figure 5.5a) are not static, but instead can rotate within the cytoplasm of a growing cell. Newly synthesized peptidoglycan (Section 5.4) is associated with the *MreB* helices at points where the helices contact the cytoplasmic membrane (Figure 5.5a). It is thought that *MreB* localizes the synthesis of new cell wall to specific locations along the long axis of a rod-shaped cell during growth. This allows new cell wall to form at several points along the cell rather than from a single location at the *FtsZ* site outward, as in spherical bacteria (see Figure 5.3). By rotating within the cell cylinder and initiating cell wall synthesis where it contacts the cytoplasmic membrane, *MreB* directs new wall synthesis in such a way that a rod-shaped cell elongates only along its long axis.

Crescentin

Caulobacter crescentus, a vibrio-shaped species of *Proteobacteria* (Section 7.12 and 14.21), produces a shape-determining protein called *crescentin* in addition to *MreB*. Copies of *crescentin* protein organize into filaments about 10 nm wide that localize onto the concave face of the curved cell. The arrangement and localization of *crescentin* filaments are thought to impart the characteristic curved morphology to the *C. crescentus* cell (Figure 5.5c). *Caulobacter* is an aquatic bacterium that undergoes a life cycle in which swimming cells, called *swarmers*, eventually form

Figure 5.5 MreB and crescentin as determinants of cell morphology.

(a) The cytoskeletal protein *MreB* is an actin analog that winds as a coil through the long axis of a rod-shaped cell, making contact with the cytoplasmic membrane in several locations (red dashed circles). These are sites of new cell wall synthesis. (b) Photomicrographs of the same cells of *Bacillus subtilis*. Left, phase contrast; right, fluorescence. The cells contain a substance that makes the *MreB* protein fluoresce, shown here as bright white. (c) Cells of *Caulobacter crescentus*, a naturally curved (vibrio-shaped) cell. Cells are stained to show the shape-determining protein *crescentin* (red), which lies along the concave surface of the cell, and with DAPI, which stains DNA and thus the entire cell blue.

a stalk and attach to surfaces. Attached cells then undergo cell division to form new swarmer cells that are released to colonize new habitats. The steps in this life cycle are highly orchestrated at the genetic level, and *Caulobacter* has been used as a model system for the study of gene expression in cellular differentiation (Section 7.12). Although *crescentin* seems to be unique to

Caulobacter, proteins similar to crescentin have been found in other helically shaped cells, such as *Helicobacter*, a pathogenic bacterium (➡ Section 29.10). This suggests that these proteins may be necessary for the formation of curved cells.

Evolution of Cell Division and Cell Shape

How do the determinants of cell shape and cell division in *Bacteria* compare with those in eukaryotes? Interestingly, MreB is structurally related to the eukaryotic protein actin and FtsZ to the eukaryotic protein tubulin. Actin forms structures called *microfilaments* that function as scaffolding in the eukaryotic cell cytoskeleton and in cell division, whereas tubulin forms *microtubules* that are important in mitosis and other processes (➡ Section 2.22). In addition, the shape-determining protein crescentin in *Caulobacter* is related to the keratin proteins that make up *intermediate filaments* in eukaryotic cells. Intermediate filaments form part of the eukaryotic cytoskeleton, and genes encoding similar proteins have been found in some other *Bacteria*. It thus appears that several proteins that control cell division and the cell cytoskeleton in eukaryotic cells have evolutionary roots in the *Bacteria*. However, with the exception of FtsZ, genes encoding homologs of these proteins appear to be absent from most *Archaea*.

MINIQUIZ

- How does MreB control the shape of a rod-shaped bacterium?
- What protein is thought to control the shape of cells of *Caulobacter*?
- What relationships exist between cytoskeletal proteins in *Bacteria* in eukaryotes?

5.4 Peptidoglycan Biosynthesis

In cells of all species of *Bacteria* that contain peptidoglycan, and most species do, preexisting peptidoglycan has to be temporarily severed to allow newly synthesized peptidoglycan to be inserted during the growth process. In cocci, new cell wall material grows out in opposite directions from the FtsZ ring (Figure 5.6), whereas as we have just seen, in rod-shaped cells, new cell wall grows at several locations along the length of the cell (Figure 5.5a). In either case, how does new peptidoglycan get made and how does it get outside the cytoplasmic membrane, where the peptidoglycan layer resides?

Biosynthesis of Peptidoglycan

Peptidoglycan can be thought of as a stress-bearing fabric, much like a thin sheet of rubber. Synthesis of new peptidoglycan during growth requires the controlled cutting of preexisting peptidoglycan along with the simultaneous insertion of peptidoglycan precursors. A lipid carrier molecule called *bactoprenol* plays a major role in the latter process. Bactoprenol is a hydrophobic C₅₅ alcohol that bonds to a *N*-acetylglucosamine/*N*-acetylmuramic acid/pentapeptide peptidoglycan precursor (Figure 5.7). Bactoprenol transports peptidoglycan precursors across the cytoplasmic membrane by rendering them sufficiently hydrophobic to pass through the membrane interior.

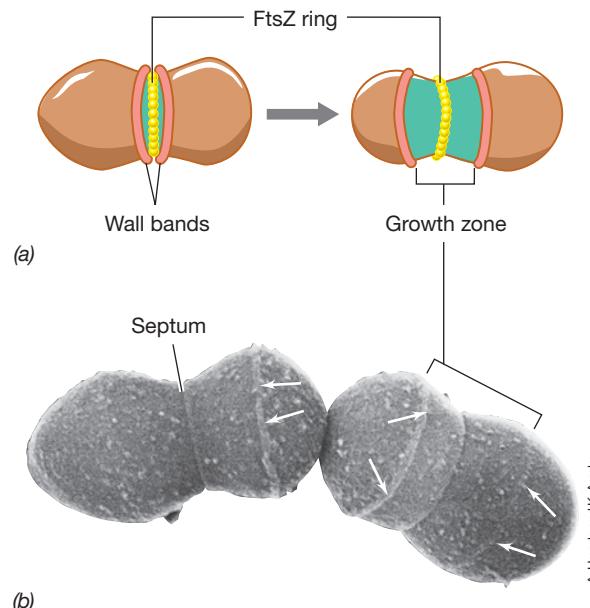

Figure 5.6 Cell wall synthesis in gram-positive *Bacteria*. (a) Localization of cell wall synthesis during cell division. In cocci, cell wall synthesis (shown in green) is localized at only one point (compare with Figure 5.5a). (b) Scanning electron micrograph of cells of *Streptococcus hemolyticus* showing wall bands (arrows). A single cell is about 1 µm in diameter.

Once in the periplasm, bactoprenol interacts with enzymes called *transglycosylases* that insert cell wall precursors into the growing point of the cell wall and catalyze glycosidic bond formation (Figure 5.8). Prior to this, small gaps in the existing peptidoglycan are made by enzymes called *autolysins*, enzymes that function to hydrolyze the bonds that connect *N*-acetylglucosamine and *N*-acetylmuramic acid in the peptidoglycan backbone. New cell wall material is then added across the gaps (Figure 5.8a). The junction between new and old peptidoglycan forms a ridge on the cell surface of gram-positive bacteria that can be observed as a *wall band* (Figure 5.6b). It is essential that peptidoglycan synthesis be a highly coordinated process. New tetrapeptide units must be spliced into existing peptidoglycan immediately after autolysin activity in order to prevent a breach in peptidoglycan integrity at the splice point; a breach could cause spontaneous cell lysis, called *autolysis*.

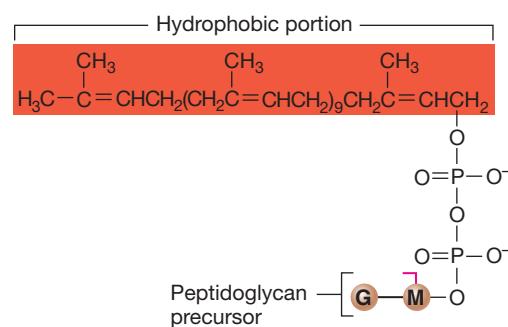

Figure 5.7 Bactoprenol (undecaprenol diphosphate). This highly hydrophobic molecule carries cell wall peptidoglycan precursors through the cytoplasmic membrane.

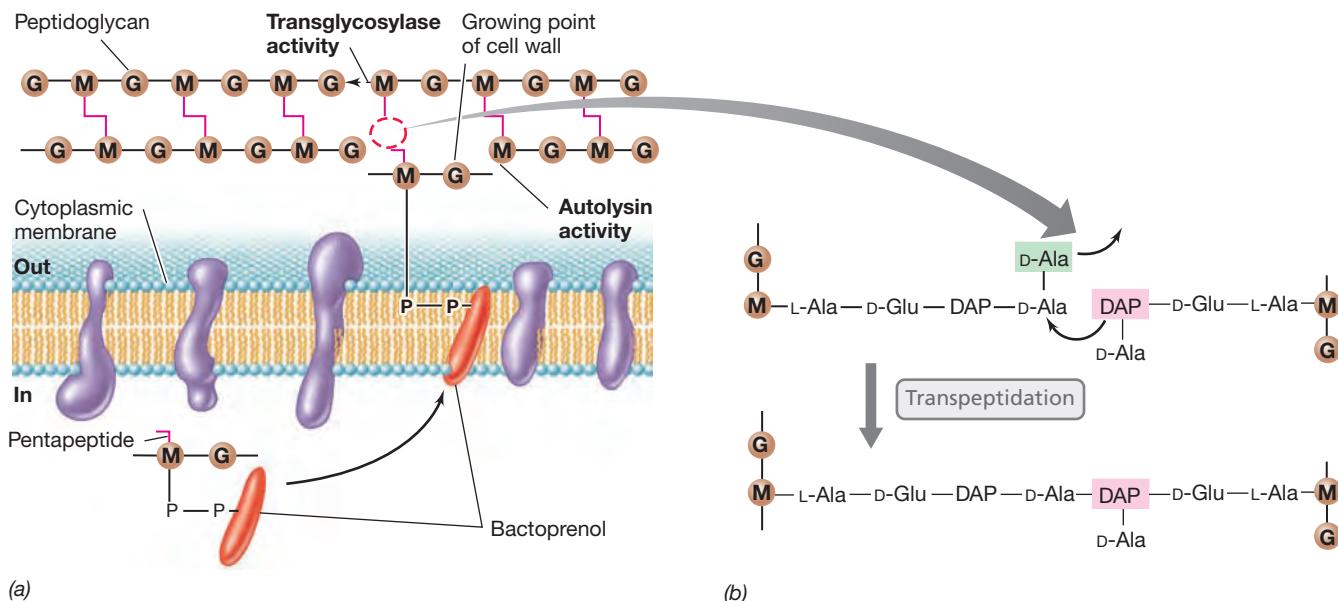

Figure 5.8 Peptidoglycan synthesis. (a) Transport of peptidoglycan precursors across the cytoplasmic membrane to the growing point of the cell wall. Autolysin breaks glycolytic bonds in preexisting peptidoglycan, while transglycosylase synthesizes them, linking old peptidoglycan with new. (b) The transpeptidation reaction that leads to the final cross-linking of two peptidoglycan chains. Penicillin inhibits this reaction.

Transpeptidation

The final step in cell wall synthesis is **transpeptidation**. Transpeptidation forms the peptide cross-links between muramic acid residues in adjacent glycan chains (► Section 2.10 and Figures 2.25 and 2.26). In gram-negative bacteria such as *Escherichia coli*, cross-links form between diaminopimelic acid (DAP) on one peptide and D-alanine on the adjacent peptide. Although there are two D-alanine residues at the end of the peptidoglycan precursor, only one remains in the final molecule as the other is removed during transpeptidation (Figure 5.8b). This reaction is exergonic (energy-releasing, ► Section 3.4) and supplies the energy necessary to drive transpeptidation forward. In *E. coli*, the protein FtsI (Figure 5.2a) functions as a transpeptidase.

Transpeptidation is medically noteworthy because it is the reaction inhibited by the antibiotic penicillin. Several penicillin-binding proteins have been identified in bacteria, including FtsI (Figure 5.2a). When penicillin is bound to penicillin-binding proteins, the proteins are inactivated. In the absence of transpeptidation in an otherwise growing cell, the continued activity of autolysins (Figure 5.8) so weakens the peptidoglycan that the cell eventually bursts.

MINIQUIZ

- What are autolysins and why are they necessary?
- What is the function of bactoprenol?
- What is transpeptidation and why is it important?

II • Population Growth

Recall that microbial growth is defined as an increase in the *number* of cells in a population. So we now move on from considering the growth and division events in an individual cell to consider the dynamics of growth in bacterial populations.

5.5 Quantitative Aspects of Microbial Growth

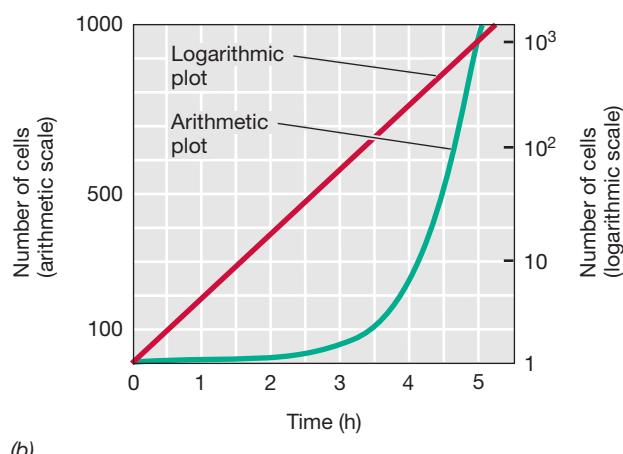

During cell division, one cell becomes two. During the time that it takes for this to occur (the generation time), both total cell *number* and *mass* double (Figure 5.1). As we will see, cell numbers in a growing bacterial culture can quickly become very large, and so we turn our attention here to dealing with these large numbers in a quantitative manner.

Plotting Growth Data

A growth experiment beginning with a single cell having a generation time of 30 min is presented in Figure 5.9. This pattern of population increase, where the number of cells doubles in a constant time interval, is called **exponential growth**. When the cell number from such an experiment is graphed on arithmetic (linear) coordinates as a function of time, one obtains a curve with a continuously increasing slope (Figure 5.9b). By contrast, when the cell number is plotted on a logarithmic (\log_{10}) scale as a function of time (a *semilogarithmic* graph), as shown in Figure 5.9b, the points fall on a straight line. This straight-line function reflects the fact that the cells are growing exponentially and the population is doubling in a constant time interval.

Time (h)	Total number of cells	Time (h)	Total number of cells
0	1	4	256 (2^8)
0.5	2	4.5	512 (2^9)
1	4	5	1,024 (2^{10})
1.5	8	5.5	2,048 (2^{11})
2	16	6	4,096 (2^{12})
2.5	32	.	.
3	64	.	.
3.5	128	10	1,048,576 (2^{20})

(a)

(b)

Figure 5.9 The rate of growth of a microbial culture. (a) Data for a population that doubles every 30 min. (b) Data plotted on arithmetic (left ordinate) and logarithmic (right ordinate) scales.

Semilogarithmic graphs are also convenient for estimating the generation time of a culture from growth data, since generation times may be inferred directly from the graph as shown in **Figure 5.10**. For example, when two points on the curve that represent one cell doubling on the Y axis are selected and vertical lines drawn from them to intersect the X axis, the time interval measured on the X axis is the generation time (Figure 5.10b).

The Mathematics of Growth and Growth Expressions

The increase in cell number in an exponentially growing bacterial culture can be expressed with simple mathematics based on a geometric progression of the number 2. As one cell divides to become two cells, we express this as $2^0 \rightarrow 2^1$. As two cells become four, we express this as $2^1 \rightarrow 2^2$, and so on (Figure 5.9a). A fixed relationship exists between the initial number of cells in a culture and the number present after a period of exponential growth, and this relationship can be expressed as

$$N = N_0 2^n$$

where N is the final cell number, N_0 is the initial cell number, and n is the number of generations during the period of exponential growth. The generation time (g) of the exponentially growing population is t/n , where t is the duration of exponential growth expressed in days, hours, or minutes. From a knowledge of the initial and final cell numbers in an exponentially growing cell

population, it is possible to calculate n , and from n and knowledge of t , the generation time, g .

The equation $N = N_0 2^n$ can be expressed in terms of n by taking the logarithms of both sides as follows:

$$\begin{aligned} N &= N_0 2^n \\ \log N &= \log N_0 + n \log 2 \\ \log N - \log N_0 &= n \log 2 \\ n &= \frac{\log N - \log N_0}{\log 2} = \frac{\log N - \log N_0}{0.301} \\ &= 3.3(\log N - \log N_0) \end{aligned}$$

Using the last expression, it is possible to calculate generation times in terms of measurable quantities, N and N_0 . As an example, consider actual growth data from the graph in Figure 5.10b, in which $N = 10^8$, $N_0 = 5 \times 10^7$, and $t = 2$:

$$\begin{aligned} n &= 3.3 [\log(10^8) - \log(5 \times 10^7)] \\ &= 3.3 (8 - 7.69) = 3.3(0.301) = 1 \end{aligned}$$

Thus, in this example, $g = t/n = 2/1 = 2$ h. If exponential growth continued for another 2 h, the cell number would be 2×10^8 . Two hours later the cell number would be 4×10^8 , and so on. Besides determining the generation time of an exponentially growing culture by inspection of graphical data (Figure 5.10b), g can also be calculated directly from the slope of the straight-line function obtained in a semilogarithmic plot of exponential growth. The slope is equal to $0.301 n/t$ (or $0.301/g$). In the above example, the slope would thus be $0.301/2$, or 0.15. Since g is equal to $0.301/\text{slope}$, we arrive at the same value of 2 for g . The term $0.301/g$ is called the *specific growth rate*, abbreviated k .

Other useful growth expressions can be calculated from these data. For example, the reciprocal of the generation time, called the *division rate*, is abbreviated v . The division rate is equal to $1/g$ and has units of reciprocal hours (h^{-1}). That is to say, whereas g is a measure of the *time* it takes for a population to double in cell number, v is a measure of the *number of generations* per unit of time in an exponentially growing culture. The slope of the line relating log cell number to time (Figure 5.10) is equal to $v/3.3$. Armed with knowledge of n and t , one can calculate g , k , and v for different microorganisms growing under different conditions. This is often useful for optimizing culture conditions for a newly isolated organism and also for testing the positive or negative effect of some treatment on a bacterial culture. For example, comparison with an unamended control allows factors that stimulate or inhibit growth to be identified by measuring their effect on the various growth parameters discussed here.

Consequences of Exponential Growth

During exponential growth, the increase in cell number is initially rather slow but increases at an ever faster rate. In the later stages of exponential growth, this results in an explosive increase in cell numbers. For example, in the experiment shown in Figure 5.9, the rate of cell production in the first 30 min of growth is 1 cell per 30 min. However, between 4 and 4.5 h of growth, the rate of cell production is 256 cells per 30 min, and between 5.5 and

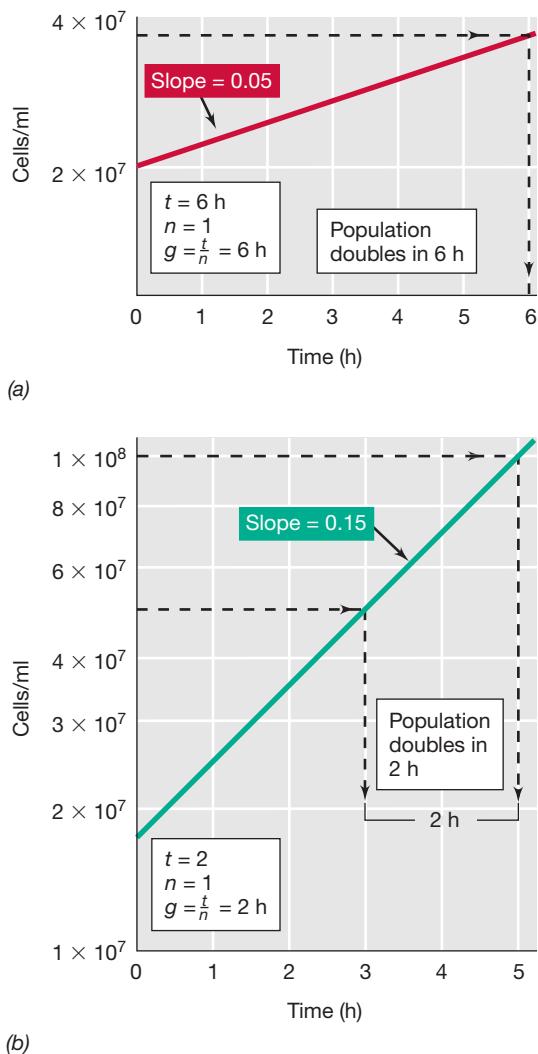

Figure 5.10 Calculating microbial growth parameters. Method of estimating the generation times (g) of exponentially growing populations with g of (a) 6 h and (b) 2 h from data plotted on semilogarithmic graphs. The slope of each line is equal to $0.301/g$, and n is the number of generations in the time t . All numbers are expressed in scientific notation; that is, $10,000,000$ is 1×10^7 , $60,000,000$ is 6×10^7 , and so on.

6 h of growth it is 2048 cells per 30 min (Figure 5.9). Because of this, cell numbers in laboratory cultures of bacteria can quickly become very large, with final population sizes of $> 10^9$ cells/ml not uncommon.

Besides being a theoretical construct, exponential growth can have implications in everyday life. Consider something as mundane as the spoilage of milk. The lactic acid bacteria responsible for the soured flavor of spoiled milk contaminate the milk during its collection and exist in fresh, pasteurized milk in low numbers; these organisms grow slowly at refrigerator temperature (4°C) but much faster at room temperature. If a bottle of fresh milk is left to stand at room temperature overnight, some lactic acid is made, but not enough to affect milk quality. However, if week-old milk, which now contains a week's worth of bacterial growth and thus much higher cell numbers, is left standing under the same conditions, a huge amount of lactic acid is made, and spoilage results.

MINIQUIZ

- What is a semilogarithmic plot and what information can we derive from it?
- Distinguish between the terms specific growth rate and generation time.
- If in 8 h, an exponentially growing culture increases from 5×10^6 cells/ml to 5×10^8 cells/ml, calculate g , n , ν , and k .

5.6 The Growth Cycle

The data presented in Figures 5.9 and 5.10 reflect only part of the growth cycle of a microbial population, the part called *exponential growth*. For several reasons, an organism growing in an enclosed vessel, such as a tube or a flask (a **batch culture**), cannot grow exponentially indefinitely. Instead, a typical *growth curve* for the population is obtained, as illustrated in **Figure 5.11**. The growth curve describes an entire growth cycle, and includes lag, exponential, stationary, and death phases.

Lag Phase

When a microbial culture is inoculated into fresh media, growth begins only after a period of time called the *lag phase*. This interval may be brief or extended, depending on the history of the inoculum and nature of the medium and growth conditions. If an exponentially growing culture is transferred into the same medium under the same conditions of growth (temperature, aeration, and the like), there will be essentially no lag and exponential growth begins immediately. However, if the inoculum is taken from an old culture there is usually a lag because the cells are depleted of various essential constituents and time is required for their biosynthesis. A lag is also encountered when the inoculum is of low viability (few live cells) or contains cells that have been damaged but not killed by some stressor, such as high or low temperature, radiation, or toxic chemicals.

A lag is also observed when a microbial culture is transferred from a rich culture medium to a poorer one (a medium downshift); for example, from a complex medium to a defined medium (see Section 3.2). To grow in any culture medium the cells must have a complete complement of enzymes for synthesis of the essential metabolites not present in that medium. Hence, upon a medium downshift, essential metabolites must be biosynthesized, and time is needed for synthesis of the new enzymes required and for these to produce a small pool of each metabolite.

Exponential Phase

As we saw in Section 5.5, during exponential growth, the cell population doubles at regular intervals for a brief or extended period, depending on the available resources and other factors. Exponentially growing cells are said to be in the *exponential phase* of growth. Exponential phase cells are typically in their healthiest state and are thus most desirable for studies of their enzymes or other cell components.

Rates of exponential growth vary greatly. The rate of exponential growth is influenced by environmental conditions (temperature, composition of the culture medium), as well as by genetic

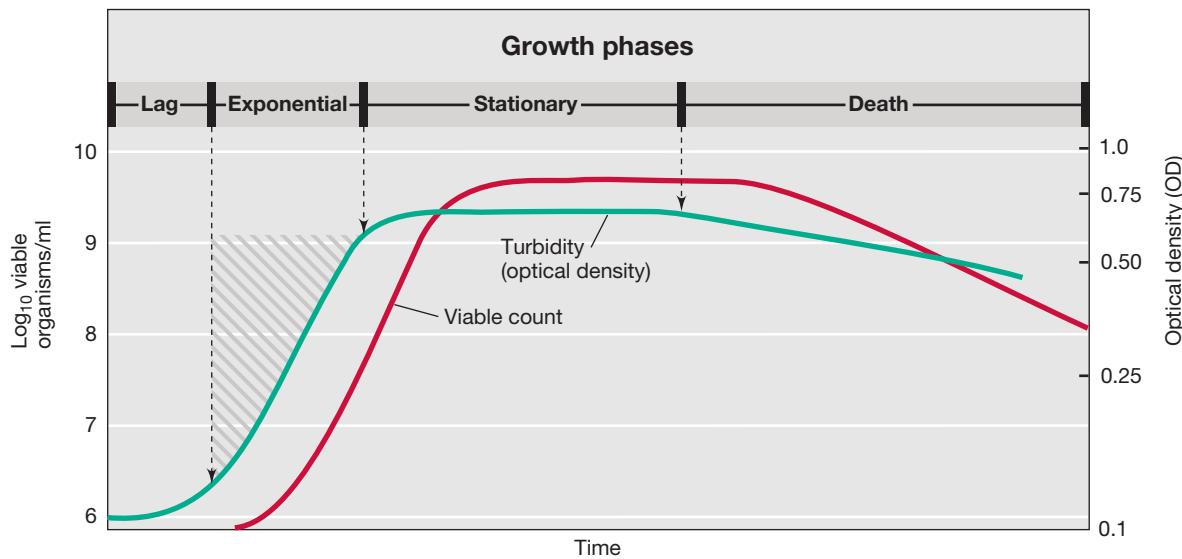

Figure 5.11 Typical growth curve for a bacterial population. A viable count measures the cells in the culture that are capable of reproducing. Optical density (turbidity), a quantitative measure of light scattering by a liquid culture, increases with the increase in cell number.

characteristics of the organism itself. In general, prokaryotes grow faster than eukaryotic microorganisms, and small eukaryotes tend to grow faster than large ones. This should remind us of the previously discussed concept of surface-to-volume ratio. Recall that small cells have an increased capacity for nutrient and waste exchange compared with larger cells, and this metabolic advantage can greatly affect their growth and other properties (➡ Section 2.6).

Stationary and Death Phases

In a batch culture, exponential growth cannot be maintained indefinitely. Consider the fact that a single cell of a bacterium weighing one-trillionth (10^{-12}) of a gram and growing exponentially with a 20-min generation time would produce, if allowed to grow exponentially in batch culture for 48 h, a population of cells that weighed 4000 times the weight of Earth! Obviously this is impossible, and growth becomes limited in such cultures because either an essential nutrient in the culture medium is depleted or the organism's waste products accumulate. When exponential growth ceases for one (or both) of these reasons, the population enters *stationary phase* (Figure 5.11).

In the stationary phase, there is no net increase or decrease in cell number and thus the growth rate of the population is zero. Despite growth arrest, energy metabolism and biosynthetic processes in stationary phase cells may continue, but typically at a greatly reduced rate. Some cells may even divide during stationary phase but no net increase in cell number occurs. This is because some cells in the population grow while others die, the two processes balancing each other out (cryptic growth). Sooner or later, however, the population will enter the *death phase* of the growth cycle, which, like the exponential phase, occurs as an exponential function (Figure 5.11). Typically, however, the rate of cell death is much slower than the rate of exponential growth and viable cells may remain in a culture for months or even years.

The phases of bacterial growth shown in Figure 5.11 are reflections of the events in a *population* of cells, not in individual cells. Thus, the terms lag phase, exponential phase, and so on have no meaning with respect to individual cells but only to cell populations. Growth of an individual cell is a necessary prerequisite for population growth. But it is population growth that is most relevant to the ecology of microorganisms, because measurable microbial activities require microbial populations, not just an individual microbial cell.

MINIQUIZ

- In which phase of the growth curve do cells divide in a constant time period?
- Under what conditions would a lag phase not occur?
- Why do cells enter stationary phase?

5.7 Continuous Culture

Up to this point our discussion of population growth has been confined to batch cultures. The environment in a batch culture is constantly changing because of nutrient consumption and waste production. It is possible to circumvent these changes in a *continuous culture device*. Unlike a batch culture, which is a *closed system*, a continuous culture is an *open system*. In the continuous culture growth vessel a known volume of fresh medium is added at a constant rate while an equal volume of spent culture medium (which also contains cells) is removed at the same rate. Once in equilibrium, the growth vessel volume, cell number, and nutrient/waste product status remain constant, and the culture attains *steady state*.

The Chemostat

The most common type of continuous culture is the **chemostat**, a device wherein both growth rate (how *fast* the cells divide) and

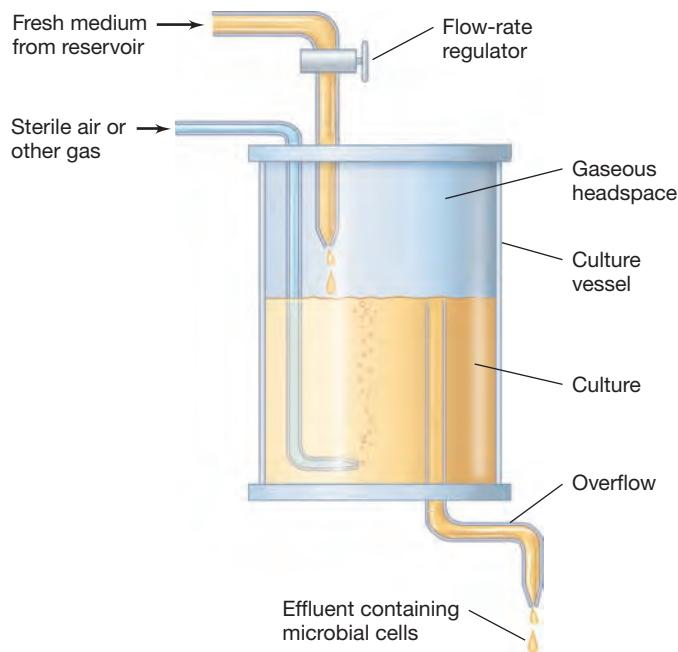

Figure 5.12 Schematic for a continuous culture device (chemostat). The population density is controlled by the concentration of limiting nutrient in the reservoir, and the growth rate is controlled by the flow rate. Both parameters can be set by the experimenter.

cell density (how *many* cells per ml are obtained) can be controlled independently (Figure 5.12). Two factors govern growth rate and cell density, respectively: (1) the *dilution rate*, which is the rate at which fresh medium is pumped in and spent medium is removed; and (2) the *concentration of a limiting nutrient*, such as a carbon or nitrogen source, present in the sterile medium entering the chemostat vessel.

In a batch culture, the nutrient concentration affects both growth rate and growth yield (Figure 5.13). At very low concentrations of a given nutrient, the growth rate is submaximal because

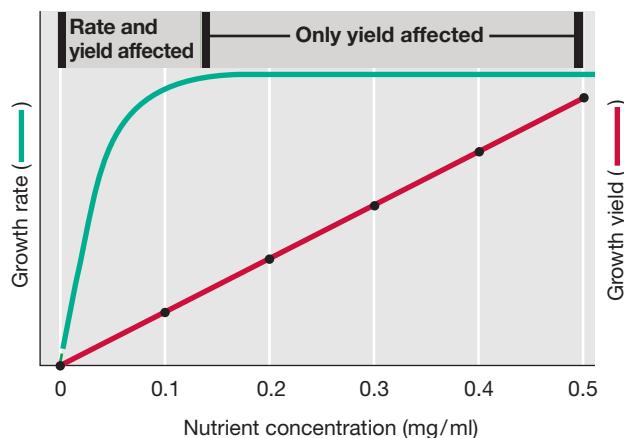

Figure 5.13 The effect of nutrients on growth. Relationship between nutrient concentration, growth rate (green curve), and growth yield (red curve) in a batch culture (closed system). Only at low nutrient concentrations are both growth rate and growth yield affected.

the nutrient cannot be transported into the cell fast enough to satisfy metabolic demand. At higher nutrient levels, the maximal growth rate may be obtained but the cell density can continue to increase in proportion to the concentration of nutrients in the medium (Figure 5.13). In a chemostat, by contrast, growth rate and growth yield are controlled independently: the growth rate by the dilution rate and the cell yield by the concentration of a limiting nutrient.

Varying Chemostat Parameters

The effects on bacterial growth of varying the dilution rate and concentration of growth-limiting nutrient in a chemostat are shown in Figure 5.14. As seen, there are rather wide limits over which the dilution rate controls growth rate, although at both very low and very high dilution rates, the steady state breaks down. At too *high* a dilution rate, the organism cannot grow fast enough to keep up with its dilution and is washed out of the chemostat. By contrast, at too *low* a dilution rate, cells may die from starvation because the limiting nutrient is not being added fast enough to support minimal cell metabolism. However, between these limits, different growth rates can be achieved by simply varying the dilution rate.

Cell density in a chemostat is controlled by a limiting nutrient, just as it is in a batch culture (Figure 5.13). If the concentration of this nutrient in the incoming medium is increased at a constant dilution rate, cell density will increase but growth rate will remain the same. Thus, by varying the chemostat dilution rate and nutrient level, one can establish dilute (for example, 10^5 cells/ml), moderate (for example, 10^7 cells/ml), or dense (for example, 10^9 cells/ml) cell populations growing at any specific growth rate.

Experimental Uses of the Chemostat

A practical advantage to the chemostat is that a cell population can be maintained in the exponential growth phase for long

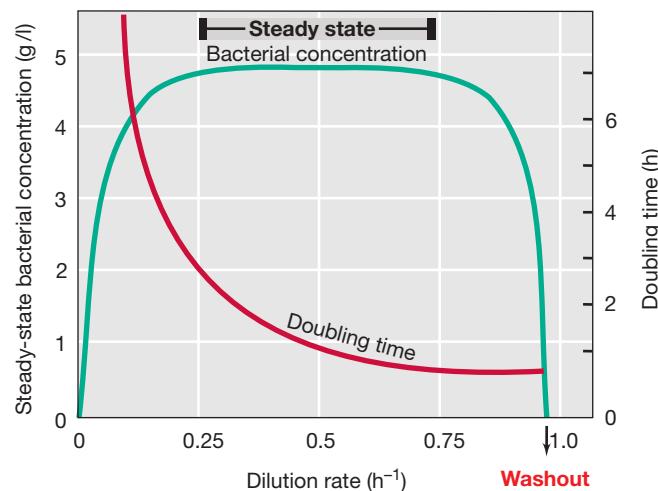

Figure 5.14 Steady-state relationships in the chemostat. The dilution rate is determined from the flow rate and the volume of the culture vessel. Thus, with a vessel of 1000 ml and a flow rate through the vessel of 500 ml/h, the dilution rate would be 0.5 h^{-1} . Note that at high dilution rates, growth cannot balance dilution, and the population washes out. Note also that although the population density remains constant during steady state, the growth rate (doubling time) can vary over a wide range.

periods, days or even weeks. Exponential phase cells are usually most desirable for physiological experiments, and such cells can be available at any time when grown in a chemostat. Moreover, repetition of experiments can be done with the knowledge that each time the cell population will be as close to being the same as possible. After a sample is removed from the chemostat, a period of time is required for the vessel to return to its original volume and for steady state to be reestablished. Once this has occurred, the vessel can be sampled again.

The chemostat has been used in microbial ecology as well as in microbial physiology. For example, because the chemostat can mimic the low substrate concentrations that are often found in nature, it is possible to ask which organisms in mixed cultures of known composition can best survive nutrient limitations. This can be done by monitoring changes in the microbial community as a function of varying nutrient conditions. Chemostats have

also been used for the enrichment and isolation of bacteria from nature. From a natural sample, one can select a stable population under the nutrient and dilution-rate conditions chosen and then slowly increase the dilution rate until a single organism remains. In this way, microbiologists studying the growth rates of various soil bacteria isolated a bacterium with a 6-min doubling time—the fastest-growing bacterium known!

MINIQUIZ

- How do microorganisms in a chemostat differ from microorganisms in a batch culture?
- What happens in a chemostat if the dilution rate exceeds the maximal growth rate of the organism?
- Do pure cultures have to be used in a chemostat?

III • Measuring Microbial Growth

Population growth is measured by monitoring changes in cell number or changes in the level of some cellular component as a proxy for cell number. These include protein, nucleic acids, or the dry weight of the cells themselves. We consider here two common measures of cell growth: cell counts and turbidity, the latter of which is a function of cell mass.

5.8 Microscopic Counts

A total count of microbial numbers in a culture or natural sample can be done by simply observing and enumerating the cells present. The most common total count method is the *microscopic cell count*. Microscopic counts can be performed either on samples dried on slides or on liquid samples. Dried samples can be stained to increase contrast between cells and their background (☞ Sections 2.2 and 18.3). With liquid samples, counting chambers consisting of a grid with squares of known area etched on the surface of a glass slide are used (Figure 5.15). When the coverslip is placed on the chamber, each square on the grid has a precisely measured volume. The number of cells per unit area of grid can be counted

under the microscope, giving a measure of the number of cells per small chamber volume. The number of cells per milliliter of suspension is calculated by employing a conversion factor based on the volume of the chamber sample (Figure 5.15).

Cells in liquid samples can also be counted in a flow cytometer. This is a machine that employs a laser beam and complex electronics to count individual cells. Flow cytometry is rarely used for the routine counting of microbial cells, but has applications in the medical field for counting and differentiating blood cells and other cell types from clinical samples. It has also been used in microbial ecology to separate different types of cells for isolation purposes (☞ Section 18.10).

Caveats of Microscopic Counting

Microscopic counting is a quick and easy way of estimating microbial cell numbers. However, it has several limitations that restrict its usefulness to rather specific applications. For example, without special staining techniques (☞ Section 18.3), dead cells cannot be distinguished from live cells, and precision is difficult to

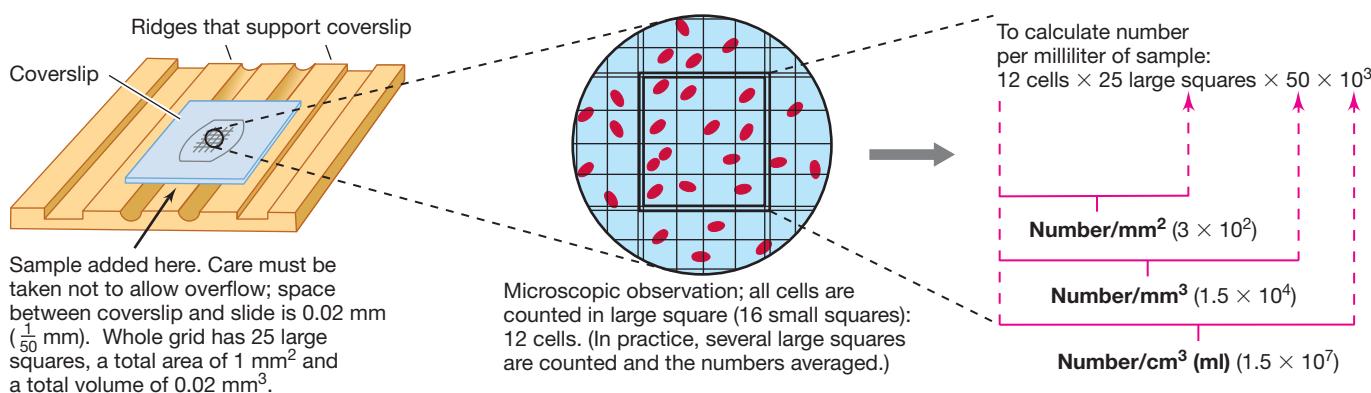

Figure 5.15 Direct microscopic counting procedure using the Petroff–Hausser counting chamber. A phase-contrast microscope is typically used to count the cells to avoid the necessity for staining.

achieve, even if replicate counts are made. Moreover, small cells are often difficult to see under the microscope, which can lead to erroneous counts, and cell suspensions of low density (less than about 10^6 cells/milliliter) will have few if any cells in a microscope field unless the sample is first concentrated and resuspended in a small volume. Finally, motile cells must be killed or otherwise immobilized before counting, and debris in the sample may easily be mistaken for microbial cells.

Microscopic Cell Counts in Microbial Ecology

Despite its many potential caveats, microbial ecologists often use microscopic cell counts on natural samples. But they do so using stains to visualize the cells, often very powerful stains that yield phylogenetic or other key information about the cells, such as their metabolic properties.

The stain DAPI (Section 2.2 and Figure 2.6c) stains all cells in a sample because it reacts with DNA. By contrast, fluorescent stains that are highly specific for certain organisms or groups of related organisms can be prepared by attaching the fluorescent dyes to specific nucleic acid probes. For example, phylogenetic stains that stain only species of *Bacteria* or only species of *Archaea* can be used in combination with nonspecific stains to determine the proportion of each domain present in a given sample; the use of these stains will be discussed in Section 18.4. Other fluorescent probes target genes that encode enzymes linked to specific metabolic processes; if a cell is stained by one of these probes, a key metabolic property can be inferred that may reveal the cell's ecological role in the microbial community. In all of these cases, if cells in the sample are present in only low numbers, for example, in a sample of ocean water, this limitation can be overcome by

first concentrating the cells on a filter and then counting them after staining.

Because they are easy to do and often yield very useful information, microscopic cell counts are very common in ecological studies of natural microbial environments. We pursue this theme in more detail in Chapter 18.

MINIQUIZ

- What are some of the problems that can arise when unstained preparations are enumerated in microscopic counts?
- Using microscopic techniques, how could you tell whether *Archaea* were present in an alpine lake where total cell numbers were only 10^5 /ml?

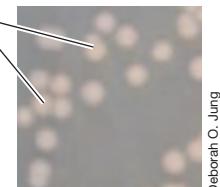

5.9 Viable Counts

A **viable** cell is one that is able to divide and form offspring, and in most cell-counting situations, these are the cells we are most interested in. For these purposes, one would use a **viable count**, also called a **plate count** because agar plates are required. The assumption made in a viable count is that each viable cell will grow and divide to yield one colony, and hence, colony numbers are a reflection of cell numbers.

Methods for Viable Counts

There are at least two ways of performing a plate count: the *spread-plate* method and the *pour-plate* method (Figure 5.16). In the spread-plate method, a volume (usually 0.1 ml or less) of an appropriately diluted culture is spread over the surface of an agar

Spread-plate method

Pour-plate method

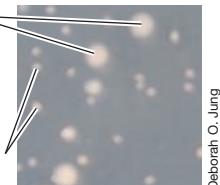

Figure 5.16 Two methods for the viable count. In the pour-plate method, colonies form within the agar as well as on the agar surface. On the far right are photos of colonies of *Escherichia coli* formed from cells plated by the spread-plate method (top) or the pour-plate method (bottom).

plate using a sterile glass spreader. In the pour-plate method, a known volume (usually 0.1–1.0 ml) of culture is pipetted into a sterile Petri plate. Molten agar medium, tempered to just above gelling temperature, is then added and mixed by gently swirling the plate on the benchtop. With both the spread-plate and pour-plate methods, it is important that the number of colonies developing on or in the medium not be too many or too few. On crowded plates some cells may not form colonies, and some colonies may fuse, leading to erroneous measurements. If the number of colonies is too small, the statistical significance of the calculated count will be low. The usual practice, which is most valid statistically, is to count colonies only on plates that have between 30 and 300 colonies.

To obtain the appropriate colony number, the sample to be counted must almost always be diluted. Because one may not know the approximate viable count ahead of time, it is usually necessary to make more than one dilution. Several 10-fold dilutions of the sample are commonly used (Figure 5.17). To make a 10-fold (10^{-1}) dilution, one can mix 0.5 ml of sample with 4.5 ml of diluent, or 1.0 ml of sample with 9.0 ml of diluent. If a 100-fold (10^{-2}) dilution is needed, 0.05 ml can be mixed with 4.95 ml of diluent, or 0.1 ml with 9.9 ml of diluent. Alternatively, a 10^{-2} dilution can be achieved by making two successive 10-fold dilutions. With dense cultures, such *serial* dilutions are needed to reach a

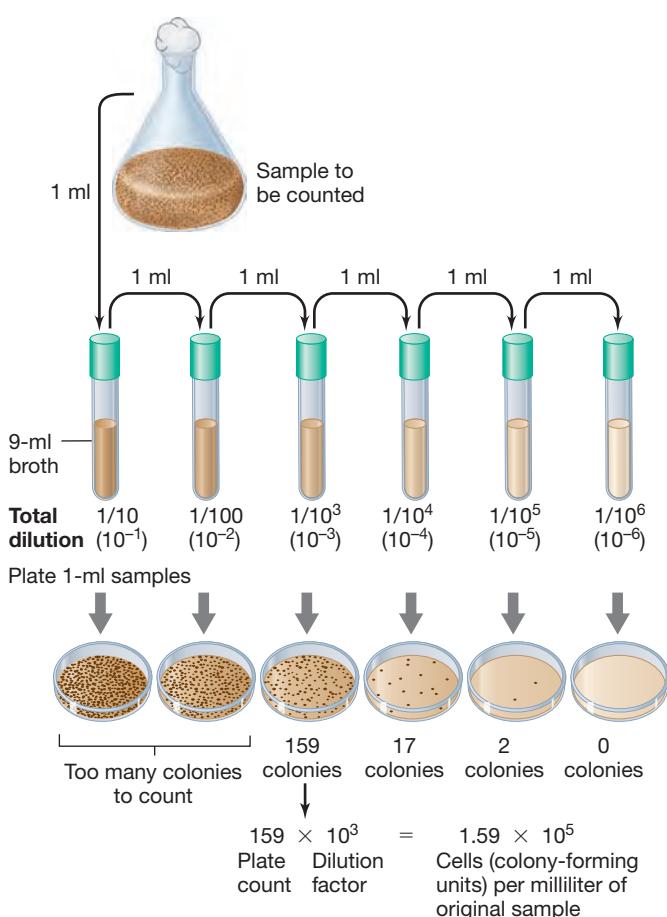

Figure 5.17 Procedure for viable counting using serial dilutions of the sample and the pour-plate method. The sterile liquid used for making dilutions can simply be water, but a solution of mineral salts or actual growth medium may yield a higher recovery. The dilution factor is the reciprocal of the dilution.

suitable dilution for plating to yield countable colonies. Thus, if a 10^{-6} ($1/10^6$) dilution is needed, it can be achieved by making three successive 10^{-2} ($1/10^2$) dilutions or six successive 10^{-1} dilutions (Figure 5.17).

Sources of Error in Plate Counting

The number of colonies obtained in a viable count experiment depends not only on the inoculum size and the viability of the culture, but also on the culture medium and the incubation conditions. The colony number can also change with the length of incubation. For example, if a mixed culture is counted, the cells deposited on the plate will not all form colonies at the same rate; if a short incubation time is used, fewer than the maximum number of colonies will be obtained. Furthermore, the size of colonies may vary. If some tiny colonies develop, they may be missed during the counting. With pure cultures, colony development is a more synchronous process and uniform colony morphology is the norm.

Viable counts can be subject to rather large errors for several reasons. These include plating inconsistencies, such as inaccurate pipetting of a liquid sample, a nonuniform sample (for example, a sample containing cell clumps), insufficient mixing, heat intolerance (if pour plates are used), and many other factors. Hence, if accurate counts are to be obtained, great care and consistency must be taken in sample preparation and plating, and replicate plates of key dilutions must be prepared. Also, if two or more cells are in a clump, they will grow to form only a single colony. So if a sample contains many cell clumps, a viable count of that sample may be erroneously low. Data from such samples are often expressed as the number of *colony-forming units* obtained rather than the actual number of viable cells, because a colony-forming unit may contain one or more cells.

Applications of the Plate Count

Despite the difficulties associated with viable counting, the procedure gives a good estimate of the number of viable cells in a sample and so is widely used in many subdisciplines of microbiology. For example, in food, dairy, medical, and aquatic microbiology, viable counts are employed routinely. The method has the virtue of high sensitivity, because as few as one viable cell per sample plated can be detected. This feature allows for the sensitive detection of microbial contamination of foods or other materials.

The use of highly selective culture media and growth conditions allows the plate count to be used to target particular species in a sample containing many organisms. For example, a complex medium containing 10% NaCl is very useful in isolating species of *Staphylococcus* from skin, because the salt inhibits growth of most other bacteria (► Section 29.9). In practical applications such as in the food industry, viable counting on both complex and selective media allows for both quantitative and qualitative assessments of the microorganisms present in a food product. That is, with a single sample one medium may be employed for a total count and a second medium used to target a particular organism, such as a specific pathogen. Targeted counting is also common in wastewater and other water analyses. For instance, enteric bacteria such as *Escherichia coli* originate from feces and are easy to target using selective media; if enteric bacteria are detected in a water sample from a swimming site, for example, their presence is a signal that the water is unsafe for human contact.

The Great Plate Count Anomaly

Direct microscopic counts of natural samples typically reveal far more organisms than are recoverable on plates of any single culture medium. Thus, although a very sensitive technique, plate counts can be highly unreliable when used to assess total cell numbers of natural samples, such as soil and water. Some microbiologists have referred to this as “the great plate count anomaly.”

Why do plate counts show lower numbers of cells than direct microscopic counts? One obvious factor is that microscopic methods count dead cells, whereas by definition, viable methods do not. More important, however, is the fact that different organisms, even those present in a very small natural sample, may have vastly different requirements for nutrients and growth conditions in laboratory culture (Sections 3.1 and 3.2). Thus, one medium and set of growth conditions can only be expected to support the growth of one subset of the total microbial community. If this subset makes up, for example, 10^6 cells/g of a total viable community of 10^9 cells/g, the plate count will reveal only 0.1% of the viable cell population, a vast underestimation of the actual number and physiological types of organisms present in the sample.

Plate count results thus carry a large caveat. Targeted plate counts using highly selective media, as in, for example, the microbial analysis of sewage or food, can often yield quite reliable data, since the physiology of the targeted organisms are known. By contrast, “total” cell counts of the same samples using a single medium and set of growth conditions may be, and usually are, underestimates of actual cell numbers by one to several orders of magnitude.

MINIQUIZ

- Why is a viable count more sensitive than a microscopic count? What major assumption is made in relating plate count results to cell number?
- Describe how you would dilute a bacterial culture by 10^{-7} .
- Explain the “great plate count anomaly.”

5.10 Spectrophotometry

During exponential growth, all cellular components increase in proportion to the increase in cell numbers. One such component is cell mass itself. Cells scatter light, and a rapid and useful method of estimating cell mass is *turbidity*. A cell suspension looks cloudy (turbid) to the eye because cells scatter light that passes through the suspension. The more cells that are present, the more light is scattered, and hence the more turbid the suspension. Because cell mass is proportional to cell number, turbidity can be used to estimate cell numbers and is a widely used technique in microbiology.

Optical Density

Turbidity is measured with a spectrophotometer, an instrument that passes light through a cell suspension and measures the unscattered light that emerges (Figure 5.18). A spectrophotometer employs a prism or diffraction grating to generate incident light of a specific wavelength (Figure 5.18a). Commonly used wavelengths for bacterial turbidity measurements include 480 nm

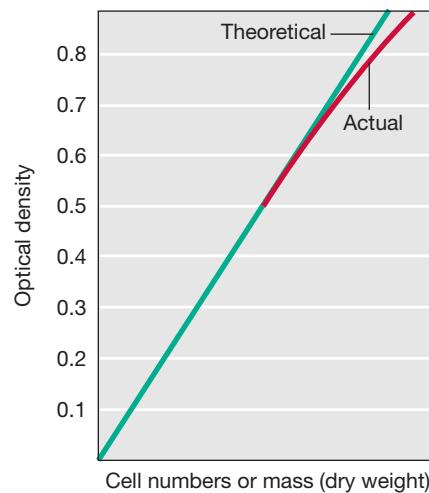

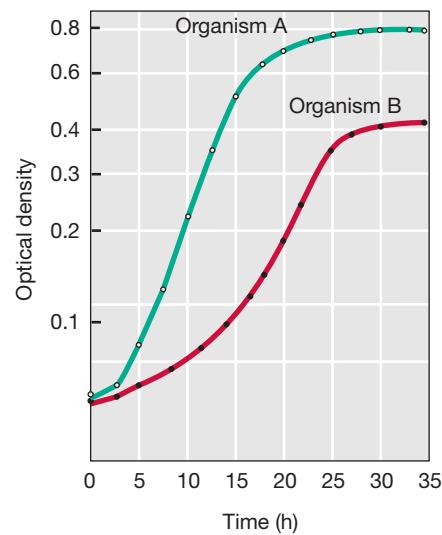

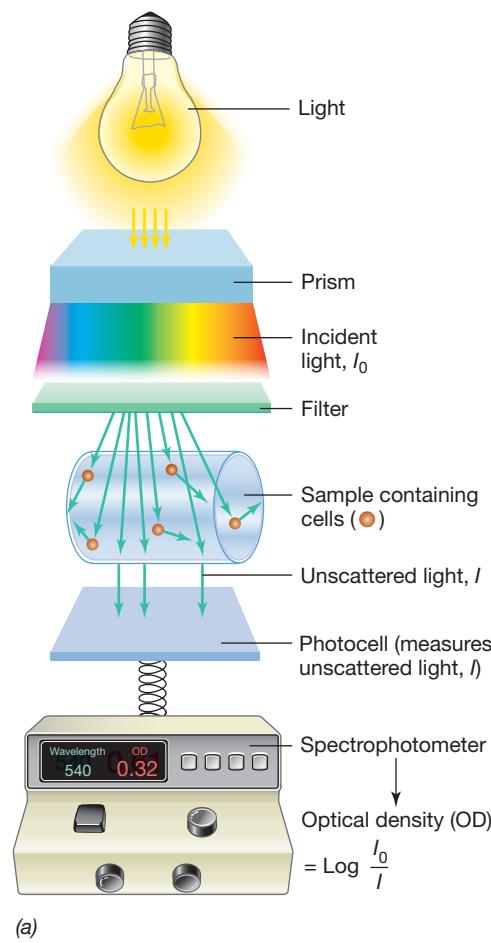

Figure 5.18 Turbidity measurements of microbial growth. (a) Measurements of turbidity are made in a spectrophotometer. The photocell measures incident light unscattered by cells in suspension and gives readings in optical density units. (b) Typical growth curve data for two organisms growing at different growth rates. For practice, calculate the generation time of the two cultures using the formula $n = 3.3(\log N - \log N_0)$ where N and N_0 are two different OD readings with a time interval t between the two (Section 5.5). Which organism is growing faster, A or B? (c) Relationship between cell number or dry weight and turbidity readings. Note that the one-to-one correspondence between these relationships breaks down at high turbidities.

(blue), 540 nm (green), 600 nm (orange), and 660 nm (red). Sensitivity is best at shorter wavelengths, but measurements of dense cell suspensions are more accurate at longer wavelengths. The unit of turbidity is *optical density (OD)* at the wavelength specified, for example, OD₅₄₀ for measurements at 540 nm (Figure 5.18). The term *absorbance (A)*, for example A₅₄₀, is also a commonly used unit, but it should be understood that it is the *scattering* of light, not the *absorbance* of light, that is actually being assessed in the spectrophotometer.

Relating Optical Density to Cell Numbers

For unicellular organisms, optical density is proportional, within certain limits, to cell number. Turbidity readings can therefore be used as a substitute for total or viable counting methods. However, before this can be done, a standard curve must be prepared that relates cell number (microscopic or viable count), dry weight, or protein content to turbidity. As can be seen in such a plot, proportionality only holds within limits (Figure 5.18c). At high cell densities, light scattered away from the spectrophotometer's photocell by one cell can be scattered back toward the photocell by another. To the photocell, this is as if light had never been scattered in the first place. At such high cell densities, the one-to-one correspondence between cell number and turbidity deviates from linearity, and OD measurements become less accurate. However, up to this limit, turbidity measurements can be highly accurate measures of cell number or dry weight. Also, because different organisms differ in size and shape, equal cell numbers of two different bacterial species will not necessarily yield the same OD value. Thus, to relate OD to actual cell numbers, a standard curve relating these two parameters must be made for each different organism grown routinely in the laboratory.

The Pluses and Minuses of Turbidimetric Growth

On the one hand, turbidity measurements are quick and easy to perform and can typically be made without destroying or

significantly disturbing the sample. For these reasons, turbidity measurements are widely employed to monitor growth of pure cultures of *Bacteria*, *Archaea*, and many microbial eukaryotes. With turbidimetric assays, the same sample can be checked repeatedly and the measurements plotted on a semilogarithmic plot versus time (Section 5.5). From these, it is easy to calculate the generation time and other parameters of the growing culture (Figure 5.18b).

On the other hand, turbidity measurements can sometimes be problematic. Although many microorganisms grow in even suspensions in liquid medium, many do not. Some bacteria routinely form small to large clumps, and in such instances, OD measurements may be quite inaccurate as a measure of total microbial mass. In addition, many bacteria grow in films on the sides of tubes or other growth vessels, mimicking in laboratory culture a common form of growth in nature (see Explore the Microbial World, "Stick or Swim"). Hence for OD measurements to be an accurate reflection of cell mass (and thus cell numbers) in a liquid culture, clumping and biofilms have to be minimized. This can often be accomplished by stirring, shaking, or in some way keeping the cells well mixed during the growth process to prevent the formation of cell aggregates and the sticking of swimming cells to surfaces, the first step in biofilm formation. Some bacteria are just naturally planktonic—staying well suspended in liquid medium for long periods—and do not form biofilms. But if a solid surface is available, most motile bacteria will eventually develop a static biofilm, and accurately quantifying cell numbers by turbidity in these can be difficult or even impossible.

MINIQUIZ

- List two advantages of using turbidity as a measure of cell growth.
- Describe how you could use a turbidity measurement to tell how many colonies you would expect from plating a culture of a given OD.

IV • Effect of Temperature on Microbial Growth

Microorganisms are greatly affected by the chemical and physical state of their environment, and four factors control growth in a major way: temperature, pH, water availability, and oxygen. We begin with temperature, the key environmental factor affecting the growth and survival of microorganisms.

5.11 Temperature Classes of Microorganisms

At either too cold or too hot a temperature, microorganisms will not be able to grow and may even die. The minimum and maximum temperatures supporting growth vary greatly among different organisms and usually reflect the temperature range and average temperature of the environments the organisms inhabit.

Cardinal Temperatures

Temperature affects microorganisms in two opposing ways. As temperatures rise, the rate of enzymatic reactions increases and growth becomes faster. However, above a certain temperature, proteins or other cell components may be denatured or otherwise irreversibly damaged. For every microorganism there is a *minimum* temperature below which growth is not possible, an *optimum* temperature at which growth is most rapid, and a *maximum* temperature above which growth is not possible. These three temperatures, called the **cardinal temperatures** (Figure 5.19), are characteristic for any given microorganism and can differ dramatically between species. For example, some organisms have growth temperature optima near 0°C while for others, this can be higher than 100°C. The temperature range throughout which microbial growth is possible is even wider than this, from

EXPLORE THE MICROBIAL WORLD

Stick or Swim

In this chapter we have discussed several ways in which microbial growth can be measured, including microscopic methods, viable counts, and measurements of light scattering (turbidity) by cells suspended in a liquid culture. The turbidimetric measures of bacterial growth assume that cells remain evenly distributed in their liquid growth medium. Under these conditions, the optical density of a culture is proportional to the log of the number of cells in suspension (**Figure 1**). This floating lifestyle, called *planktonic*, is the way some bacteria, for example, organisms that inhabit the water column of a lake, actually live in nature. However, many other microorganisms are *sessile*, meaning that they grow attached to a surface. These attached cells can then develop into **biofilms**.

Humans encounter bacterial biofilms on a daily basis, for example, when cleaning out a pet's water bowl that has been sitting unattended for a few days or when you sense with your tongue the "film" that develops on your unbrushed teeth.

A biofilm is an attached polysaccharide matrix containing embedded bacterial cells. Biofilms form in stages: (1) reversible attachment of planktonic cells, (2) irreversible attachment of the same cells, (3) cell growth and production of polysaccharide, and (4) further

development to form the tenacious and nearly impenetrable mature biofilm. In the early stages of biofilm formation, the attachment of bacterial cells to a surface triggers biofilm-specific gene expression. Genes that encode proteins that produce cell surface polysaccharides are transcribed, and the increased amount of slime facilitates attachment of more cells.

The motility structures of swimming bacteria—flagella—are necessary for initially establishing the biofilm state. Thin hairlike structures called type IV pili (☞ Section 2.13), which resemble flagella but do not rotate like flagella do, are crucial for biofilm maturation. Eventually, through growth and recruitment, entire microbial communities develop within the slimy polysaccharide matrix.

Bacterial biofilms can dramatically affect humans. For example, bacterial infections are often linked to pathogens that develop in biofilms during the disease process. The genetic disease cystic fibrosis (CF) is characterized by development of a biofilm containing *Pseudomonas aeruginosa* and other bacteria in the lungs of CF patients (**Figure 2**). The biofilm matrix, which contains alginate and other polysaccharides as well as bacterial DNA, greatly reduces the ability of antimicrobial agents, such as antibiotics, to penetrate, and thus bacteria within the biofilm are little

affected by the drugs. Bacterial biofilms have also been implicated in difficult-to-treat infections of implanted medical devices, such as replacement heart valves and artificial joints.

Biofilms are also a major problem in industry. Microbial biofilms can cause fouling of equipment and the contamination of products, especially if the liquid is nutrient-rich, such as milk. Biofilms can also do long-term damage to water distribution facilities and other public utilities (☞ Sections 21.10 and 21.11). Biofilms that develop in bulk storage containers, such as fuel storage tanks, can contaminate the fuel and cause souring from chemicals, such as hydrogen sulfide (H_2S), excreted by the biofilm bacteria.

Biofilms are a common form of bacterial growth in nature. Not only does the biofilm offer protection from harmful chemicals, the thick matrix of the biofilm provides a barrier to grazing by protists and prevents bacterial cells from being washed away into a less-favorable habitat. So, while optical densities give us a laboratory picture of the perfectly suspended bacterial culture, in the "real" world bacterial growth in the biofilm state is often observed.

We examine biofilms in more detail in our focus on surfaces as microbial habitats in Sections 19.4 and 19.5.

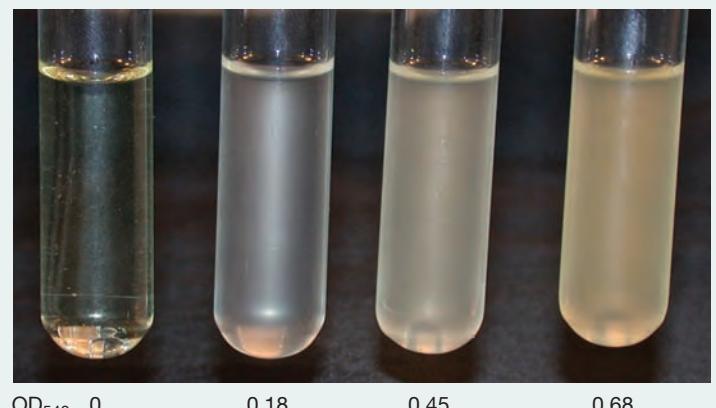

Figure 1 Liquid cultures of *Escherichia coli*. In these cultures cells are in a planktonic state and are evenly suspended in the medium. The increasing (left to right) optical density (OD_{540}) of each culture is shown below the tube. Optical density is a measure of light scattering and was measured at 540 nm here as described in Figure 5.18a. Although it is shown growing in suspension here, *E. coli* can also form biofilms. Attachment of *E. coli* cells is facilitated by their Type I fimbriae and conjugative pili (☞ Section 2.13).

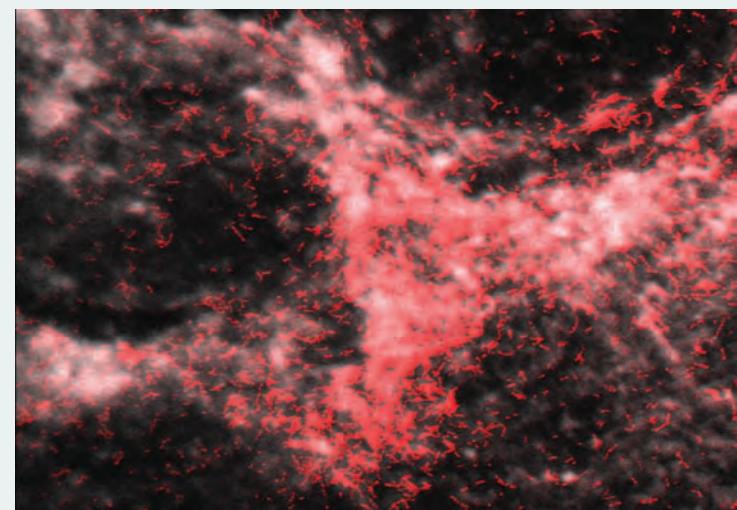

Figure 2 Fluorescently stained cells of *Pseudomonas aeruginosa*. The cells were from a sputum sample of a cystic fibrosis patient. The red cells are *P. aeruginosa* and the white material is alginate, a polysaccharide-like material that is produced by cells of *P. aeruginosa*.

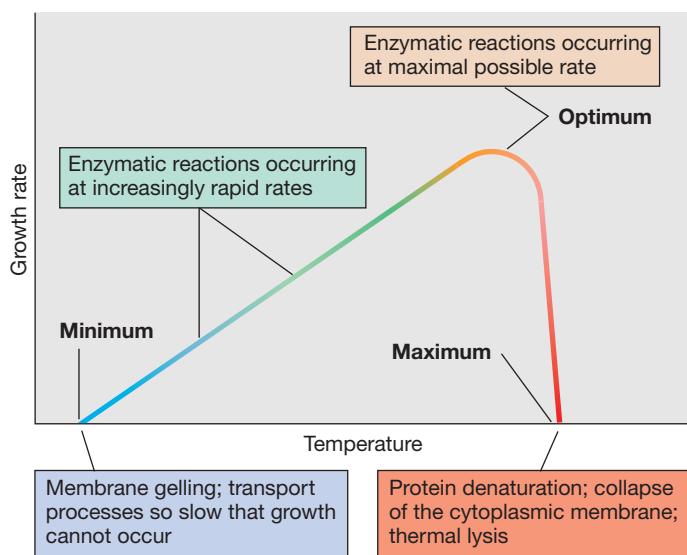

Figure 5.19 The cardinal temperatures: minimum, optimum, and maximum. The actual values may vary greatly for different organisms (see Figure 5.20).

as low as -15°C to at least 122°C . However, no single organism can grow over this whole temperature range, as the range for any given organism is typically less than 40°C .

The maximum growth temperature of an organism reflects the temperature above which denaturation of one or more essential cell components, such as a key enzyme, occurs. The factors controlling an organism's minimum growth temperature are not as clear. However, the cytoplasmic membrane must remain in a semifluid state for nutrient transport and bioenergetic functions to take place. That is, if an organism's cytoplasmic membrane stiffens to the point that it no longer functions properly in

transport or can no longer develop or consume a proton motive force, the organism cannot grow. In contrast to the minimum and maximum, the growth temperature *optimum* reflects a state in which all or most cellular components are functioning at their maximum rate and typically lies closer to the maximum than to the minimum (see Figure 5.20).

Temperature Classes of Organisms

Although there is a continuum of organisms, from those with very low temperature optima to those with high temperature optima, it is possible to distinguish four broad classes of microorganisms in relation to their growth temperature optima: **psychrophiles**, with low temperature optima; **mesophiles**, with midrange temperature optima; **thermophiles**, with high temperature optima; and **hyperthermophiles**, with very high temperature optima (Figure 5.20).

Mesophiles are widespread in nature and are the most commonly studied microorganisms. Mesophiles are found in warm-blooded animals and in terrestrial and aquatic environments in temperate and tropical latitudes. Psychrophiles and thermophiles are found in unusually cold and unusually hot environments, respectively. Hyperthermophiles are found in extremely hot habitats such as hot springs, geysers, and deep-sea hydrothermal vents.

Escherichia coli is a typical mesophile, and its cardinal temperatures have been precisely defined. The optimum temperature for most strains of *E. coli* is near 39°C , the maximum is 48°C , and the minimum is 8°C . Thus, the temperature range for *E. coli* is about 40 degrees, near the high end for prokaryotes (Figure 5.20).

We now consider the interesting cases of microorganisms that inhabit very low or very high temperature environments. We examine some of the physiological problems they face and some of the biochemical solutions they have evolved to survive under these extreme conditions.

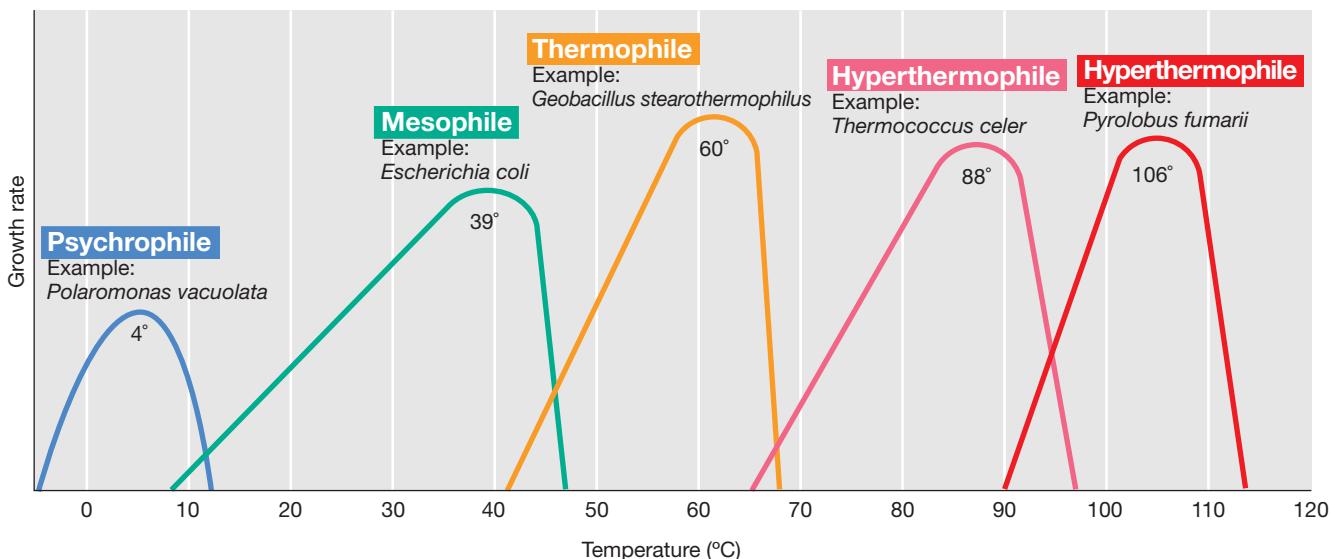

Figure 5.20 Temperature and growth response in different temperature classes of microorganisms. The temperature optimum of each example organism is shown on the graph.

MINIQUIZ

- How does a hyperthermophile differ from a psychrophile?
- What are the cardinal temperatures for *Escherichia coli*? To what temperature class does it belong?
- *E. coli* can grow at a higher temperature in a complex medium than in a defined medium. Why?

5.12 Microbial Life in the Cold

Because humans live and work on the surface of Earth where temperatures are generally moderate, it is natural to consider very hot and very cold environments as “extreme.” However, many microbial habitats are very hot or very cold, and organisms that inhabit these environments are called *extremophiles* (☞ Section 1.4 and Table 1.1). We consider the biology of these fascinating organisms here and in the next section.

Cold Environments

Much of Earth’s surface is cold. The oceans, which make up over half of Earth’s surface, have an average temperature of 5°C, and the depths of the open oceans have constant temperatures of 1–3°C. Vast land areas of the Arctic and Antarctic are permanently frozen or are unfrozen for only a few weeks in summer (Figure 5.21). These cold environments support diverse microbial life, as do glaciers where the network of liquid water channels that run through and under the glacier are teeming with microorganisms. Even in solidly frozen materials there remain small pockets of liquid water where solutes have concentrated and microorganisms can metabolize and grow slowly (☞ Chapter 1, page 1).

In considering cold environments, it is important to distinguish between environments that are *constantly* cold and those that are only *seasonally* cold. The latter, characteristic of temperate climates, may have summer temperatures as high as 40°C. A temperate lake, for example, may have ice cover in the winter,

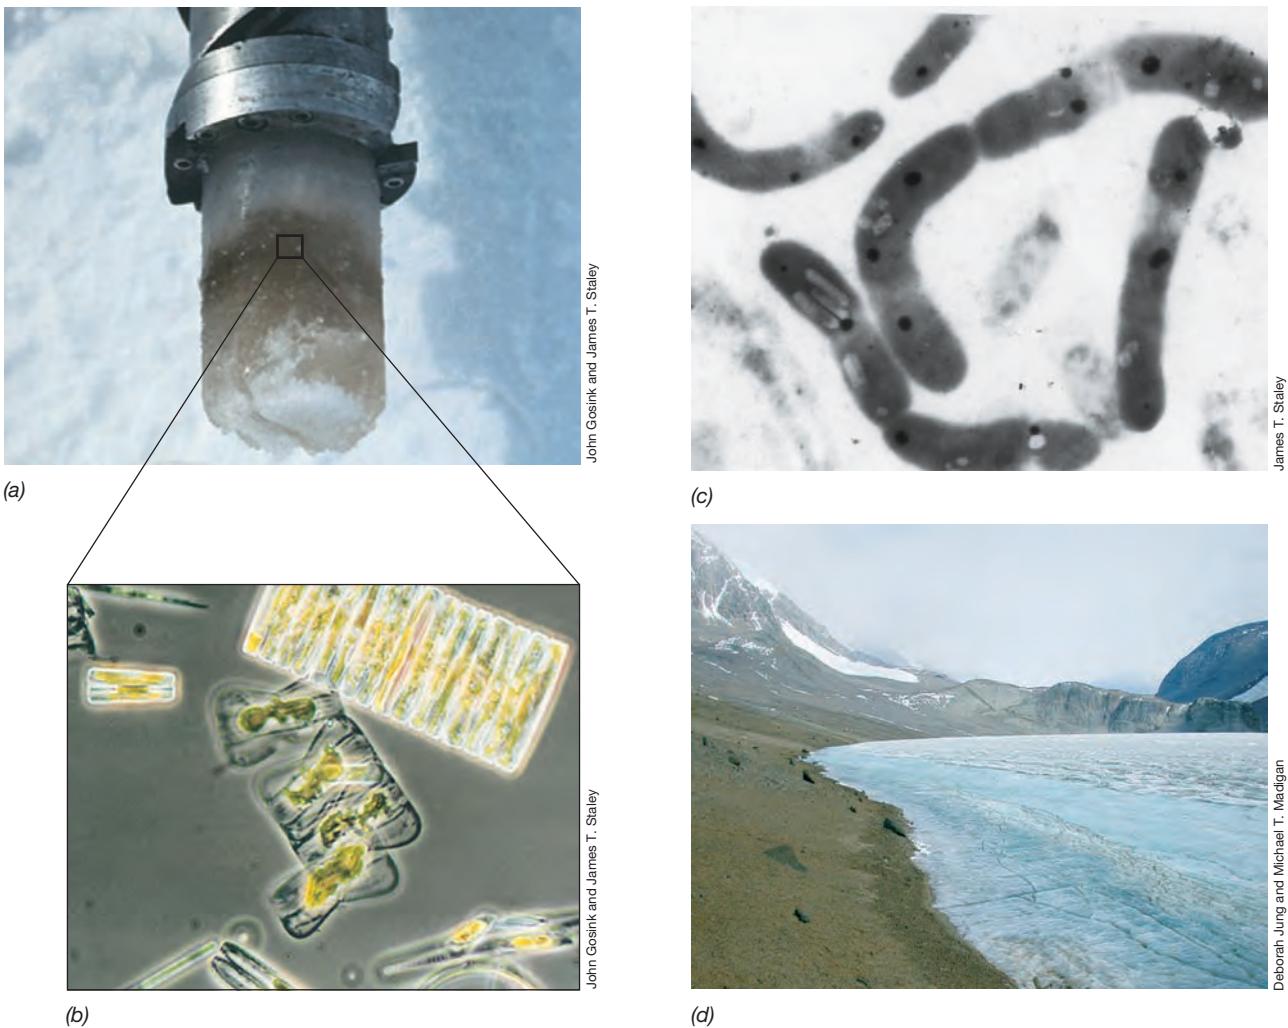

Figure 5.21 Antarctic microbial habitats and microorganisms. (a) A core of frozen seawater from McMurdo Sound, Antarctica. The core is about 8 cm wide. Note the dense coloration due to pigmented microorganisms. (b) Phase-contrast micrograph of phototrophic microorganisms from the core shown in part a. Most organisms are either diatoms or green algae (both eukaryotic phototrophs). (c) Transmission electron micrograph of *Polaromonas*, a gas vesiculate bacterium that lives in sea ice and grows optimally at 4°C. (d) Lake Bonney, McMUrdo Dry Valleys, Antarctica. Although the lake is permanently ice-covered, the water column under the ice remains near 0°C and contains a diverse array of prokaryotes and microbial eukaryotes.

but the time that the water remains at 0°C is relatively brief. By contrast, Antarctic lakes contain a permanent ice cover several meters thick (Figure 5.21d), and the water column below the ice in these lakes remains at 0°C or colder year round. Marine sediments are also constantly cold. It is thus not surprising that the best examples of cold-active *Bacteria* and *Archaea* have emerged from these two environments.

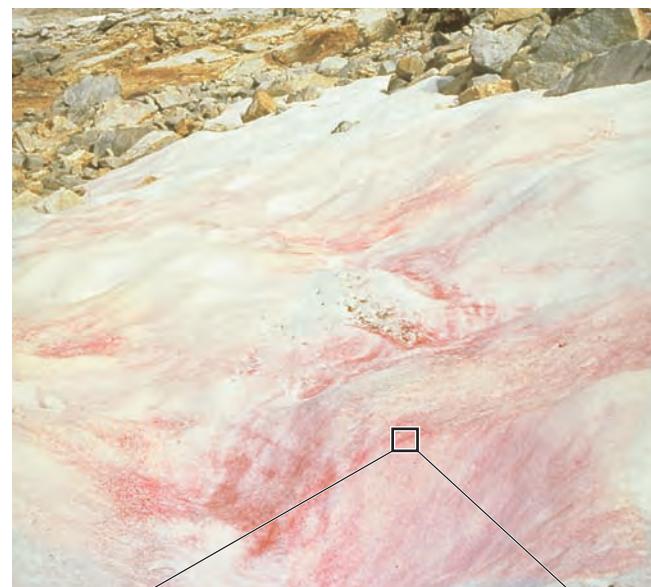

Psychrophilic and Psychrotolerant Microorganisms

A psychrophile is an organism with an optimal growth temperature of 15°C or lower, a maximum growth temperature below 20°C, and a minimal growth temperature at 0°C or lower. Organisms that grow at 0°C but have optima of 20–40°C are called **psychrotolerant**. Psychrophiles are found in environments that are constantly cold and may be killed by warming, even to as little as 20°C. For this reason, their laboratory study requires that great care be taken to ensure that they never warm up during sampling, transport to the laboratory, isolation, or other manipulations. Seasonally cold environments, by contrast, cannot support true psychrophiles because they cannot survive the warming.

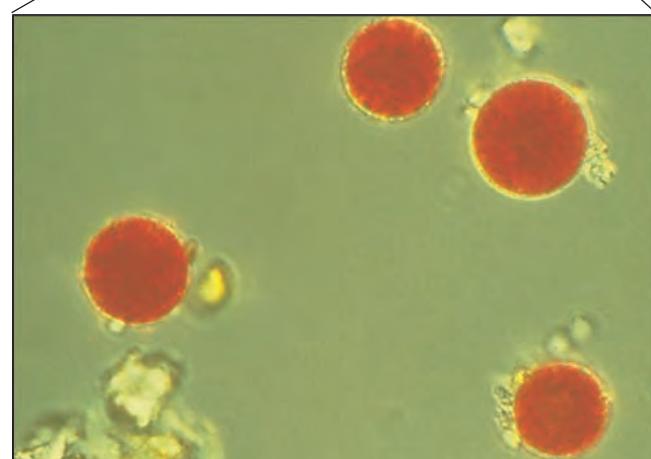

Psychrophilic algae and bacteria often grow in dense masses within and under sea ice (frozen seawater that forms seasonally) in polar regions (Figure 5.21a, b, c), and can also be found on the surfaces of permanent snowfields and glaciers where they impart a distinctive coloration to the surface (Figure 5.22a). The common snow alga *Chlamydomonas nivalis* is an example of this, its spores being responsible for the brilliant red color of the snow surface (Figure 5.22b). This green alga grows within the snow as a green-pigmented vegetative cell and then sporulates. As the snow dissipates by melting, erosion, and ablation (evaporation and sublimation), the spores become concentrated on the surface. Related species of snow algae contain different carotenoid pigments, and thus fields of snow algae can also be green, orange, brown, or purple.

Several psychrophilic bacteria have been isolated, and some of these show very low growth temperature optima. A species of the sea ice bacterium *Psychromonas* grows at -12°C, the lowest temperature for any known bacterium. However, the lower temperature limit for bacterial growth is probably closer to -20°C. Even at this cold temperature, pockets of liquid water can exist, and studies have shown that enzymes from cold-active bacteria still function under such conditions. Growth rates at such cold temperatures would likely be extremely low, with doubling times of months, or even years. But if an organism can grow, even if only at a very slow rate, it can remain competitive and maintain a population in its habitat.

Psychrotolerant microorganisms are more widely distributed in nature than are psychrophiles and can be isolated from soils and water in temperate climates as well as from meat, dairy products, cider, vegetables, and fruit stored at standard refrigeration temperatures (4°C). Although psychrotolerant microorganisms grow at 0°C, most do not grow well, and one must often wait several weeks before visible growth is seen in laboratory cultures. By contrast, the same organism cultured at 30 or 35° may show growth rates similar to that of many mesophiles. Various *Bacteria*, *Archaea*, and microbial eukaryotes are psychrotolerant.

Figure 5.22 Snow algae. (a) Snow bank in the Sierra Nevada, California, with red coloration caused by the presence of snow algae. Pink snow such as this is common on summer snow banks at high altitudes throughout the world. (b) Photomicrograph of red-pigmented spores of the snow alga *Chlamydomonas nivalis*. The spores germinate to yield motile green algal cells. Some strains of snow algae are true psychrophiles but many are psychrotolerant, growing best at temperatures above 20°C. From a phylogenetic standpoint, *C. nivalis* is a green alga, and these organisms are covered in Section 17.16.

Molecular Adaptations That Support Psychrophily

Psychrophiles produce enzymes that function—often optimally—in the cold and that may be denatured or otherwise inactivated at even very moderate temperatures. The molecular basis for this is not entirely understood, but is clearly linked to protein structure. Several cold-active enzymes whose structure is known show a greater content of α -helix and lesser content of β -sheet secondary structure (see Section 4.14) than do enzymes that show little or no activity in the cold. Because β -sheet secondary structures tend to be more rigid than α -helices, the greater α -helix content

of cold-active enzymes allows these proteins greater flexibility for catalyzing their reactions at cold temperatures. Cold-active enzymes also tend to have greater polar and lesser hydrophobic amino acid content (☞ Figure 4.30 for structures of amino acids) and lower numbers of weak bonds, such as hydrogen and ionic bonds, compared with the corresponding enzyme from mesophiles. Collectively, these molecular features are likely to keep cold-active enzymes flexible and functional under cold conditions.

Another characteristic feature of psychrophiles is that their cytoplasmic membranes remain functional at low temperatures. Cytoplasmic membranes from psychrophiles tend to contain a higher content of unsaturated and shorter-chain fatty acids, and this helps the membrane remain in a semifluid state at low temperatures to carry out important transport and bioenergetic functions. Some psychophilic bacteria even contain *polyunsaturated* fatty acids, and unlike monounsaturated or saturated fatty acids that tend to stiffen at low temperatures, these remain flexible even at very cold temperatures.

Other molecular adaptations to cold temperatures include “cold-shock” proteins and cryoprotectants, and these are not limited to psychrophiles. Cold-shock proteins are even present in *Escherichia coli* and have several functions that include maintaining other proteins in an active form under cold conditions or binding specific mRNAs and facilitating their translation. The latter include, in particular, mRNAs that encode other cold-functional proteins, most of which are not produced when the cell is growing at a higher temperature. Cryoprotectants include dedicated antifreeze proteins or specific solutes, such as glycerol or certain sugars that are produced in large amounts at cold temperatures; these agents help prevent the formation of ice crystals that can puncture the cytoplasmic membrane. Highly psychophilic bacteria often produce abundant levels of exopolysaccharides as well, and these are thought to have cryoprotectant properties too.

Although freezing temperatures may prevent microbial growth, they do not necessarily cause death. Some psychrophiles have been shown to metabolize at temperatures far lower than those supporting growth, and microbial respiration (as measured by CO₂ production) has been measured in tundra soils at nearly -40°C. Hence, enzymes continue to function at temperatures far below those that support cell growth. The medium in which cells are suspended also affects their sensitivity to freezing temperatures, and this has been exploited for the preservation of bacterial cells in microbial culture collections. For example, cells suspended in growth medium containing 10% dimethyl sulfoxide (DMSO) or glycerol and frozen at -80°C (ultracold-freezer) or -196°C (liquid nitrogen) remain viable in a frozen state for years.

MINIQUIZ

- How do psychrotolerant organisms differ from psychophilic organisms?
- What molecular adaptations to cold temperatures are seen in the cytoplasmic membrane of psychrophiles? Why are they necessary?

5.13 Microbial Life at High Temperatures

Microbial life flourishes in high-temperature environments, from sun-heated soils and pools of water to boiling hot springs, and the organisms that live in these environments are typically highly adapted to their environmental temperature. We examine them now (☞ Sections 15.18 and 15.19, and Chapter 16).

Thermal Environments

Organisms whose growth temperature optimum exceeds 45°C are called *thermophiles* and those whose optimum exceeds 80°C are called *hyperthermophiles* (Figure 5.20). The surface of soils subject to full sunlight can be heated to above 50°C at midday, and some surface soils may become warmed to even 70°C. Fermenting materials such as compost piles and silage can also reach temperatures of 70°C. Thermophiles abound in such environments. The most extreme high-temperature environments in nature, however, are hot springs, and these are home to a huge diversity of thermophiles and hyperthermophiles.

Many terrestrial hot springs have temperatures at or near boiling while those at the bottom of the ocean, called *hydrothermal vents*, can have temperatures of 350°C or greater. Hot springs can be found throughout the world, but they are especially abundant in the western United States, New Zealand, Iceland, Japan, Italy, Indonesia, Central America, and central Africa. The largest concentration of hot springs in the world is in Yellowstone National Park, Wyoming (USA). Although some hot springs vary widely in temperature, many are nearly constant, varying less than 1–2°C over many years. In addition, different springs have different chemical compositions and pH values. Above 65°C, only prokaryotes are present (Table 5.1), but the diversity of *Bacteria* and *Archaea* is often extensive.

Hyperthermophiles in Hot Springs

A variety of hyperthermophiles are typically present in boiling hot springs (Figure 5.23), including both chemotrophic and chemolithotrophic species. Growth rates of hyperthermophiles can be studied very simply in the field by immersing a microscope slide into a spring and then retrieving it a few days later; microscopic examination reveals microcolonies of prokaryotes that have developed from single cells that attached to and grew on the glass surface (Figure 5.23b). Simple ecological studies such as this have shown that microbial growth rates are often quite high, even in boiling springs; doubling times as short as 1 h have been recorded.

Cultures of diverse hyperthermophiles have been obtained, and a variety of morphological and physiological types of both *Bacteria* and *Archaea* are known. Some hyperthermophilic *Archaea* have growth-temperature optima above 100°C, while no species of *Bacteria* are known that grow above 95°C. Growing laboratory cultures of organisms with optima above the boiling point requires pressurized vessels that permit temperatures in the growth medium to rise above 100°C. The most heat-tolerant organisms known inhabit hydrothermal vents, with the most thermophilic example thus far being the methane-producing archaeon *Methanopyrus*, capable of growth at 122°C.

Table 5.1 Presently known upper temperature limits for growth of living organisms

Group	Upper temperature limits (°C)
Macroorganisms	
Animals	
Fish and other aquatic vertebrates	38
Insects	45–50
Ostracods (crustaceans)	49–50
Plants	
Vascular plants	45 (60 for one species)
Mosses	50
Microorganisms	
Eukaryotic microorganisms	
Protozoa	56
Algae	55–60
Fungi	60–62
Prokaryotes	
<i>Bacteria</i>	
Cyanobacteria	73
Anoxygenic phototrophs	70–73
Chemoorganotrophs/chemolithotrophs	95
<i>Archaea</i>	
Chemoorganotrophs/chemolithotrophs	122

Thermophiles

Many thermophiles (optima 45–80°C) are also present in hot springs, but many are found elsewhere as well. As boiling water leaves a hot spring, it gradually cools, setting up a thermal gradient. Along this gradient, microorganisms become established, with different species growing in the different temperature ranges (**Figure 5.24**). By studying the species distribution along such natural thermal gradients, it has been possible to determine the upper temperature limits for each major group of microorganism (Table 5.1). From this information we can conclude that (1) prokaryotic organisms are able to grow at far higher temperatures than are eukaryotes, (2) the most thermophilic of all prokaryotes are certain species of *Archaea*, and (3) nonphototrophic organisms can grow at higher temperatures than can phototrophs.

Thermophilic prokaryotes have also been found in artificial thermal environments, such as hot water heaters, which typically operate at 60–80°C. Organisms resembling *Thermus aquaticus*, a common hot spring thermophile, have been isolated from both domestic and industrial hot water heaters. Electric power plants, hot water discharges, and other artificial thermal sources also provide sites where thermophiles can flourish. Many of these organisms can be easily isolated on complex media incubated at the temperature of the habitat from which the sample originated.

Protein Stability at High Temperatures

How do thermophiles and hyperthermophiles survive at high temperature? First, their enzymes and other proteins are much

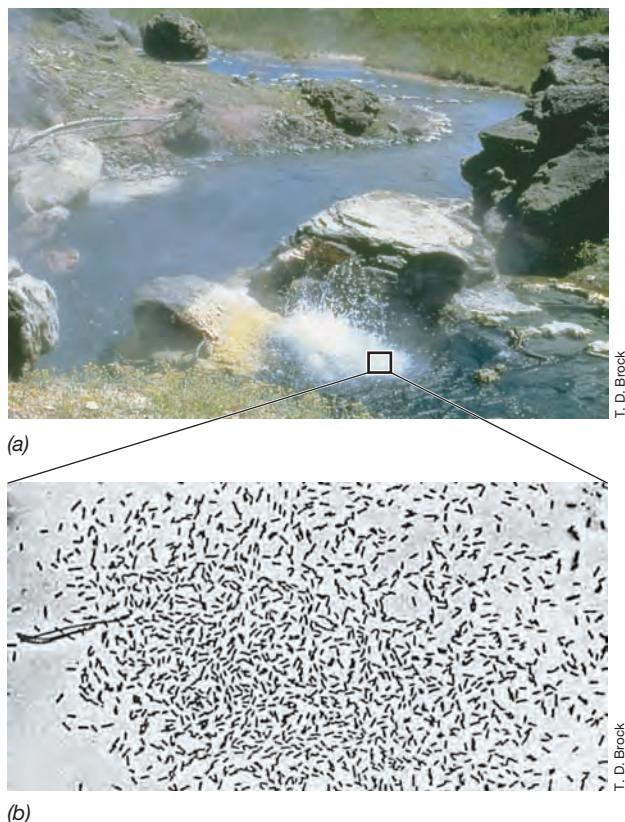

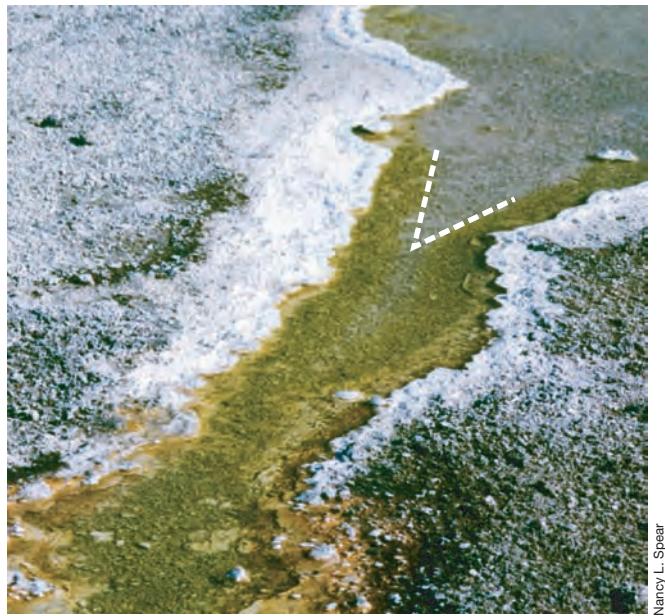

Figure 5.23 Growth of hyperthermophiles in boiling water. (a) Boulder Spring, a small boiling spring in Yellowstone National Park. This spring is superheated, having a temperature 1–2°C above the boiling point. The mineral deposits around the spring consist mainly of silica and sulfur. (b) Photomicrograph of a microcolony of prokaryotes that developed on a microscope slide immersed in such a boiling spring.

more heat-stable than are those of mesophiles and actually function *optimally* at high temperatures. Amazingly, however, studies of several heat-stable enzymes have shown that they often differ very little in amino acid sequence from heat-sensitive forms of the same enzyme from mesophiles. Apparently, critical amino acid substitutions at only a few locations in the enzyme allow the protein to fold in a unique, heat-stable way.

Heat stability of proteins from hyperthermophiles is also bolstered by an increased number of ionic bonds between basic and acidic amino acids and their often highly hydrophobic interiors. These combine to make a protein more resistant to unfolding. Finally, solutes such as di-inositol phosphate, diglycerol phosphate, and mannosylglycerate are produced at high levels in certain hyperthermophiles, and these are also thought to help stabilize their proteins against thermal denaturation.

Enzymes from thermophiles and hyperthermophiles have many commercial uses. Such enzymes can catalyze biochemical reactions at high temperatures and are in general more stable than enzymes from mesophiles, thus prolonging the shelf life of purified enzyme preparations. A classic example of this is the DNA polymerase isolated from *T. aquaticus*. *Taq polymerase*, as this enzyme is known, is used to automate the repetitive steps in the polymerase chain reaction (PCR), a technique for making multiple copies of a DNA sequence and

Figure 5.24 Growth of thermophilic cyanobacteria in a hot spring in Yellowstone National Park. Characteristic V-shaped pattern (shown by the dashed white lines) formed by cyanobacteria at the upper temperature for phototrophic life, 70–73°C, in the thermal gradient formed from a boiling hot spring. The pattern develops because the water cools more rapidly at the edges than in the center of the channel. The spring flows from the back of the picture toward the foreground. The light-green color is from a high-temperature strain of the cyanobacterium *Synechococcus*. As water flows down the gradient, the density of cells increases, less thermophilic strains enter, and the color becomes more intensely green.

a mainstay of modern biology (☞ Section 11.3). Several other uses of heat-stable enzymes and other heat-stable cell products are also known or are being developed for specific industrial applications.

Membrane Stability at High Temperatures

Besides enzymes and other macromolecules in the cell, the cytoplasmic membranes of thermophiles and hyperthermophiles must be heat-stable. Heat naturally peels apart the lipid bilayer that makes up the cytoplasmic membrane. In thermophiles, this is counteracted by constructing membranes with more long-chain and saturated fatty acid content and lower unsaturated fatty acid content than is found in the cytoplasmic membranes of mesophiles. Saturated fatty acids form a stronger hydrophobic environment than do unsaturated fatty acids, and longer-chain fatty acids have a higher melting point than shorter-chain fatty acids; collectively, these increase membrane stability.

Hyperthermophiles, most of which are *Archaea*, do not contain fatty acids in their membranes but instead have C₄₀ hydrocarbons composed of repeating units of isoprene (☞ Figures 2.16c and 2.17) bonded by ether linkage to glycerol phosphate. In addition, however, the architecture of the cytoplasmic membranes of hyperthermophiles takes a unique twist: The membrane forms a lipid *monolayer* rather than a lipid *bilayer* (☞ Figure 2.17e). The monolayer structure covalently links one side of the membrane with the other and this prevents the membrane from melting at the high growth temperatures of hyperthermophiles. We consider other aspects of heat stability in hyperthermophiles, including that of DNA stability, in Chapter 16.

MINIQUIZ

- Which domain of prokaryotes includes species with optima of >100°C? What special techniques are required to culture them?
- How does the membrane structure of hyperthermophilic *Archaea* differ from that of *Escherichia coli* and why is this structure helpful for growth at high temperature?
- What is *Taq* polymerase and why is it important?

V • Other Environmental Effects on Microbial Growth

As we have seen, temperature has a major effect on the growth of microorganisms. But many other factors do as well, chief among them being pH, osmolarity, and oxygen.

5.14 Effects of pH on Microbial Growth

Acidity or alkalinity of a solution is expressed by its **pH** on a logarithmic scale in which neutrality is pH 7 (Figure 5.25). pH values less than 7 are *acidic* and those greater than 7 are *alkaline*. In analogy to a temperature range, every microorganism has a pH range, typically about 2–3 pH units, within which growth is possible. Also, each organism shows a well-defined pH optimum, where growth occurs best. Most natural environments have a pH between 3 and 9, and organisms with pH growth optima in this range are most common. Terms used to describe organisms that grow best in particular pH ranges are shown in Table 5.2.

Acidophiles

Organisms that grow optimally at a pH value in the range termed *circumneutral* (pH 5.5 to 7.9) are called **neutrophiles** (Table 5.2).

By contrast, organisms that grow best below pH 5.5 are called **acidophiles**. There are different classes of acidophiles, some growing best at moderately acidic pH and others at very low pH. Many fungi and bacteria grow best at pH 5 or even below, while a more restricted number grow best below pH 3. An even more restricted group grow best below pH 2 and those with pH optima below 1 are extremely rare. Most acidophiles cannot grow at pH 7 and many cannot grow at pH values more than two units above their optimum.

A critical factor governing acidophily is the stability of the cytoplasmic membrane. When the pH is raised to neutrality, the cytoplasmic membranes of strongly acidophilic bacteria are destroyed and the cells lyse. This indicates that these organisms are not just acid-tolerant but that high concentrations of protons are actually *required* for cytoplasmic membrane stability. For example, the most acidophilic prokaryote known is *Picrophilus oshimae*, a species of *Archaea* that grows optimally at pH 0.7 and 60°C (the organism is also a thermophile). Above pH 4, cells of *P. oshimae* spontaneously lyse. As one would expect, *P. oshimae* inhabits extremely acidic thermal soils associated with volcanic activity.

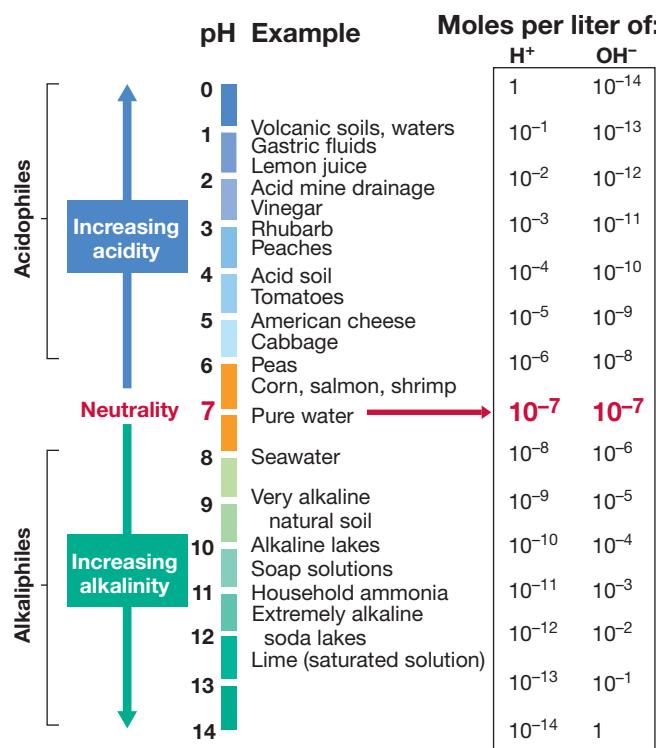

Figure 5.25 The pH scale. Although some microorganisms can live at very low or very high pH, the cell's internal pH remains near neutrality.

Alkaliphiles

A few extremophiles have very high pH optima for growth, sometimes as high as pH 10, and some of these can still grow, albeit poorly, at even higher pH. Microorganisms showing growth pH optima of 8 or higher are called **alkaliphiles**. Alkaliphilic microorganisms are typically found in highly alkaline habitats, such as soda lakes and high-carbonate soils. The most well-studied alkaliphilic prokaryotes are certain *Bacillus* species, such as *Bacillus firmus*. This organism is alkaliphilic, but has an unusually broad range for growth, from pH 7.5 to 11. Some extremely alkaliphilic bacteria are also halophilic (salt-loving), and most of these are *Archaea* (see Section 16.1). Some phototrophic purple bacteria (see Section 14.4) are also strongly alkaliphilic. Certain alkaliphiles have industrial uses because they produce hydrolytic exoenzymes, such as proteases and lipases. Exoenzymes are those that are excreted from the cell, and in the case of alkaliphiles, their exoenzymes must function well at alkaline pH. These enzymes are produced commercially on a large scale and added as supplements to laundry detergents to remove protein and fat stains from clothing.

Alkaliphiles are of interest for several reasons, particularly how they manage bioenergetics. Imagine how a cell might generate a proton motive force (see Section 3.11) when the external surface of its cytoplasmic membrane is so alkaline. One strategy for circumventing this problem in *B. firmus* is the use of sodium (Na^+) rather than H^+ to fuel transport reactions and motility; that is, a sodium motive instead of a proton motive force. Remarkably, however, a proton motive force is coupled to ATP synthesis in *B. firmus*, even though the external membrane surface is highly

Table 5.2 Relationships of microorganisms to pH

Physiological class (optima range)	Approximate pH optimum for growth	Example organism ^a
Neutrophile (pH > 5.5 and < 8)	7	<i>Escherichia coli</i>
Acidophile (pH < 5.5)	5	<i>Rhodopila globiformis</i>
	3	<i>Acidithiobacillus ferrooxidans</i>
	1	<i>Picrophilus oshimae</i>
Alkaliphile (pH ≥ 8)	8	<i>Chloroflexus aurantiacus</i>
	9	<i>Bacillus firmus</i>
	10	<i>Natronobacterium gregoryi</i>

^a*Picrophilus* and *Natronobacterium* are *Archaea*; all others are *Bacteria*.

alkaline. Exactly how this can happen is unclear, although it is thought that hydrogen ions are in some way kept very near the outer surface of the cytoplasmic membrane such that they cannot spontaneously combine with hydroxyl ions to form water.

Cytoplasmic pH and Buffers

The optimal pH for growth of an organism refers to the *extracellular* environment only; the *intracellular* pH must remain near neutrality in order to prevent the destruction of macromolecules. DNA is acid-labile and RNA is alkaline-labile, and thus a cell must maintain these key macromolecules in a stable state. Nevertheless, measurements of cytoplasmic pH in some strong acidophiles and alkaliphiles have shown a range of pH values from as low as just under pH 5 to a high of just over pH 9. If these are not the lower and upper limits of cytoplasmic pH, respectively, they are extremely close to the limits.

To prevent major shifts in pH during microbial growth in batch cultures, *buffers* are commonly added to culture media along with the nutrients required for growth. However, any given buffer works over only a relatively narrow pH range. Hence, different buffers are used for different pH classes of microorganism. Near neutral pH, potassium phosphate (KH_2PO_4) or sodium bicarbonate ($NaHCO_3$) is often employed. In addition, a suite of organic molecules called Good buffers (named for the chemist who invented them) have been designed, each of which buffers best in a specific pH range. These can be used in growth medium or for other buffering needs. In the final analysis, the best buffer for the growth of any given organism must usually be determined empirically. Various buffers are also widely used for assaying enzymes *in vitro*. The buffer keeps the enzyme solution at optimal pH during the assay, thus ensuring that the enzyme remains catalytically active and unaffected by any protons or hydroxyl ions generated in the enzymatic reaction.

MINIQUIZ

- How does the concentration of H^+ change when a culture medium at pH 5 is adjusted to pH 9?
- What terms are used to describe organisms whose growth pH optimum is very high? Very low?

5.15 Osmolarity and Microbial Growth

Water is the solvent of life, and water availability is an important factor affecting the growth of microorganisms. Water availability not only depends on how moist or dry an environment is but is also a function of the concentration of solutes (salts, sugars, or other substances) dissolved in the water that is present. Solutes bind water, making it less available to organisms. Hence, for organisms to thrive in high-solute environments, physiological adjustments are necessary.

Water availability is expressed in terms of **water activity (a_w)**, the ratio of the vapor pressure of air in equilibrium with a substance or solution to the vapor pressure of pure water. Values of a_w vary between 0 and 1; some a_w values are listed in **Table 5.3**. Water diffuses from regions of high water concentration (low solute concentration) to regions of lower water concentration (higher solute concentration) in the process of osmosis. The cytoplasm of a cell typically has a higher solute concentration than the environment, so the tendency for water is to diffuse into the cell. Under such conditions, the cell is said to be in *positive water balance*, which is the normal state of the cell. However, when a cell finds itself in an environment where the solute concentration exceeds that of the cytoplasm, water will flow out of the cell. If a cell has no strategy to counteract this, it will become dehydrated and unable to grow.

Halophiles and Related Organisms

In nature, osmotic effects are of interest mainly in habitats with high concentrations of salts. Seawater contains about 3% NaCl plus small amounts of many other minerals and elements. Micro-organisms that inhabit marine environments almost always have a NaCl requirement and typically grow optimally at the water activity of seawater (Figure 5.26). Such organisms are called **halophiles**. Although halophiles require at least some NaCl for growth, the NaCl optimum observed varies with the organism and is habitat dependent. For example, marine microorganisms typically grow best with 1–4% NaCl, organisms from hypersaline environments

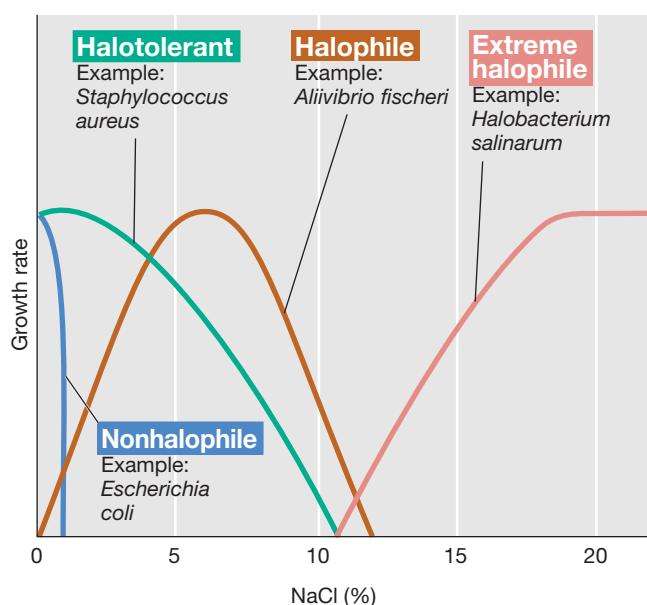

Figure 5.26 Effect of NaCl concentration on growth of microorganisms of different salt tolerances or requirements. The optimum NaCl concentration for marine microorganisms such as *Aliivibrio fischeri* is about 3%; for extreme halophiles, it is between 15 and 30%, depending on the organism.

(environments that are more salty than seawater), 3–12%, and organisms from extremely hypersaline environments require even higher levels of NaCl. In addition, the requirement for NaCl by halophiles is absolute and cannot be replaced by other salts, such as potassium chloride (KCl), calcium chloride (CaCl₂), or magnesium chloride (MgCl₂).

In contrast to halophiles, **halotolerant** organisms can tolerate some level of dissolved solutes but grow best in the absence of the added solute (Figure 5.26). Halophiles capable of growth in very salty environments are called **extreme halophiles** (Figure 5.26). These organisms require very high levels of NaCl, typically 15–30%, for optimum growth and are often unable to grow at all at NaCl concentrations below this. Organisms able to live in environments high in sugar are called **osmophiles** and those able to grow in very dry environments (made dry by lack of water rather than from dissolved solutes) are called **xerophiles**. Examples of these various classes of organisms are given in **Table 5.4**.

Compatible Solutes

When an organism is transferred from a medium of high a_w to one of low a_w , it maintains positive water balance by increasing its internal solute concentration. This is possible by either pumping solutes into the cell from the environment or by synthesizing a cytoplasmic solute (Table 5.4). In either case, the solute must not inhibit cellular processes in any significant way. Such compounds are called **compatible solutes**, and are typically highly water-soluble organic molecules including sugars, alcohols, or amino acid derivatives (Table 5.4). Glycine betaine, a highly soluble analog of the amino acid glycine, is widely distributed among halophilic bacteria (Table 5.4). Other common compatible solutes include sugars such as sucrose and trehalose, dimethylsulfonio-propionate, produced by marine algae, and glycerol, a common

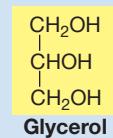

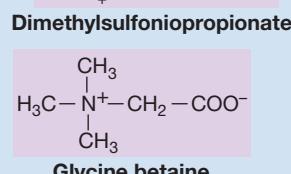

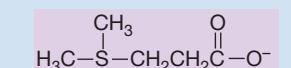

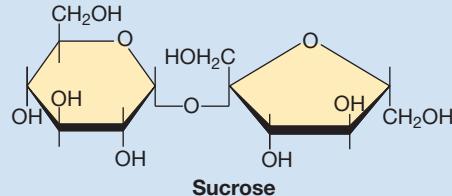

Table 5.3 Water activity of several substances

Water activity (a_w)	Material	Example organisms ^a
1.000	Pure water	<i>Caulobacter, Spirillum</i>
0.995	Human blood	<i>Streptococcus, Escherichia</i>
0.980	Seawater	<i>Pseudomonas, Vibrio</i>
0.950	Bread	Most gram-positive rods
0.900	Maple syrup, ham	Gram-positive cocci such as <i>Staphylococcus</i>
0.850	Salami	<i>Saccharomyces rouxii</i> (yeast)
0.800	Fruit cake, jams	<i>Saccharomyces bailii, Penicillium</i> (fungus)
0.750	Salt lakes, salted fish	<i>Halobacterium, Halococcus</i>
0.700	Cereals, candy, dried fruit	<i>Xeromyces bisporus</i> and other xerophilic fungi

^aSelected examples of prokaryotes or fungi capable of growth in culture media adjusted to the stated water activity.

Table 5.4 Compatible solutes of microorganisms

Organism	Major cytoplasmic solute(s)	Minimum a_w for growth
Nonphototrophic Bacteria/freshwater cyanobacteria	Amino acids (mainly glutamate or proline ^a)/sucrose, trehalose ^b	0.98–0.90
Marine cyanobacteria	α -Glucosylglycerol ^b	0.92
Marine algae	Mannitol, ^b various glycosides, dimethylsulfoniopropionate	0.92
Salt lake cyanobacteria	Glycine betaine	0.90–0.75
Halophilic anoxygenic phototrophic purple Bacteria	Glycine betaine, ectoine, trehalose ^b	0.90–0.75
Extremely halophilic Archaea and some Bacteria	KCl	0.75
<i>Dunaliella</i> (halophilic green alga)	Glycerol	0.75
Xerophilic and osmophilic yeasts	Glycerol	0.83–0.62
Xerophilic filamentous fungi	Glycerol	0.72–0.61

^aSee Figure 4.30 for the structures of amino acids.

^bStructures not shown. Like sucrose, trehalose is a C₁₂ disaccharide; glucosylglycerol is a C₉ alcohol; mannitol is a C₆ alcohol.

solute in xerophilic fungi, organisms that grow at the lowest water activities known (Table 5.4). In contrast to these organic solutes, the compatible solute of extremely halophilic Archaea, such as *Halobacterium*, and a few extremely halophilic Bacteria, is KCl (Section 16.1).

The concentration of compatible solute in a cell is a function of the levels of solute in its environment, and adjustments are made in response to the challenge from external solutes. However, in any given organism the maximal level of compatible solute is a genetically encoded characteristic. As a result, different organisms have evolved to thrive in different ranges of water activity (Tables 5.3 and 5.4). In fact, organisms designated as *nonhalotolerant*, *halotolerant*, *halophilic*, or *extremely halophilic* (Figure 5.26) are a reflection of the genetic capacity of the organisms in each group to produce or accumulate compatible solutes.

MINIQUIZ

- What is the a_w of pure water?
- What are compatible solutes, and when and why are they needed by the cell? What is the compatible solute of *Halobacterium*?

5.16 Oxygen and Microbial Growth

For many microorganisms, oxygen (O_2) is an essential nutrient; they are unable to metabolize or grow without it. Other organisms, by contrast, cannot grow in the presence of O_2 and may even be killed by it. We therefore see, just as we did for other environmental factors considered in this chapter, classes of microorganisms based on their needs or tolerance of O_2 .

Oxygen Classes of Microorganisms

Microorganisms can be grouped according to their relationship with O_2 as outlined in Table 5.5. **Aerobes** can grow at full oxygen tensions (air is 21% O_2) and respire O_2 in their metabolism. **Microaerophiles**, by contrast, are aerobes that can use O_2 only when it is present at levels reduced from that in air (microoxic conditions). This is because of the limited capacity of these organisms to respire or because they contain some O_2 -sensitive molecule such as an O_2 -labile enzyme. Many aerobes are **facultative**, meaning that under the appropriate nutrient and culture conditions they can grow in the absence of O_2 .

Some organisms cannot respire oxygen and are called **anaerobes**. There are two kinds of anaerobes: **aerotolerant anaerobes**, which can tolerate O_2 and grow in its presence even though they

Table 5.5 Oxygen relationships of microorganisms

Group	Relationship to O ₂	Type of metabolism	Example ^a	Habitat ^b
Aerobes				
Obligate	Required	Aerobic respiration	<i>Micrococcus luteus</i> (B)	Skin, dust
Facultative	Not required, but growth better with O ₂	Aerobic respiration, anaerobic respiration, fermentation	<i>Escherichia coli</i> (B)	Mammalian large intestine
Microaerophilic	Required but at levels lower than atmospheric	Aerobic respiration	<i>Spirillum volutans</i> (B)	Lake water
Anaerobes				
Aerotolerant	Not required, and growth no better when O ₂ present	Fermentation	<i>Streptococcus pyogenes</i> (B)	Upper respiratory tract
Obligate	Harmful or lethal	Fermentation or anaerobic respiration	<i>Methanobacterium formicum</i> (A)	Sewage sludge, anoxic lake sediments

^aLetters in parentheses indicate phylogenetic status (B, *Bacteria*; A, *Archaea*). Representatives of either domain of prokaryotes are known in each category. Most eukaryotes are obligate aerobes, but facultative aerobes (for example, yeast) and obligate anaerobes (for example, certain protozoa and fungi) are known.

^bListed are typical habitats of the example organism; many others could be listed.

cannot respire, and **obligate anaerobes**, which are inhibited or even killed by O₂ (Table 5.5). Anoxic (O₂-free) microbial habitats are common in nature and include muds and other sediments, bogs, marshes, water-logged soils, intestinal tracts of animals, sewage sludge, the deep subsurface of Earth, and many other environments. As far as is known, obligate anaerobiosis is characteristic of only three groups of microorganisms: a wide variety of *Bacteria* and *Archaea*, a few fungi, and a few protozoa. Some of the best-known obligate anaerobes are *Clostridium*, a genus of gram-positive endospore-forming *Bacteria*, and the methanogens, a group of methane-producing *Archaea*. Among obligate anaerobes, the sensitivity to O₂ varies greatly. Many clostridia, for example, although requiring anoxic conditions for growth, can tolerate traces of O₂ or even full exposure to air. Others, such as the methanogens, are killed rapidly by O₂ exposure.

Culture Techniques for Aerobes and Anaerobes

For the growth of aerobes, it is necessary to provide extensive aeration. This is because the O₂ that is consumed by the organisms during growth is not replaced fast enough by simple diffusion from the air. Therefore, forced aeration of liquid cultures is needed and can be achieved by either vigorously shaking the flask or tube on a shaker or by bubbling sterilized air into the medium through a fine glass tube or porous glass disc.

For the culture of anaerobes, the problem is not to provide O₂, but to exclude it. Bottles or tubes filled completely to the top with culture medium and fitted with leakproof closures provide suitably anoxic conditions for organisms that are not overly sensitive to small amounts of O₂. A chemical called a *reducing agent* may be added to such vessels to remove traces of O₂ by reducing it to water (H₂O). An example is thioglycolate, which is present in thioglycolate broth, a medium commonly used to test an organism's requirements for O₂ (Figure 5.27). Thioglycolate broth is a complex medium containing a small amount of agar, making the medium viscous but still fluid. After thioglycolate reacts with O₂ throughout the tube, O₂ can penetrate only near the top of the tube where the medium contacts air. Obligate aerobes grow only at the top of such tubes. Facultative organisms grow throughout the tube

but grow best near the top. Microaerophiles grow near the top but not right at the top. Anaerobes grow only near the bottom of the tube, where O₂ cannot penetrate. The redox indicator dye *resazurin* is present in thioglycolate broth to signal oxic regions; the dye is pink when oxidized and colorless when reduced and so

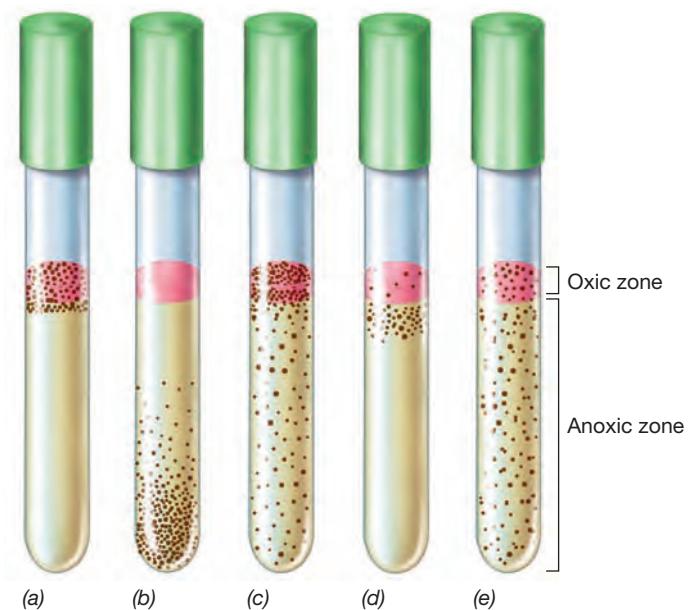

Figure 5.27 Growth versus O₂ concentration. From left to right, aerobic, anaerobic, facultative, microaerophilic, and aerotolerant anaerobe growth, as revealed by the position of microbial colonies (depicted here as black dots) within tubes of thioglycolate broth culture medium. A small amount of agar has been added to keep the liquid from becoming disturbed. The redox dye resazurin, which is pink when oxidized and colorless when reduced, has been added as a redox indicator. (a) O₂ penetrates only a short distance into the tube, so obligate aerobes grow only close to the surface. (b) Anaerobes, being sensitive to O₂, grow only away from the surface. (c) Facultative aerobes are able to grow in either the presence or the absence of O₂ and thus grow throughout the tube. However, growth is better near the surface because these organisms can respire. (d) Microaerophiles grow away from the most oxic zone. (e) Aerotolerant anaerobes grow throughout the tube. Growth is not better near the surface because these organisms can only ferment.

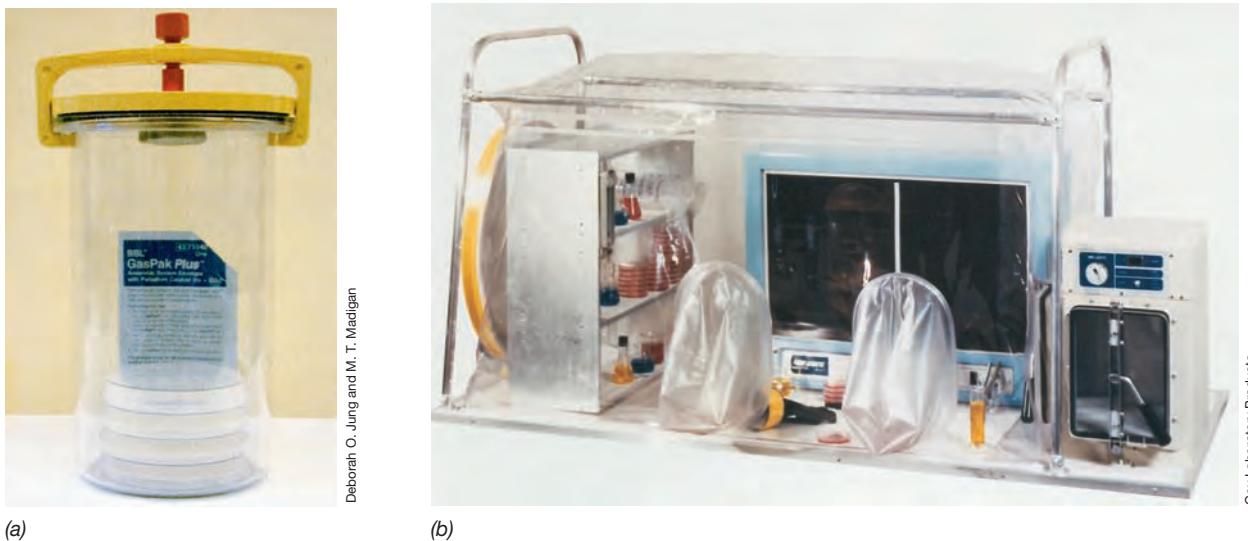

Figure 5.28 Incubation under anoxic conditions. (a) Anoxic jar. A chemical reaction in the envelope in the jar generates $\text{H}_2 + \text{CO}_2$. The H_2 reacts with O_2 in the jar on the surface of a palladium catalyst to yield H_2O ; the final atmosphere contains N_2 , H_2 , and CO_2 . (b) Anoxic glove bag for manipulating and incubating cultures under anoxic conditions. The airlock on the right, which can be evacuated and filled with O_2 -free gas, serves as a port for adding and removing materials to and from the glove bag.

gives a visual assessment of the degree of penetration of O₂ into the medium (Figure 5.27).

To remove all traces of O₂ for the culture of strict anaerobes, one can incubate tubes or plates in a glass jar flushed with an O₂-free gas or fitted with an O₂ consumption system (**Figure 5.28a**). For manipulating cultures in an anoxic atmosphere, special enclosures called *anoxic glove bags* permit work with open cultures in completely anoxic atmospheres (**Figure 5.28b**).

Why Is Oxygen Toxic?

Why are anaerobic microorganisms inhibited in their growth or even killed by oxygen? Molecular oxygen (O_2) is not toxic, but O_2 can be converted to toxic oxygen by-products, and it is these that can harm or kill cells not able to deal with them. These include *superoxide anion* (O_2^-), *hydrogen peroxide* (H_2O_2), and *hydroxyl radical* ($OH\cdot$). All of these are by-products of the reduction of O_2 to H_2O in respiration (Figure 5.29). Flavoproteins, quinones, and iron–sulfur proteins, electron carriers found in virtually all cells (Section 3.10), also catalyze some of these reductions. Thus, regardless of whether it can respire O_2 , an organism exposed to O_2 will experience toxic forms of oxygen, and if not destroyed, these molecules can wreak havoc in cells. For example,

Reactants	Products
$O_2 + e^- \rightarrow O_2^-$	(superoxide)
$O_2^- + e^- + 2 H^+ \rightarrow H_2O_2$	(hydrogen peroxide)
$H_2O_2 + e^- + H^+ \rightarrow H_2O + OH^\bullet$	(hydroxyl radical)
$OH^\bullet + e^- + H^+ \rightarrow H_2O$	(water)

Figure 5.29 Four-electron reduction of O_2 to H_2O by stepwise addition of electrons. All the intermediates formed are reactive and toxic to cells; water is not.

superoxide anion and OH[·] are strong oxidizing agents that can oxidize macromolecules and any other organic compounds in the cell. Peroxides such as H₂O₂ can also damage cell components but are not as toxic as O₂[−] or OH[·]. It should thus be clear that a major requirement for inhabiting an oxic world is to keep toxic oxygen molecules under control. We turn now to how this is done.

Superoxide Dismutase and Other Enzymes That Destroy Toxic Oxygen

Superoxide anion and H_2O_2 are the most abundant toxic oxygen species, and cells have enzymes that destroy these compounds (**Figure 5.30**). The enzymes catalase and peroxidase attack H_2O_2 ,

(a) Catalase

(b) Peroxidase

(c) Superoxide dismutase

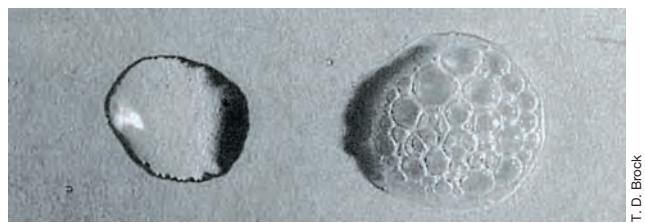

(d) Superoxide dismutase/catalase in combination

(e) Superoxide reductase

Figure 5.30 Enzymes that destroy toxic oxygen species. (a) Catalases and (b) peroxidases are porphyrin-containing proteins, although some flavoproteins may consume toxic oxygen species as well. (c) Superoxide dismutases are metal-containing proteins, the metals being copper and zinc, manganese, or iron. (d) Combined reaction of superoxide dismutase and catalase. (e) Superoxide reductase catalyzes the one-electron reduction of O_2^- to H_2O_2 .

T.D. Brock

Figure 5.31 Method for testing a microbial culture for the presence of catalase. A heavy loopful of cells from an agar culture was mixed on a slide (right) with a drop of 30% hydrogen peroxide. The immediate appearance of bubbles is indicative of the presence of catalase. The bubbles are O₂ produced by the reaction H₂O₂ + H₂O₂ → 2 H₂O + O₂.

forming O₂ and H₂O, respectively (Figure 5.30 and **Figure 5.31**). Superoxide anion is destroyed by the enzyme *superoxide dismutase*, an enzyme that generates H₂O₂ and O₂ from two molecules of O₂⁻ (Figure 5.30c). Superoxide dismutase and catalase (or peroxidase) thus work in series to convert O₂⁻ to harmless products (Figure 5.30d).

Aerobes and facultative aerobes typically contain both superoxide dismutase and catalase. Superoxide dismutase is an essential enzyme for aerobes. Some aerotolerant anaerobes lack superoxide dismutase and use protein-free manganese complexes instead to carry out the dismutation of O₂⁻ to H₂O₂ and O₂. Such a system is not as efficient as superoxide dismutase, but it is sufficient to protect the cells from O₂⁻ damage. In some strictly anaerobic *Archaea* and *Bacteria*, superoxide dismutase is absent and instead the enzyme *superoxide reductase* functions to remove O₂⁻. Unlike superoxide dismutase, superoxide reductase reduces O₂⁻ to H₂O₂ without the production of O₂ (Figure 5.30e), thus avoiding exposure of the organism to O₂.

MINIQUIZ

- How does an obligate aerobe differ from a facultative aerobe?
- How does a reducing agent work? Give an example of a reducing agent.
- How does superoxide dismutase or superoxide reductase protect a cell?

VI • Control of Microbial Growth

Thus far in this chapter we have discussed microbial growth with a focus on *promoting* growth. We close this chapter by considering the opposite side of the coin, microbial *growth control*. Many aspects of microbial growth control have significant practical applications. For example, we wash fresh produce to remove attached microorganisms and we inhibit microbial growth on body surfaces by washing. However, neither of these processes kills or removes all microorganisms. Only **sterilization**—the killing or removal of all microorganisms (including viruses)—ensures that this is the case. In certain circumstances, sterility is not attainable or practical. In others, however, sterilization is absolutely essential. We review methods of growth control now.

5.17 General Principles and Growth Control by Heat

Microorganisms and their effects can be controlled in many cases by simply limiting or inhibiting growth of the cells. Methods for inhibiting microbial growth include **decontamination**, the treatment of an object or surface to make it safe to handle, and **disinfection**, a process that directly targets pathogens although it may not eliminate all microorganisms. Decontamination could be as simple as wiping off food utensils to remove food fragments (and their attached organisms) before using them, while disinfection requires agents called *disinfectants* that actually kill microorganisms or severely inhibit their growth. A solution of bleach (sodium hypochlorite), for example, is an effective disinfectant for a wide variety of applications.

Physical methods of microbial growth control are used in industry, medicine, and in the home to achieve decontamination, disinfection, and sterilization. Heat, radiation, and filtration are the most common of these methods. Perhaps the most

widespread growth control method is heat. Factors that affect a microorganism's susceptibility to heat include the temperature and duration of the heat treatment and whether the heat is moist or dry.

Heat Sterilization

All microorganisms have a maximum growth temperature beyond which growth is impossible, typically because one or more key cellular structures are destroyed or a key protein is denatured (Figure 5.19). The effectiveness of heat as a sterilant is measured by the time required for a 10-fold reduction in the viability of a microbial population at a given temperature. This is called the *decimal reduction time* or *D*. The relationship between *D* and temperature is exponential, as the logarithm of *D* plotted against temperature yields a straight line (**Figure 5.32**). Moreover, heat killing is an exponential (first-order) function, proceeding more rapidly as the temperature rises. The type of heat is also important: Moist heat has better penetrating power than dry heat and, at a given temperature, produces a faster reduction in the number of living organisms.

Determination of a decimal reduction time requires a large number of viable count measurements (Section 5.9). An easier way to characterize the heat sensitivity of an organism is to measure its *thermal death time*, the time it takes to kill all cells at a given temperature. To determine the thermal death time, samples of a cell suspension are heated for different times, mixed with culture medium, and incubated. If all the cells have been killed, no growth is observed in the incubated samples. However, unlike a decimal reduction time measurement that is independent of the original cell number, the thermal death time is greatly affected by population size; a longer time is required to kill all cells in a large population than in a small one.

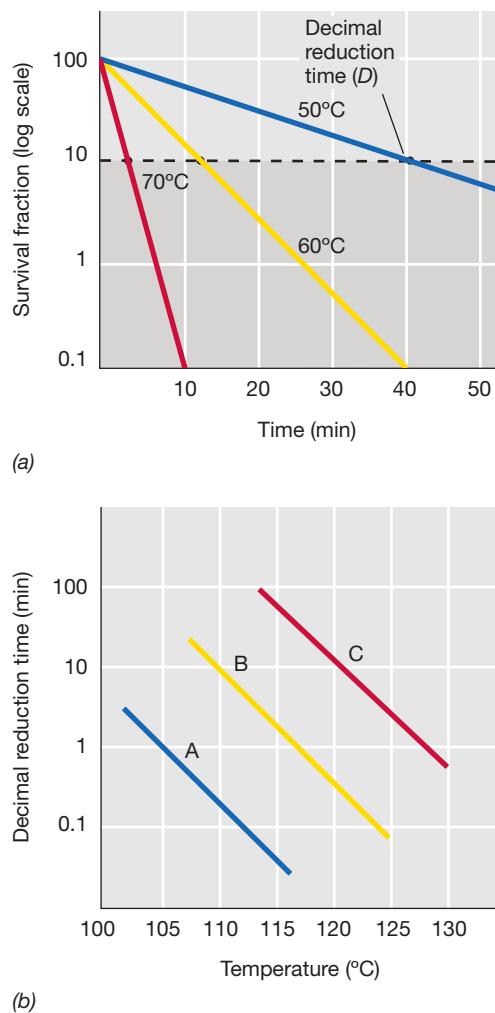

Figure 5.32 The effect of temperature on the heat killing of microorganisms.

(a) The decimal reduction time (D) is the time at which only 10% of the original population of a given organism (in this case, a mesophile) remains viable at a given temperature. For 70°C, $D = 3$ min; for 60°C, $D = 12$ min; for 50°C, $D = 42$ min. (b) D values for model organisms of different temperature classes: A, mesophile; B, thermophile; C, hyperthermophile.

The presence of endospore-forming bacteria in a heat-treated sample can influence both the decimal reduction time and thermal death time. The heat resistance of vegetative cells and endospores from the same organism differs considerably. Recall that the mature endospore is very dehydrated and contains special chemicals, such as calcium dipicolinate, and proteins, such as small acid-soluble spore proteins (SASPs), that help confer heat stability on the structure (Section 2.16). One cannot be sure that endospores have been killed unless autoclave temperatures (at least 121°C) are reached for at least 15 min. The decimal reduction time is also a function of the inherent heat resistance of the microorganisms present; as one would expect, thermophiles and hyperthermophiles are more resistant than are mesophiles (Figure 5.32b).

The medium in which heating takes place also influences the killing of both vegetative cells and endospores. Microbial death is more rapid at acidic pH, and acid foods such as tomatoes, fruits, and pickles are much easier to sterilize than neutral pH foods such as corn and beans. High concentrations of sugars, proteins,

and fats decrease heat penetration and usually increase the resistance of organisms to heat, whereas high salt concentrations may either increase or decrease heat resistance, depending on the organism. Dry cells and endospores are more heat resistant than moist ones; consequently, heat sterilization of dry objects such as endospores always requires higher temperatures and longer heat application times than sterilization of wet objects such as liquid bacterial cultures.

The Autoclave and Pasteurization

The **autoclave** is a sealed heating device that uses steam under pressure to kill microorganisms (Figure 5.33). Killing of heat-resistant endospores requires heating at temperatures above the boiling point of water at 1 atm. The autoclave places steam under a pressure of 1.1 kg/cm² (15 lb/in²), which yields a temperature of 121°C. At 121°C, the time to achieve sterilization of small amounts of endospore-containing material is about 15 min (Figure 5.33b). If the object to be autoclaved is bulky or large volumes of liquids are to be sterilized, heat transfer to the interior is retarded, and thus the total heating time must be extended. Note that it is not the *pressure* inside the autoclave that kills the microorganisms but the high *temperatures* that are achieved when steam is placed under pressure.

Pasteurization uses precisely controlled heat to significantly reduce the total number of microorganisms found in milk and other liquids that would be destroyed if autoclaved. The process, named for Louis Pasteur (Section 1.7), was first used for controlling the spoilage of wine. Pasteurization does not kill all organisms and is therefore not a method of sterilization. Pasteurization does, however, reduce the *microbial load*, the number of viable microorganisms in a sample. At temperatures and times used for pasteurization of food products such as milk, all known pathogenic bacteria that can be transmitted in infected milk, especially the organisms causing tuberculosis, brucellosis, Q fever, and typhoid fever, are killed. In addition, by decreasing the overall microbial load, pasteurization retards the growth of spoilage organisms, increasing the shelf life of perishable liquids (Section 31.6).

To achieve pasteurization, the liquid is passed through a tubular heat exchanger. Careful control of flow rate and the size and temperature of the heat source raises the temperature of the liquid to 71°C for 15 seconds (or even higher temperatures for shorter time periods; see Figure 5.32), after which it is rapidly cooled. This process is called *flash pasteurization*. Ultrahigh-temperature pasteurization of milk requires heat treatment at 135°C for 1 min. Milk can also be pasteurized by heating it in large vats to 63–66°C for 30 min. However, this *bulk pasteurization* method is less satisfactory because the milk heats and cools slowly, thus altering the taste of the final product, and it is a less efficient process.

MINIQUIZ

- Why is heat an effective sterilizing agent?
- What steps are necessary to ensure the sterility of material contaminated with bacterial endospores?
- Distinguish between the sterilization of microbiological media and the pasteurization of dairy products.

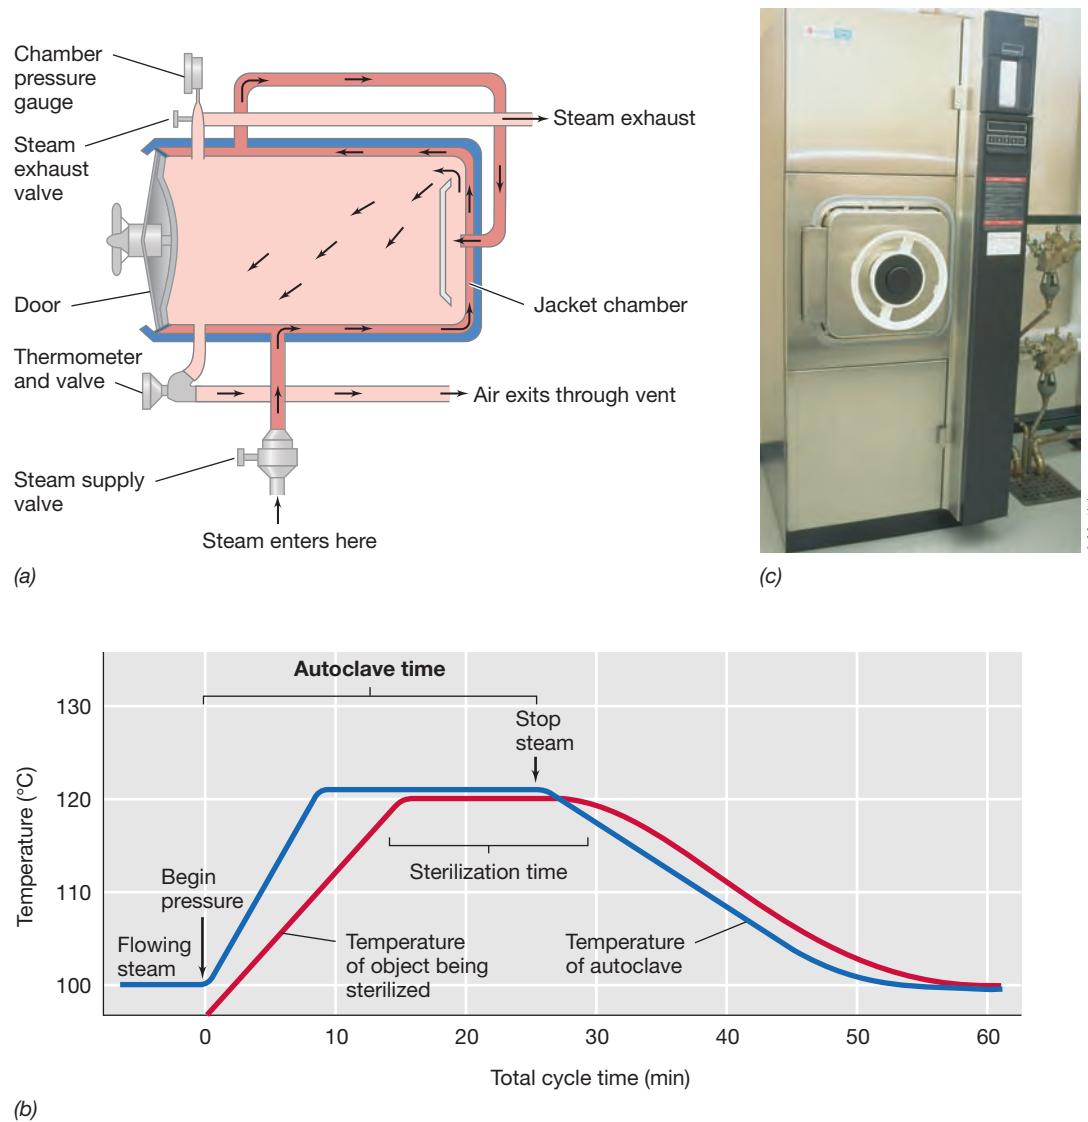

Figure 5.33 The autoclave and moist heat sterilization. (a) The flow of steam through an autoclave. (b) A typical autoclave cycle. The temporal heating profile of a fairly bulky object is shown. The temperature of the object rises and falls more slowly than the temperature of the autoclave. The temperature of the object must reach the target temperature and be held for 10–15 min to ensure sterility, regardless of the temperature and time recorded in the autoclave. (c) A modern research autoclave. Note the pressure-lock door and the automatic cycle controls on the right panel. The steam inlet and exhaust fittings are on the right side of the autoclave.

5.18 Other Physical Control Methods: Radiation and Filtration

Heat is just one form of energy that can sterilize or reduce microbial load. Ultraviolet (UV) radiation, X-rays, and gamma rays are also effective killing agents. However, each type of energy has a different mode of action and killing efficacy and thus their applications can vary widely.

Ultraviolet and Ionizing Radiation

Ultraviolet radiation between 220 and 300 nm is absorbed by DNA and can cause mutations or other serious effects on DNA that lead to death of the exposed organism (see Section 10.4). UV radiation is useful for disinfecting surfaces and air, and is widely used to

decontaminate and disinfect the work surface of laboratory laminar flow hoods equipped with a “germicidal” UV light (Figure 5.34) and also to disinfect air circulating in hospital and food preparation rooms. However, UV radiation has very poor penetrating power, limiting its use to the disinfection of exposed surfaces or air rather than bulk objects such as canned foods or surgical clothing.

Ionizing radiation is electromagnetic radiation of sufficient energy to produce ions and other reactive molecular species from molecules with which the radiation particles collide. Ionizing radiation generates higher-energy electrons, hydroxyl radicals (OH^\cdot), and hydride radicals (H^\cdot), and each of these can damage macromolecules and kill irradiated cells (Section 5.16).

The unit of ionizing radiation is the *roentgen*, and the standard for biological applications such as sterilization is the *absorbed*

Figure 5.34 A laminar flow hood. An ultraviolet light source prevents contamination of the hood when it is not in use. When the hood is in use, air is drawn into the cabinet through a HEPA filter. The filtered air inside the cabinet is exhausted out of the cabinet, preventing contamination of the inside of the hood. The cabinet provides a contaminant-free workspace for microbial and tissue culture manipulations.

radiation dose, measured in *rads* (100 erg/g) or *grays* (1 Gy = 100 rad). Ionizing radiation is typically generated from X-ray sources or the radioactive nuclides ^{60}Co and ^{137}Cs , which are relatively inexpensive by-products of nuclear fission. These nuclides produce X-rays or gamma rays (γ -rays), both of which have sufficient energy and penetrating power to efficiently kill microorganisms in bulk items such as food products and medical supplies.

Table 5.6 shows the dose necessary for a 10-fold reduction (D_{10}) in number of selected microorganisms. The D_{10} value is analogous to the decimal reduction time for heat sterilization, and the killing curve of ionizing radiation yields a similar plot (Figure 5.35; compare with Figure 5.32). As is also true of heat treatments, killing endospores with ionizing radiation is more difficult than killing vegetative cells, and viruses are more difficult to kill than bacteria (Table 5.6). In addition, microorganisms in general are much more resistant to ionizing radiation than are multicellular organisms. For example, the lethal radiation dose for humans can be as low as 10 Gy if delivered over a short time period.

In the United States, the Food and Drug Administration (FDA) has approved the use of radiation for sterilization of such diverse items as surgical supplies, plastic labware, drugs, and even tissue grafts. Certain foods and food products such as fresh produce, poultry, meat products, and spices are also routinely irradiated to ensure that they are sterile or at least free of pathogens and also free of insects.

Filter Sterilization

Heat is an effective way to decontaminate most liquids, but heat-sensitive liquids and gases must be sterilized by other methods. To do this, the liquid or gas is passed through a filter with pores sufficiently small to trap any cells that may be present. For sterilization, a filter with pores of average size 0.2 μm is desirable; however, even such tiny holes will not trap most viruses. Commonly used filter pore sizes for the filter sterilization of small volumes, such as laboratory solutions, are 0.45 μm and 0.2 μm .

Table 5.6 Radiation sensitivity of some representative microorganisms

Type of microorganism	Characteristics	D_{10}^a (Gy)
Bacteria		
<i>Clostridium botulinum</i>	Gram-positive anaerobe; forms endospores	3300
<i>Deinococcus radiodurans</i>	Gram-negative, radiation-resistant coccus	2200
<i>Lactobacillus brevis</i>	Gram-positive, rod-shaped	1200
<i>Bacillus subtilis</i>	Gram-positive aerobe; forms endospores	600
<i>Escherichia coli</i>	Gram-negative, rod-shaped	300
<i>Salmonella typhimurium</i>	Gram-negative, rod-shaped	200
Fungi		
<i>Aspergillus niger</i>	Common mold	500
<i>Saccharomyces cerevisiae</i>	Baker's and brewer's yeast	500
Viruses		
Foot-and-mouth	Pathogen of cloven-hoofed animals	13,000
Coxsackie	Human pathogen	4500

^a D_{10} is the amount of radiation necessary to reduce the initial population or activity level 10-fold (1 logarithm). Gy, grays. 1 Gy is equivalent to 100 rads. The lethal dose for humans is 10 Gy.

Several types of filters are in routine use in microbiology, including depth filters, membrane filters, and nucleopore filters. A depth filter is a fibrous sheet or mat made from a random array of overlapping paper or borosilicate (glass) fibers that traps particles in the network of fibers (Figure 5.36a). Depth filters are important in biosafety applications. For example, manipulations of cell cultures, microbial cultures, and growth media require that contamination of both the operator and the experimental materials be minimized. These operations can be efficiently performed

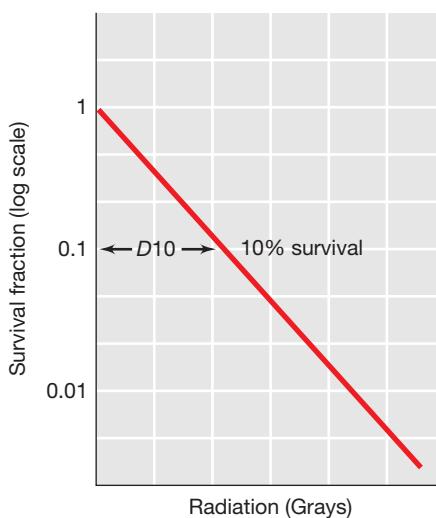

Figure 5.35 Relationship between the survival fraction and the radiation dose of a microorganism. The D_{10} , which is the decimal reduction dose, can be interpolated from the data as shown.

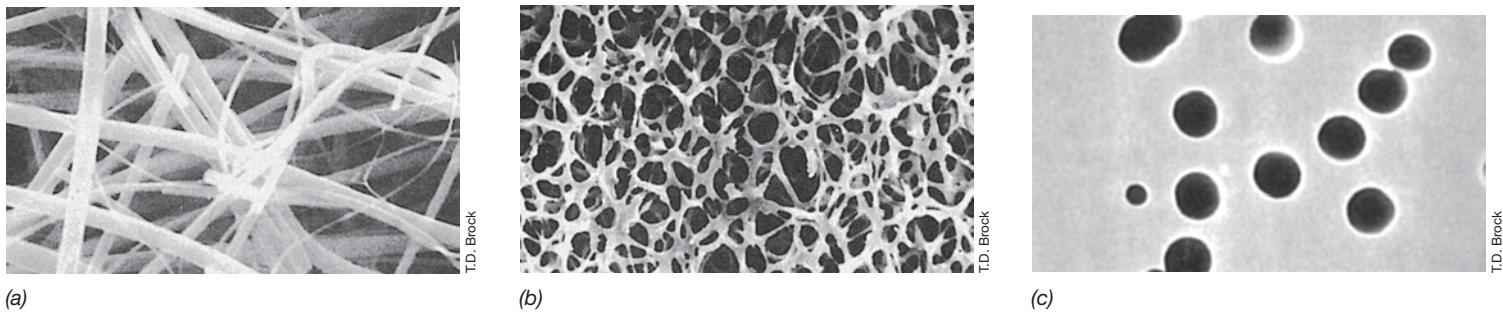

Figure 5.36 Microbiological filters. Scanning electron micrograph showing the structure of (a) a depth filter, (b) a conventional membrane filter, and (c) a nucleopore filter.

in a biological safety cabinet with airflow, both in and out of the cabinet, directed through a depth filter called a **HEPA filter**, or *high-efficiency particulate air filter* (Figure 5.34). HEPA filters typically remove 0.3- μm or larger particles from an airstream with an efficiency of greater than 99.9%.

Membrane filters are the most common type of filters used for liquid sterilization in the microbiology laboratory (Figure 5.36b and Figure 5.37). Membrane filters are composed of high tensile strength polymers such as cellulose acetate, cellulose nitrate, or polysulfone, manufactured in such a way as to contain a large number of tiny pores. Sterile membrane filter assemblies for the sterilization of relatively small volumes of liquids such as growth media are routinely used in research and clinical laboratories. Filtration is accomplished by using a syringe or a pump to force the liquid through the filtration apparatus into a sterile collection vessel (Figure 5.37).

Another type of membrane filter is the nucleopore filter (Figure 5.38). Nucleopore filters are made from a 10- μm -thick polycarbonate film that is treated with radiation and then etched with a chemical, yielding very uniform holes (Figure 5.36c). Nucleopore filters are commonly used to isolate specimens for scanning electron microscopy. Microorganisms are removed from a liquid or a natural sample, such as lake water, and concentrated on the filter where they can be observed directly with the microscope (Figure 5.38a).

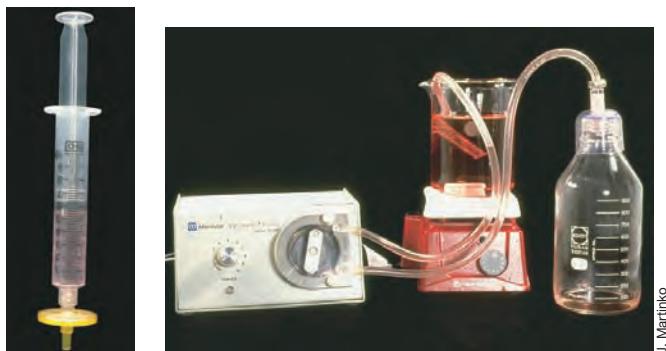

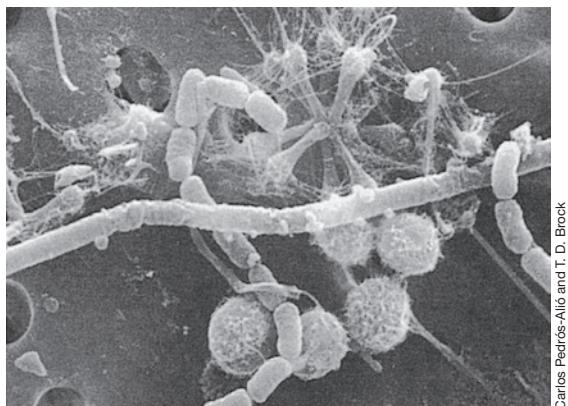

Figure 5.37 Membrane filters. Disposable, presterilized, and assembled membrane filter units. Left: a filter system designed for small volumes. Right: a filter system designed for larger volumes.

MINIQUIZ

- Define D_{10} and explain why the killing dose for radiation (Table 5.6) is not the same for all bacteria.
 - Why is ionizing radiation more effective than UV radiation for sterilization of food products?
 - Distinguish between the major types of sterilization filters used in the microbiology laboratory.

(a)

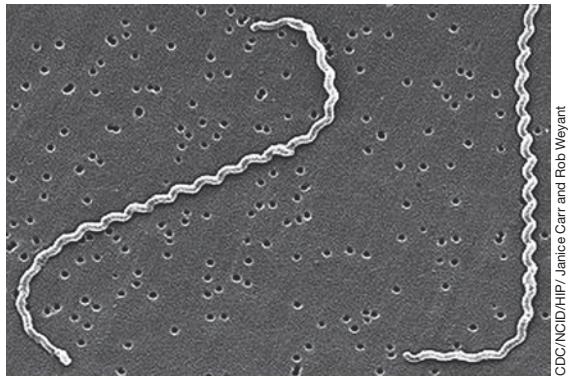

Figure 5.38 Scanning electron micrographs of bacteria trapped on nucleopore membrane filters. (a) Aquatic bacteria and algae. The pore size is 5 μm . (b) *Leptospira interrogans*. The bacterium is about 0.1 μm in diameter and up to 20 μm in length. The pore size of the filter is 0.2 μm .

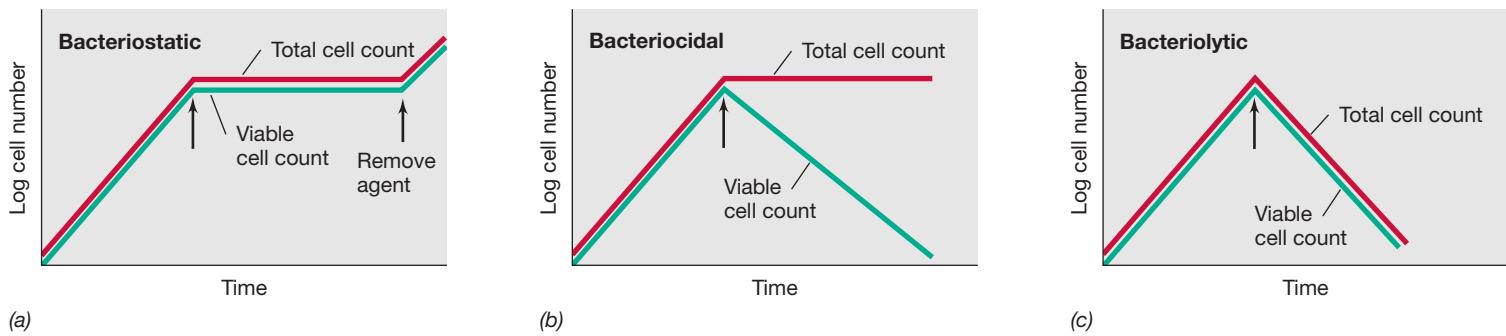

Figure 5.39 Different types of antimicrobial agents. (a) Bacteriostatic agents inhibit but do not kill. (b) Bacteriocidal agents kill. (c) Bacteriolytic agents lyse cells. At the time indicated by the arrow, a growth-inhibitory concentration of each antimicrobial agent was added to an exponentially growing culture. The turbidity and viable counts shown are characteristic of each type of agent.

5.19 Chemical Control of Microbial Growth

Chemicals are routinely used to control microbial growth, and an **antimicrobial agent** is a natural or synthetic chemical that kills or inhibits the growth of microorganisms. Agents that actually kill organisms are called *-cidal* agents, with a prefix indicating the type of microorganism killed. Thus, **bacteriocidal**, **fungicidal**, and **viricidal** agents kill bacteria, fungi, and viruses, respectively. Agents that do not kill but only inhibit growth are called *-static* agents, and include **bacteriostatic**, **fungistatic**, and **viristatic** compounds.

Effect of Antimicrobial Agents on Growth

Antibacterial agents are classified as bacteriostatic, bacteriocidal, or bacteriolytic (cell lysing) by observing their effects on bacterial cultures using viable and turbidimetric growth assays (Figure 5.39). Bacteriostatic agents are typically inhibitors of some important biochemical process, such as protein synthesis, and bind relatively weakly; if the agent is removed, the cells can resume growing. Many antibiotics fall into this category. Bacteriocidal agents, by contrast, bind tightly to their cellular targets and by definition kill the cell. However, the dead cells are not lysed, and

total cell numbers, reflected in the turbidity of the culture, remain constant (Figure 5.39b). Formaldehyde would be an example of a bacteriocidal agent. Bacteriolytic agents kill cells by lysing them and releasing their cytoplasmic contents. Lysis decreases both the viable cell number and the total cell number (Figure 5.39c). An example of a bacteriolytic agent would be a detergent that ruptures the cytoplasmic membrane.

Assaying Antimicrobial Activity

Antimicrobial activity is measured by determining the smallest amount of the agent needed to inhibit the growth of a test organism, a value called the **minimum inhibitory concentration (MIC)**. To determine the MIC of a given agent against a given organism growing in a liquid medium (Figure 5.40), a series of tubes

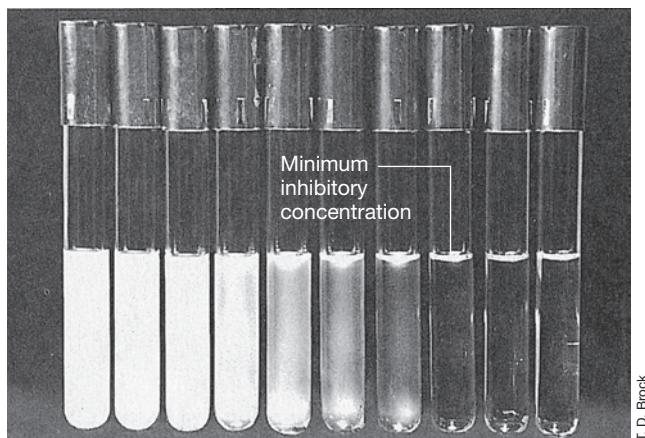

Figure 5.40 Antimicrobial agent susceptibility assay using dilution methods.

The assay defines the minimum inhibitory concentration (MIC). A series of increasing concentrations of antimicrobial agent is prepared in the culture medium. Each tube is inoculated with a specific concentration of a test organism, followed by a defined incubation period. Growth, measured as turbidity, occurs in those tubes with antimicrobial agent concentrations below the MIC.

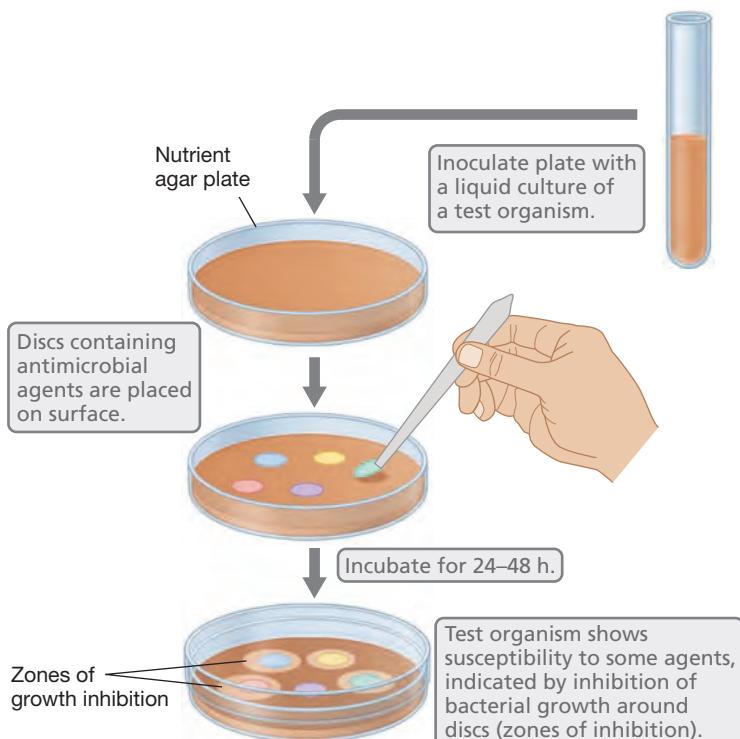

Figure 5.41 Antimicrobial agent susceptibility assay using diffusion methods.

The antimicrobial agent diffuses from paper discs into the surrounding agar, inhibiting growth of susceptible microorganisms.

Table 5.7 Antiseptics, sterilants, disinfectants, and sanitizers^a

Agent	Mode of action	Use
Antiseptics (germicides)		
Alcohol (60–85% ethanol or isopropanol in water)	Lipid solvent and protein denaturant	Topical antiseptic
Phenol-containing compounds (hexachlorophene, triclosan, chloroxylenol, chlorhexidine)	Disrupts cytoplasmic membrane	Soaps, lotions, cosmetics, deodorants, topical disinfectants; paper, leather, and textile industries
Cationic detergents, especially quaternary ammonium compounds (benzalkonium chloride)	Disrupts cytoplasmic membrane	Soaps, lotions, topical disinfectants; metal and petroleum industries
Hydrogen peroxide (3% solution)	Oxidizing agent	Topical antiseptic
Iodophors (Betadine®)	Iodinates proteins, rendering them nonfunctional; oxidizing agent	Topical antiseptic
Octenidine	Cationic surfactant, disrupts cytoplasmic membrane	Topical antiseptic
Sterilants, disinfectants, and sanitizers		
Alcohol (60–85% ethanol or isopropanol in water)	Lipid solvent and protein denaturant	General purpose disinfectant for virtually any surface
Cationic detergents (quaternary ammonium compounds, Lysol® and many related disinfectants)	Interact with phospholipids	Disinfectant/sanitizer for medical instruments, food and dairy equipment
Chlorine gas	Oxidizing agent	Disinfectant for drinking water and electrical/nuclear cooling towers
Chlorine compounds (chloramines, sodium hypochlorite, sodium chlorite, chlorine dioxide)	Oxidizing agent	Disinfectant/sanitizer for medical instruments, food/dairy equipment, and in water purification
Copper sulfate	Protein precipitant	Algicide in swimming pools
Ethylene oxide (gas)	Alkylating agent	Sterilant for temperature-sensitive materials such as plastics
Formaldehyde	Alkylating agent	Dilute (3% solution) as surface disinfectant/sterilant; concentrated (37% solution) as sterilant
Glutaraldehyde	Alkylating agent	Disinfectant or sterilant as 2% solution
Hydrogen peroxide	Oxidizing agent	Vapor used as sterilant
Iodophors (Wescodyne®)	Iodinates proteins; oxidizing agent	General disinfectant
OPA (ortho-phthalaldehyde)	Alkylating agent	Powerful disinfectant used for sterilizing medical instruments
Ozone	Strong oxidizing agent	Disinfectant for drinking water
Peroxyacetic acid	Strong oxidizing agent	Disinfectant/sterilant
Phenolic compounds	Protein denaturant	General purpose disinfectant
Pine oils (Pine-Sol®) (contains phenolics and detergents)	Protein denaturant	General purpose disinfectant for household surfaces

^aAlcohols, hydrogen peroxide, and iodophors can be antiseptics, disinfectants, sanitizers, or sterilants depending on concentration, length of exposure, and form of delivery.

is inoculated with the test organism and a given amount of the agent added. After incubation, the tubes are scored for growth (turbidity), and the MIC is the lowest concentration of agent that completely inhibits the growth of the test organism.

Antimicrobial activity can also be assessed using solid media (**Figure 5.41**). Known amounts of an antimicrobial agent are added to filter-paper discs and the discs arranged on the surface of a uniformly inoculated agar plate. During incubation, the agent diffuses from the disc into the agar, establishing a gradient; the farther the chemical diffuses away from the filter paper, the lower is the concentration of the agent. A *zone of inhibition* is created with a diameter proportional to the amount of antimicrobial agent added to the disc, the solubility of the agent, the diffusion coefficient, and the overall effectiveness of the agent. The disc diffusion assay is routinely used to test clinically isolated pathogens for their antibiotic susceptibility (➡ Section 27.5).

Chemical Antimicrobial Agents

Several antimicrobial agents are used to prevent growth of human pathogens on inanimate surfaces and on external body surfaces. These include sterilants, disinfectants, sanitizers, and antiseptics (**Table 5.7**).

Sterilants (also called *sterilizers* or *sporicides*) destroy all microorganisms, including endospores. Chemical sterilants are used for decontamination or sterilization in situations where it is impractical to use heat or radiation. Hospitals and laboratories, for example, must routinely decontaminate and sterilize heat-sensitive materials such as thermometers, lensed instruments, polyethylene tubing, catheters, and reusable medical equipment such as respirometers. *Cold sterilization*, a process by which gases such as ethylene oxide, formaldehyde, or peroxyacetic acid are used to treat objects within an enclosed device that resembles an autoclave, is the usual method employed. Liquid sterilants such

as a sodium hypochlorite or amyłphenol are used for instruments that cannot withstand high temperatures or gas.

Disinfectants are chemicals that kill microorganisms but not necessarily endospores and are used on inanimate objects. For example, phenol and cationic detergents are used to disinfect floors, tables, bench tops, walls, and so on (Table 5.7) and are important for infection control in hospitals and other medical settings. **Sanitizers**, by contrast, are less harsh chemicals than disinfectants and function to reduce microbial numbers but not necessarily sterilize the object. Sanitizers are widely used in the food industry to treat surfaces such as mixing and cooking equipment, dishes, and utensils, and are also used for dry handwashing when water is unavailable. **Antiseptics**, often called **germicides**, are chemicals that kill or inhibit the growth of microorganisms but are sufficiently nontoxic to animals to be applied to living tissues. Most germicides are used for handwashing or for treating surface wounds (Table 5.7). Certain antiseptics are also effective disinfectants. Ethanol, for example, can be both an antiseptic and a disinfectant, depending on the concentration and exposure time employed.

Several factors affect the efficacy of any chemical antimicrobial agent. For example, many antimicrobial agents are bound and inactivated by organic matter; thus, disinfecting a kitchen countertop littered with spilled foods is more difficult than disinfecting a clean countertop. Furthermore, bacteria often form

biofilms, covering surfaces of tissue or medical devices with layers of microbial cells embedded in polysaccharides. Biofilms may slow or even completely prevent penetration of antimicrobial agents, reducing or negating their effectiveness.

Only sterilants are effective against endospores; these structures are extremely resistant because their spore coats prevent the penetration of most chemical agents (☞ Section 2.16). Likewise, the bacterium *Mycobacterium tuberculosis*, the causal agent of tuberculosis, is resistant to common disinfectants because of the waxy nature of its cell wall (☞ Sections 15.11 and 29.4). Thus, the ultimate efficacy of antiseptics, disinfectants, sterilants, and other antimicrobial compounds must be determined empirically and under the actual conditions of use. Only by actually testing the chemical and assaying for microbial growth both before and after treatment can one be confident that the agent is working as it should.

MINIQUIZ

- Distinguish between the antimicrobial effects of -static, -cidal, and -lytic agents.
- Describe how the minimum inhibitory concentration of an antibacterial agent is determined.
- Distinguish between a sterilant, a disinfectant, and an antiseptic. What is cold sterilization?

BIG IDEAS

5.1 • Microbial growth is defined as an increase in cell numbers and is the final result of the doubling of all cell components prior to actual division that yields two daughter cells. Most microorganisms grow by binary fission.

5.2 • Cell division and chromosome replication are coordinately regulated, and the Fts proteins are keys to these processes. With the help of MinE, FtsZ defines the cell division plane and helps assemble the divisome, the protein complex that orchestrates cell division.

5.3 • MreB helps define cell shape, and in rod-shaped cells, MreB forms a cytoskeletal coil that directs cell wall synthesis along the long axis of the cell. The protein crescentin plays an analogous role in *Caulobacter*, leading to formation of a curved cell. The eukaryotic shape and cell division proteins actin and tubulin have prokaryotic counterparts.

5.4 • During bacterial growth, new cell peptidoglycan is synthesized by the insertion of new glycan tetrapeptide units into preexisting peptidoglycan. Bactoprenol facilitates transport of these units through the cytoplasmic membrane. Transpeptidation completes the process of cell wall synthesis by cross-linking adjacent ribbons of peptidoglycan at muramic acid residues.

5.5 • Microbial cells undergo exponential growth, and a semilogarithmic plot of cell numbers with time can reveal the doubling time of the population. Simple mathematics can be used to calculate various growth expressions from cell numbers data. Key expressions here are n , the number of generations; t , time; and g , generation time. The generation time is expressed as $g = t/n$.

5.6 • Microorganisms show a characteristic growth pattern when inoculated into a fresh culture medium. There is usually a lag phase and then growth commences in an exponential fashion. As essential nutrients are depleted or toxic products build up, growth ceases and the population enters the stationary phase. Further incubation can lead to cell death.

5.7 • The chemostat is an open system used to maintain cell populations in exponential growth for extended periods. In a chemostat, the rate at which a culture is diluted with fresh growth medium controls the doubling time of the population, while the cell density (cells/ml) is controlled by the concentration of a growth-limiting nutrient dissolved in the fresh medium.

5.8 • Cell counts can be done under the microscope using counting chambers. Microscopic counts measure the total number of cells in the sample and are useful for assessing the

total cell numbers in a microbial habitat. Certain stains can be used to target specific cell populations in a sample.

5.9 • Viable cell counts (plate counts) measure only the living population present in the sample with the assumption that each colony originates from the growth and division of a single cell. Depending on the growth medium and conditions employed, plate counts can be fairly accurate assessments or can be highly unreliable.

5.10 • Turbidity measurements are an indirect but very rapid and useful method of measuring microbial growth. However, in order to relate a turbidity value to a direct cell number, a standard curve plotting these two parameters against one another must first be established.

5.11 • Temperature is a major environmental factor controlling microbial growth. An organism's cardinal temperatures describe the minimum, optimum, and maximum temperatures at which it grows. Microorganisms can be grouped by their cardinal temperature from cold-loving to heat-loving as psychrophiles, mesophiles, thermophiles, and hyperthermophiles.

5.12 • Organisms with temperature optima below 20°C are called psychrophiles, and the most extreme representatives inhabit constantly cold environments. Psychrophiles have evolved macromolecules that remain flexible and functional at cold temperatures, but that can be unusually sensitive to warm temperatures.

5.13 • Organisms with growth temperature optima between 45 and 80°C are called thermophiles while those with optima greater than 80°C are hyperthermophiles. These organisms inhabit hot environments that can have temperatures even above 100°C. Thermophiles and hyperthermophiles produce heat-stable macromolecules.

5.14 • The acidity or alkalinity of an environment can greatly affect microbial growth. Some organisms grow best at low or high pH (acidophiles and alkaliphiles, respectively), but most organisms grow best between pH 5.5 and 8. The internal pH of a cell must stay relatively close to neutral to prevent the destruction of DNA or RNA.

5.15 • The water activity of an aqueous environment is controlled by its dissolved solute concentration. To survive in high-solute environments, organisms produce or accumulate compatible solutes to maintain the cell in positive water balance. Some microorganisms grow best at reduced water potential and some even require high levels of salts for growth.

5.16 • Aerobes require O₂ to live, whereas anaerobes do not and may even be killed by O₂. Facultative organisms can live with or without O₂. Special techniques are needed to grow aerobic and anaerobic microorganisms. Several toxic forms of oxygen can form in the cell, but enzymes are present that neutralize most of them. Superoxide is a major toxic form of oxygen.

5.17 • Sterilization is the killing of all organisms and viruses, and heat is the most widely used method of sterilization. An autoclave employs moist heat under pressure, achieving temperatures above the boiling point of water. Pasteurization does not sterilize liquids, but it reduces microbial load, kills most pathogens, and inhibits the growth of spoilage microorganisms.

5.18 • Radiation can effectively inhibit or kill microorganisms. Ultraviolet radiation is used for

decontaminating surfaces and air. Ionizing radiation is used for sterilization and decontamination where penetration is required. Filters remove microorganisms from air or liquids. Membrane filters are used for sterilization of heat-sensitive liquids, and nucleopore filters are used to isolate specimens for electron microscopy.

5.19 • Chemicals are commonly used to control microbial growth. Chemicals that kill organisms are called -cidal agents while those that arrest growth but do not kill are called -static agents. Antimicrobial agents are tested for efficacy by determining their ability to inhibit growth *in vitro*. Sterilants, disinfectants, and sanitizers are used to decontaminate nonliving material, while antiseptics and germicides are used to reduce the microbial load on living tissues.

REVIEW OF KEY TERMS

Acidophile an organism that grows best at low pH; typically below pH 5.5

Aerobe an organism that can use O₂ in respiration; some require O₂

Aerotolerant anaerobe a microorganism unable to respire O₂ but whose growth is unaffected by it

Alkaliphile an organism that has a growth pH optimum of 8 or higher

Anaerobe an organism that cannot use O₂ in respiration and whose growth is typically inhibited by O₂

Antimicrobial agent a chemical compound that kills or inhibits the growth of microorganisms

Antiseptic (germicide) a chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues

Autoclave a sealed heating device that destroys microorganisms with temperature and steam under pressure

Bacteriocidal agent an agent that kills bacteria

Bacteriostatic agent an agent that inhibits bacterial growth

Batch culture a closed-system microbial culture of fixed volume

Binary fission cell division following enlargement of a cell to twice its minimum size

Biofilm an attached polysaccharide matrix containing bacterial cells

Cardinal temperatures the minimum, maximum, and optimum growth temperatures for a given organism

Chemostat a device that allows for the continuous culture of microorganisms with independent control of both growth rate and cell number

Compatible solute a molecule that is accumulated in the cytoplasm of a cell for adjustment of water activity but that does not inhibit biochemical processes

Decontamination treatment of a surface or object to make it safe to handle

Disinfectant an antimicrobial agent used only on inanimate objects

Disinfection rendering a surface or object free of all pathogen microorganisms

Divisome a complex of proteins that directs cell division processes in prokaryotes

Exponential growth growth of a microbial population in which cell numbers double within a specific time interval

Extreme halophile a microorganism that requires very large amounts of NaCl, usually greater than 10% and in some cases near to saturation, for growth

Facultative with respect to O₂, an organism that can grow in either its presence or absence

FtsZ a protein that forms a ring along the mid-cell division plane to initiate cell division

Fungicidal agent an agent that kills fungi

Fungistatic agent an agent that inhibits fungal growth

Generation time the time required for a population of microbial cells to double

Germicide (antiseptic) a chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues

Growth an increase in cell number

Halophile a microorganism that requires NaCl for growth

Halotolerant a microorganism that does not require NaCl for growth but can grow in the

presence of NaCl, in some cases, substantial levels of NaCl	Osmophile an organism that grows best in the presence of high levels of solute, typically a sugar	Sterilization the killing or removal of all living organisms and viruses
HEPA filter a high-efficiency particulate air filter that removes particles, including microorganisms, from intake or exhaust air flow	Pasteurization the heat treatment of milk or other liquids to reduce its total number of microorganisms	Thermophile an organism whose growth temperature optimum lies between 45 and 80°C
Hyperthermophile a prokaryote that has a growth temperature optimum of 80°C or greater	pH the negative logarithm of the hydrogen ion (H^+) concentration of a solution	Transpeptidation formation of peptide cross-links between muramic acid residues in peptidoglycan synthesis
Mesophile an organism that grows best at temperatures between 20 and 40°C	Plate count a method of counting viable cells; the number of colonies on a plate is used as a measure of cell numbers	Viable capable of reproducing
Microaerophile an aerobic organism that can grow only when O ₂ tensions are reduced from that present in air	Psychrophile an organism with a growth temperature optimum of 15°C or lower and a maximum growth temperature below 20°C	Viable count a measurement of the concentration of live cells in a population
Minimum inhibitory concentration (MIC) the minimum concentration of a substance necessary to prevent microbial growth	Psychrotolerant capable of growing at low temperatures but having an optimum above 20°C	Viricidal agent an agent that stops viral replication and activity
Neutrophile an organism that grows best at neutral pH, between pH 5.5 and 8	Sanitizer an agent that reduces microorganisms to a safe level, but may not eliminate them	Viristatic agent an agent that inhibits viral replication
Obligate anaerobe an organism that cannot grow in the presence of O ₂	Sterilant (sterilizer, sporicide) a chemical agent that destroys all forms of microbial life	Water activity the ratio of the vapor pressure of air in equilibrium with a solution to the vapor pressure of pure water
		Xerophile an organism that is able to live, or that lives best, in very dry environments

REVIEW QUESTIONS

- Describe the key molecular processes that occur when a cell grows and divides. (Section 5.1)
- Describe the role of proteins present at the divisome. Does the FtsZ ring form before or after chromosome replication? (Section 5.2)
- How do cells of *Escherichia coli* that carry a mutation in *mreB* (the gene encoding the protein MreB) look different microscopically from wild-type (unmutated) cells? What is the reason for this? (Section 5.3)
- Describe how new peptidoglycan subunits are inserted into the growing cell wall. How does the antibiotic penicillin kill bacterial cells, and why does it kill only growing cells? (Section 5.4)
- What is the difference between the specific growth rate (*k*) of an organism and its generation time (*g*)? (Section 5.5)
- Describe the growth cycle of a population of bacterial cells from the time this population is first inoculated into fresh medium. (Section 5.6)
- How does a chemostat regulate growth rate and cell numbers independently? (Section 5.7)
- What is the difference between a total cell count and a viable cell count? (Sections 5.8 and 5.9)
- How can turbidity be used as a measure of cell numbers? (Section 5.10)
- Examine the graph describing the relationship between growth rate and temperature (Figure 5.19). Give an explanation, in biochemical terms, of why the optimum temperature for an organism is usually closer to its maximum than its minimum. (Section 5.11)
- Describe a habitat where you would find a psychrophile, and one where you would find a hyperthermophile. How can these organisms survive under such harsh conditions? (Sections 5.12 and 5.13)
- Concerning the pH of the environment and of the cell, in what ways are acidophiles and alkaliphiles different? In what ways are they similar? (Section 5.14)
- Write an explanation in molecular terms for how a halophile is able to make water flow into the cell while growing in a solution high in NaCl. (Section 5.15)
- Contrast an aerotolerant and an obligate anaerobe in terms of sensitivity to O₂ and ability to grow in the presence of O₂. How does an aerotolerant anaerobe differ from a microaerophile? (Section 5.16)
- Compare and contrast the enzymes catalase, superoxide dismutase, and superoxide reductase as regards their substrates and products. (Section 5.16)
- Contrast the terms thermal death time and decimal reduction time. How would the presence of bacterial endospores affect either value? (Section 5.17)
- Describe the principle of the autoclave. How does it differ from simple boiling? Microbial culture media does not boil in the autoclave; why not? (Section 5.17)
- Describe the effects of a lethal dose of ionizing radiation at the molecular level. (Section 5.18)
- What type of filter would be used to filter sterilize a heat-sensitive liquid? (Section 5.18)
- Describe the procedure for obtaining the minimum inhibitory concentration (MIC) for a chemical that is bacteriocidal for *Escherichia coli*. (Section 5.19)
- Contrast the action of disinfectants and antiseptics. Disinfectants are not used on living tissue; why not? (Section 5.19)

APPLICATION QUESTIONS

1. Calculate g and k in a growth experiment in which a medium was inoculated with 5×10^6 cells/ml of *Escherichia coli* cells and, following a 1-h lag, grew exponentially for 5 h, after which the population was 5.4×10^9 cells/ml.
2. *Escherichia coli* but not *Pyrolobus fumarii* will grow at 40°C, while *P. fumarii* but not *E. coli* will grow at 110°C. What is happening (or not happening) to prevent growth of each organism at the nonpermissive temperature?
3. In which direction (into or out of the cell) will water flow in cells of *Escherichia coli* (an organism found in your large intestine) suddenly suspended in a solution of 20% NaCl? What if the cells were suspended in distilled water? If growth nutrients were added to each cell suspension, which (if either) would support growth, and why?

6 • Microbial Genomics

microbiologynow

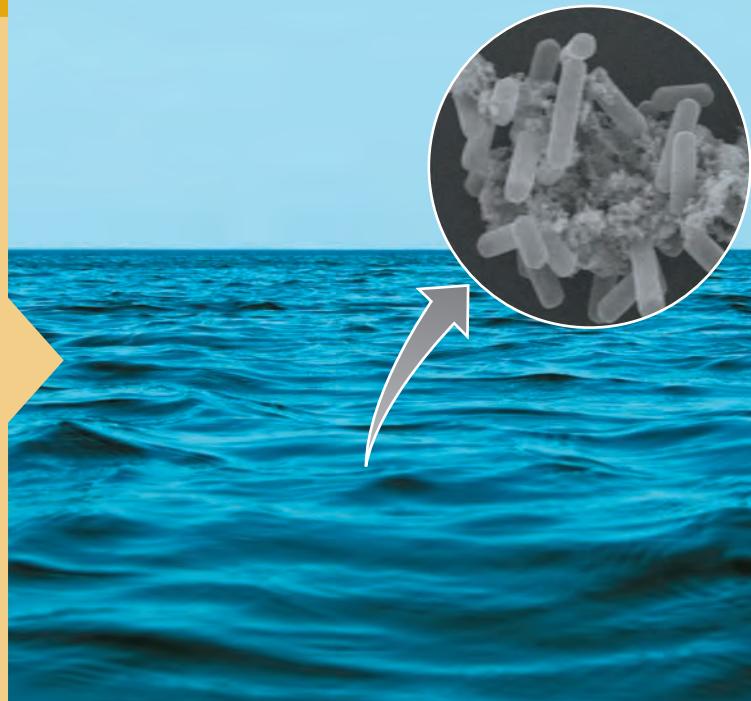

Genomics and New Archaea

Until recently, three phyla of Archaea were known, the *Euryarchaeota*, *Crenarchaeota*, and *Nanoarchaeota*. Curiously, every cultured species was isolated from an extreme environment, habitats that were either strictly anoxic or punishingly hot, salty, or acidic. This led many microbiologists to conclude that Archaea were mainly extremophiles and that they did not inhabit oceans, lakes, and soil in significant numbers. But microbial ecologists began to question this assumption when, using fluorescent microscopy, Archaea only marginally affiliated with *Crenarchaeota* were detected in marine and freshwater samples. Who were these organisms, and how were they making a living?

A group of microbiologists at the University of Washington in Seattle had a hunch about the metabolism of these Archaea and set about to isolate these organisms from marine samples (photo). With persistence, patience, and good scientific intuition, the group successfully isolated *Nitrosopumilus*, the first ammonia-oxidizing (nitrifying) archaeon known (photo inset). Although many species of *Bacteria* can nitrify, *Nitrosopumilus* can oxidize the trace amounts of ammonia found in open ocean waters, something nitrifying *Bacteria* cannot. With pure cultures of these organisms in hand, their phylogeny was more deeply explored using the powerful tools of genomics. Were nitrifying Archaea really just “highly divergent *Crenarchaeota*”?

Genomics is able to answer such questions, and careful analyses of the genomes of two archaeal nitrifiers¹ clearly showed that they formed their own phylum, now called the *Thaumarchaeota*. Genomic analyses allowed the entire gene set of these Archaea to be compared with that of all other Archaea. Besides revealing a fourth phylum of Archaea, genomics unveiled the metabolic peculiarities of *Thaumarchaeota* and this in turn provided a window into the ecological role they may play in their nutrient-deficient habitats.

¹Spang, A., et al., 2010. Distinct gene set in two different lineages of ammonia-oxidizing Archaea supports the phylum *Thaumarchaeota*. *Trends in Microbiol.* 18: 331–340.

- I **Investigating Genomes 184**
- II **Microbial Genomes 190**
- III **Functional Genomics 198**
- IV **The Evolution of Genomes 206**

The **genome** is an organism's entire complement of genetic information, including genes that encode proteins, RNAs, and regulatory sequences, and any noncoding DNA that may be present. The genome sequence of an organism not only reveals its genes but also yields important clues to how the organism functions and its evolutionary history. Genomics encompasses not only the complete sequencing of the DNA and identification of all the genes but also the study of gene expression at a genome-wide level. The traditional approach to studying gene expression was to focus on a single gene or group of related genes. In the genomics era, the expression of

all or most of an organism's genes can be examined in a single experiment.

Advances in genomics rely heavily on improvements in molecular technology and computing power. Major advances include the automation of DNA sequencing, the miniaturization of analytical procedures, and the development of powerful computational methods for analysis of DNA and protein sequences. New advances arrive every year and have driven down the cost and increased the speed at which genomes are analyzed. Here we focus on microbial genomes, some techniques used to analyze these genomes, and what microbial genomics has revealed thus far.

I • Investigating Genomes

The word **genomics** refers to the discipline of mapping, sequencing, analyzing, and comparing genomes. Several thousand genomes from prokaryotes have been sequenced, including those from multiple strains of some important species of *Bacteria* and *Archaea*. Because new advances in DNA sequencing appear frequently, the number of sequenced genomes will continue to grow rapidly. Today the major bottleneck in genomics is the analysis and visualization of vast amounts of nucleic acid sequence data. Nevertheless, genome sequences continue to provide new insights in areas as diverse as medicine and microbial evolution.

6.1 Introduction to Genomics

The first genome sequenced was the 3569-nucleotide RNA genome of the virus MS2 (Section 9.8) in 1976. The first DNA genome sequenced was the 5386-nucleotide sequence of the single-stranded DNA virus φX174 (Section 9.3) in 1977. The first bacterial genome sequenced was the 1,830,137-base-pair (bp) chromosome of *Haemophilus influenzae* published in 1995. The DNA sequences of several thousand prokaryotic genomes are now available in public databases (for an up-to-date list search <http://www.genomesonline.org/>), and Table 6.1 lists some representative examples. These include species of both *Bacteria* and *Archaea*, and both circular and linear genomes. Although rare, linear chromosomes are present in several *Bacteria*, including *Borrelia burgdorferi*, the agent of Lyme disease, and the important antibiotic-producing genus *Streptomyces*. Bacterial genomes range in size from approximately 0.5 to 13 megabase pairs (Mbp) and encode roughly 500 to 10,000 protein-coding genes, respectively.

The genomes of many higher organisms, including the haploid human genome, which contains about 3 billion bp but only around 25,000 protein-coding genes, have also been sequenced. The largest genomes so far sequenced, in terms of their total number of genes, are those of the black cottonwood tree (a species of poplar) with around 45,000 genes and the protozoan *Trichomonas* with an estimated 60,000 protein-encoding genes; both have many more genes than do humans.

The genomes of many pathogens have been sequenced. In some cases multiple strains of a pathogen that vary in virulence have been compared in the hope of revealing which genes are medically

relevant. Moreover, hyperthermophiles (Section 5.12) have important uses in biotechnology because their enzymes are heat-stable. Originally the needs of the biomedical and biotechnology industries greatly affected the choice of organisms to sequence. However, genome sequencing is now so routine that projects are less governed by medical or technological needs. Indeed, a recent trend is to sequence and compare several different strains of the same organism to get a picture of genes held in common versus those that are optional (core/pan genome, Section 6.13). The genome list in Table 6.1 also includes widely studied model organisms such as *Bacillus subtilis* (sporulation), *Escherichia coli* (general biology and model gram-negative bacterium), and *Pseudomonas aeruginosa* (pathogen and model gram-negative bacterium).

MINIQUIZ

- How many genes are in the human genome?
- Name some organisms whose genomes are larger than the human genome.

6.2 Sequencing Genomes

In biology the term **sequencing** refers to determining the precise order of subunits in a macromolecule. In the case of DNA (or RNA), the sequence is the *order* in which the nucleotides are aligned. DNA sequencing technology is advancing so quickly that two or three new methods appear every year, although only a few gain widespread acceptance or stand the test of time. This is well illustrated by the drop in cost of sequencing 1 megabase of DNA. Between 2001 and 2011 this dropped 10,000-fold! Table 6.2 summarizes the sequencing methods discussed here.

First-Generation DNA Sequencing: The Sanger Dideoxy Method

The first widely used method for sequencing DNA was the dideoxy method invented by the British scientist Fred Sanger, who won a Nobel Prize for this accomplishment. Although superseded for genome sequencing by newer technologies, the dideoxy method is still used for some sequencing applications. Sanger introduced several important concepts that are still used in many newer sequencing

Table 6.1 Select prokaryotic genomes^a

Organism	Lifestyle ^b	Size (bp)	ORFs ^c	Comments
Bacteria				
<i>Hodgkinia cicadicola</i>	E	143,795	169	Degenerate cicada endosymbiont

^cOpen reading frames. Genes encoding known proteins are included, as well as ORFs that could encode a protein greater than 100 amino acid residues. Smaller ORFs are not included unless they show similarity to a gene from another organism or unless the codon bias is typical of the organism being studied.

schemes. These include sequencing by DNA synthesis rather than breakdown, using dideoxynucleotides to block chain extension, and using labeled precursors for detection.

In sequencing by DNA synthesis, short DNA oligonucleotides (typically 10–20 nucleotides) with defined sequences are used as

primers. These are synthesized artificially. **Primers** are short segments of DNA or RNA that initiate the synthesis of new strands of nucleic acid. During DNA replication *in vivo*, RNA primers are used (► Section 4.4), but in biotechnology, DNA primers are used because they are more stable than RNA primers.

Table 6.2 DNA sequencing methods

Generation	Method	Features
First generation	Sanger dideoxy method (radioactivity or fluorescence; DNA amplification)	Read length: 700–900 bases Used for the human genome project
Second generation	454 Pyrosequencing (fluorescence; DNA amplification; massively parallel)	Read length: 400–500 bases Used to sequence genome of James Watson (completed 2007)
	Illumina/Solexa method (fluorescence; DNA amplification; massively parallel)	Read length: 50–100 bases Giant panda genome (2009; Beijing Genome Institute) Denisovan genome (2010)
	SOLiD method (fluorescence; DNA amplification; massively parallel)	Read length 50–100 bases
Third generation	HeliScope Single Molecule Sequencer (fluorescence; single molecule) Pacific Biosciences SMRT (fluorescence; single molecule; zero mode waveguide)	Read length: up to 55 bases Fossil DNA accuracy greatly improved Read length: 2500–3000 bases
Fourth generation	Ion torrent (electronic—pH; DNA amplification)	Read length: 100–200 bases Sequenced genome of Intel cofounder Gordon Moore (originator of Moore's law), 2011
	Oxford nanopore (electronic—current; single molecule; real time)	Read length: thousands of bases Portable MinION unit is approximately the size of a flash drive

In the Sanger procedure the sequence is determined by making a copy of the original single-stranded DNA using the enzyme DNA polymerase. As previously discussed (☞ Section 4.4), this enzyme adds deoxyribonucleoside triphosphates to a growing DNA chain. However, in Sanger sequencing, small amounts of the corresponding dideoxynucleotide are included in each of four incubation mixtures, one for each of the four bases—adenine,

guanine, cytosine, and thymine (Figure 6.1). The dideoxy analog is a specific *chain-termination* reagent, and because it lacks a 3'-hydroxyl, it prevents further elongation of the chain after its insertion. Because dideoxynucleotides insert randomly, DNA chains of varying length are obtained and are separated on the basis of size by gel electrophoresis (Figure 6.2).

Originally four separate reactions (and four separate gel lanes) were used for each sequence determination, one for fragments ending with each of the four bases. The positions of the bands were located by using labeled precursors (originally radioactive but now fluorescent). By aligning the four dideoxynucleotide lanes and noting the vertical position of each fragment relative to its neighbor, the DNA sequence is read directly from the gel (Figure 6.2).

Automated DNA-sequencing systems use fluorescent dye-labeled primers (or nucleotides) instead of radioactive ones. The products are separated by electrophoresis in a capillary tube and the bands are scanned by a fluorescence-detecting laser. Since each of the four bases uses a fluorescent label of a different color, all four reactions are run in a single lane; the results are then analyzed by computer (Figure 6.2).

Shotgun Sequencing

Shotgun sequencing refers to the *preparation* of DNA for sequencing, not the sequencing itself. Most genomic sequencing projects employ shotgun sequencing. Analysis of a genome usually begins with the construction of a **genomic library**—the molecular cloning of DNA fragments that cover the entire genome (☞ Section 11.4). In the shotgun approach, the entire genome, cleaved into fragments, is cloned. The fragments are then sequenced. At this point the order and orientation of the DNA fragments are unknown. The sequences are analyzed by a computer that searches for overlapping sequences and assembles the sequenced fragments in the correct order. By its very nature, much sequencing in the shotgun method is redundant. To ensure

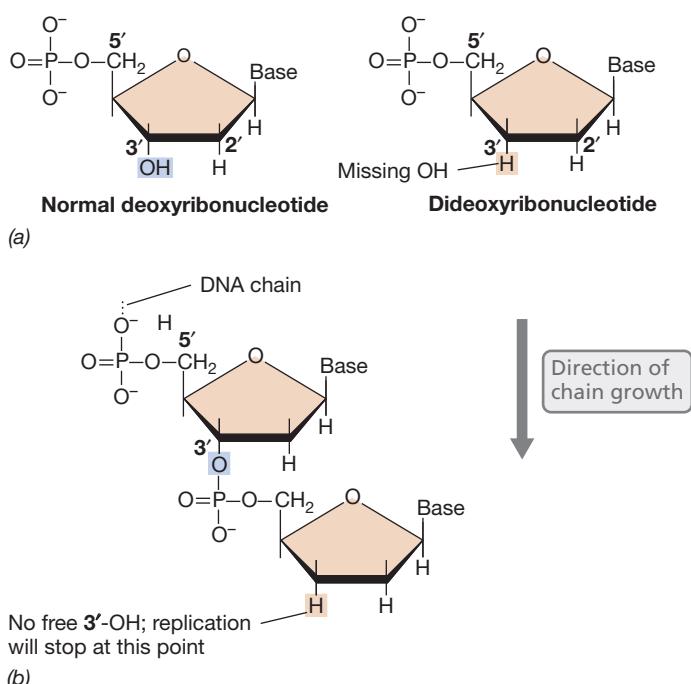

Figure 6.1 Dideoxynucleotides and Sanger sequencing. (a) A normal deoxyribonucleotide has a hydroxyl group on the 3'-carbon and a dideoxynucleotide does not. (b) Elongation of the chain terminates where a dideoxynucleotide is incorporated.

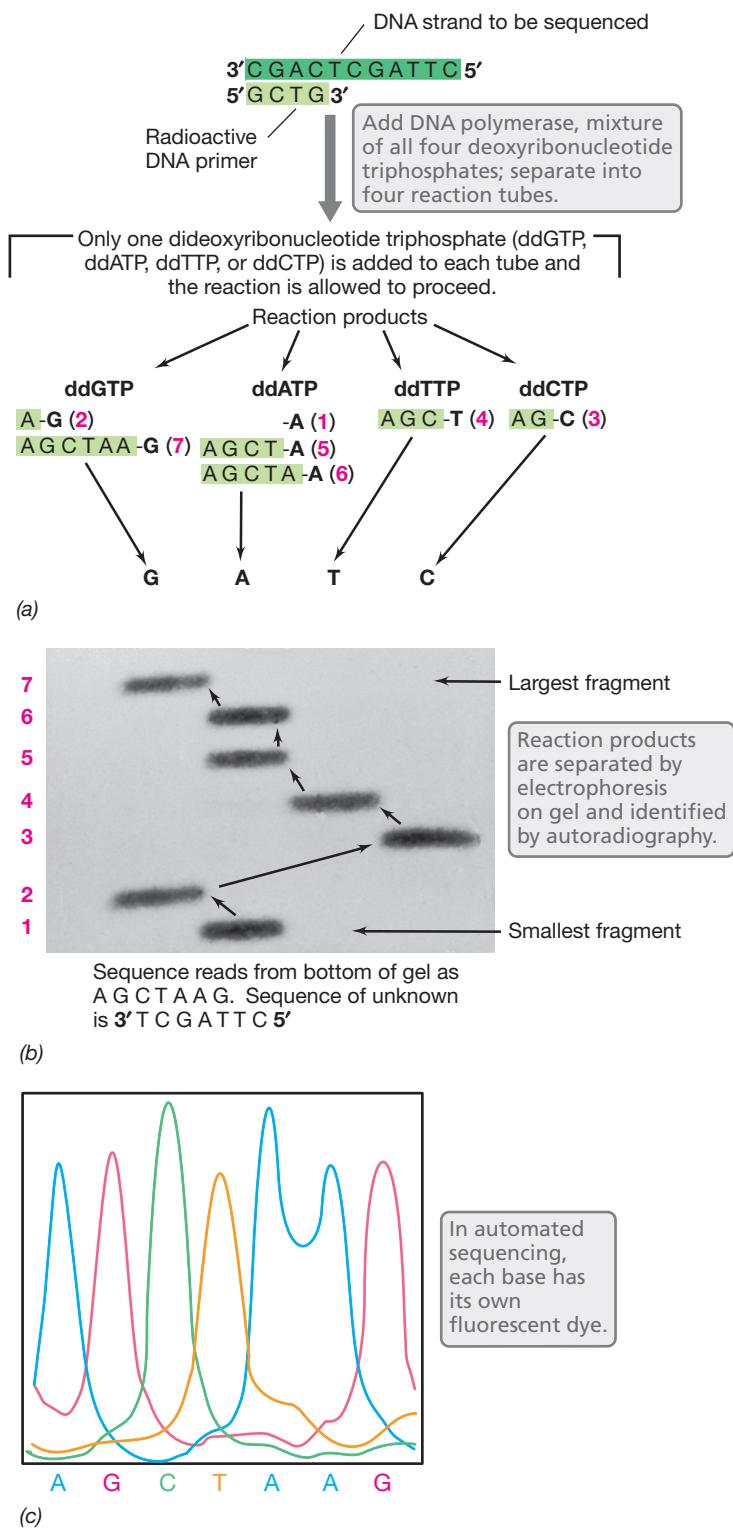

Figure 6.2 DNA sequencing using the Sanger method. (a) Note that four different reactions must be run, one with each dideoxynucleotide. Because these reactions are run *in vitro*, the primer for DNA synthesis can be DNA. (b) A portion of a gel containing the reaction products from part a. (c) Results of sequencing the same DNA as shown in parts a and b, but using an automated sequencer and fluorescent labels. The DNA fragments are separated by size on a single capillary column and each fluorescently labeled dideoxynucleotide detected with a laser detector.

full coverage of a genome it is necessary to sequence a very large number of clones, many of which are identical or nearly identical. Typically, 7–10 replicate sequences (referred to as *7- to 10-fold coverage*) are obtained for any given part of the genome. This greatly reduces errors because the redundancy in sequencing allows for a consensus nucleotide to be selected at any ambiguous point.

For shotgun sequencing to be successful, the cloning must be efficient (many clones are needed) and, as far as possible, the cloned DNA fragments should be randomly generated. This may be done by enzymatic digestion of the DNA or by physical methods. The DNA fragments can be purified by size using gel electrophoresis (Section 11.1) before cloning and sequencing.

Second-Generation DNA Sequencing

The term “generation” in DNA sequencing refers to successive major changes in technology that confer significant increases in speed combined with a drop in the cost of sequencing. The defining characteristic of *second-generation* sequencing is the use of *massively parallel methods*. In other words, very large numbers of samples are sequenced side-by-side in the same machine. Two major requirements for this are miniaturization and increased computing power. Second-generation methods generate sequence data 100 times faster than earlier methods. The three most widely used second-generation methods are 454 Life Sciences pyrosequencing, Illumina/Solexa sequencing, and the SOLiD/Applied Biosystems method.

In the 454 system, the DNA is broken into single-stranded segments a few hundred bases long. Each fragment is then attached to a small bead. The DNA is amplified by the polymerase chain reaction (PCR, Section 11.3), resulting in each bead carrying several identical copies of the DNA. Using robotics, the beads are then put into a fiber-optic plate containing more than a million wells, each of which holds just one bead.

Like Sanger sequencing (Figure 6.2), pyrosequencing uses synthesis of a complementary strand by DNA polymerase (Figure 6.3). However, instead of chain termination, each time a deoxyribonucleotide is incorporated, a molecule of pyrophosphate is released. This provides the energy necessary for activity of the light-emitting enzyme *luciferase*, which is included in each well. The four nucleotides flow sequentially over the plate in a fixed order. The one that yields a light pulse identifies which base was inserted. The Illumina/Solexa method resembles Sanger sequencing in using DNA synthesis and nucleotide chain terminators. However, in the Illumina system, the terminators are deoxy (rather than dideoxy) ribonucleotides and can be reversibly incorporated. In addition, each of the four different deoxyribonucleotides carries its own fluorescent tag that functions as a blocking group for the 3'-OH, thus causing chain termination.

Third- and Fourth-Generation DNA Sequencing

The key characteristic of *third-generation* sequencing is the sequencing of *single molecules* of DNA. There are two main approaches: one based on microscopy and the other on nanotechnology. In the *HeliScope Single Molecule Sequencer*, single-stranded fragments of DNA about 32 bases long are attached in an array on a glass slide. As the complementary strand is synthesized,

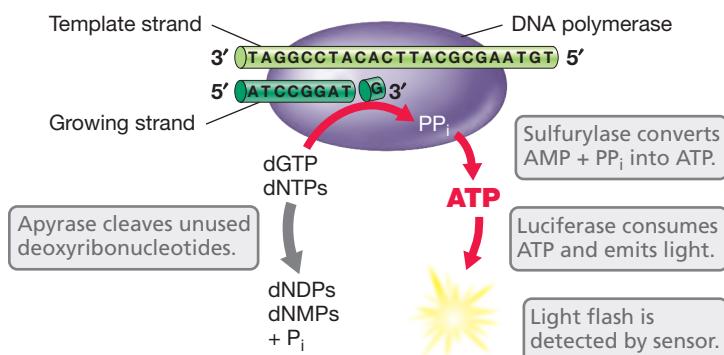

Figure 6.3 Mechanism of pyrosequencing. Whenever a new deoxyribonucleotide is inserted into the growing strand of DNA (red arrows), pyrophosphate (PP_i) is released and is used to make ATP from AMP by the enzyme sulfurylase. The ATP is consumed by the enzyme luciferase, which releases light. Unused deoxyribonucleotides are degraded by the enzyme apyrase (gray arrow).

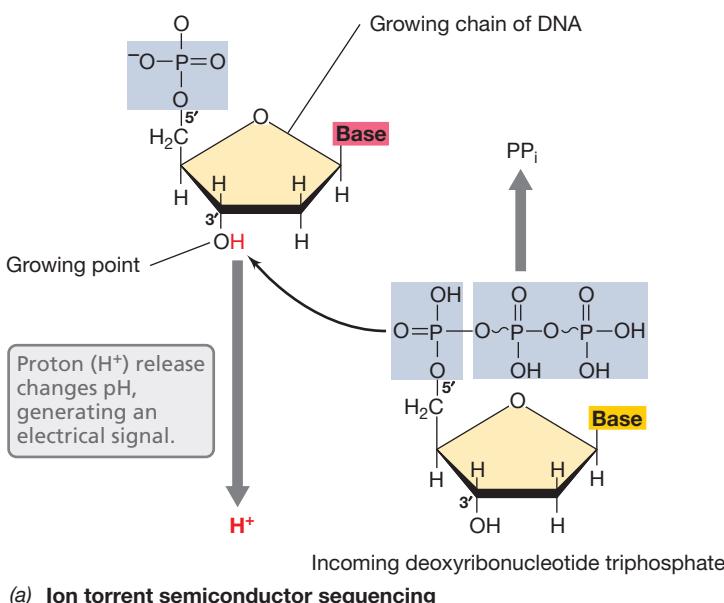

fluorescent tags on the incoming nucleotides are monitored on a microscope. The machine can monitor a billion DNA fragments simultaneously. A computer then assembles the fragments into a complete sequence.

Pacific Biosciences SMRT (single-molecule real-time) sequencing uses a technique known as *zero-mode waveguides*. In this method, DNA polymerase extends a growing chain by adding deoxyribonucleotides tagged with four different fluorescent dyes. Incoming deoxyribonucleotides emit a flash of light as they are linked in place. Two novel features are critical for sequencing single molecules. First, reactions are carried out inside nanocontainers (the zero-mode waveguides). These are tiny cylindrical metal wells 20 nm wide that reduce background light sufficiently

to allow the detection of single flashes of light from individual nucleotides. Second, the fluorescent tags are attached to the pyrophosphate group that is discarded rather than the part of the deoxyribonucleotide that is incorporated into the chain. Thus, colored tags are not accumulated by the DNA; instead each reaction releases a microscopic burst of color.

The key characteristic of *fourth-generation sequencing*, also called “post light sequencing,” is that optical detection is no longer used. The *ion torrent sequencing method* does not use single-molecule sequencing. Instead of using labeled deoxyribonucleotides, it measures the release of protons (H⁺) whenever a new deoxyribonucleotide is added to a growing strand of DNA (Figure 6.4a). A silicon chip dubbed “the world’s smallest pH meter” detects the protons. Sequencing is extremely fast by this method and the instruments are much less expensive than those of previous technologies. For example, the ion torrent machine is capable of sequencing an entire human genome—almost 3000 Mbp—in less than a day!

Nanopore technology (Figure 6.4b) is based on microscopic machinery that operates on the scale of single molecules. Nanopore detectors for DNA are extremely narrow pores that permit single strands of DNA to pass through one at a time. The Oxford Nanopore Technologies system passes DNA through nanoscale biological pores made from a protein (Figure 6.4b). As the DNA molecule transits the pore, a detector records the change in electrical current across the nanopore. This change is different for each of the four bases or combinations of those bases. The major advantages of nanopore technology are its high speed and its ability to sequence long DNA molecules (rather than short fragments like most other methods). In addition, many nanopores can be assembled into a very small area

(a) Ion torrent semiconductor sequencing

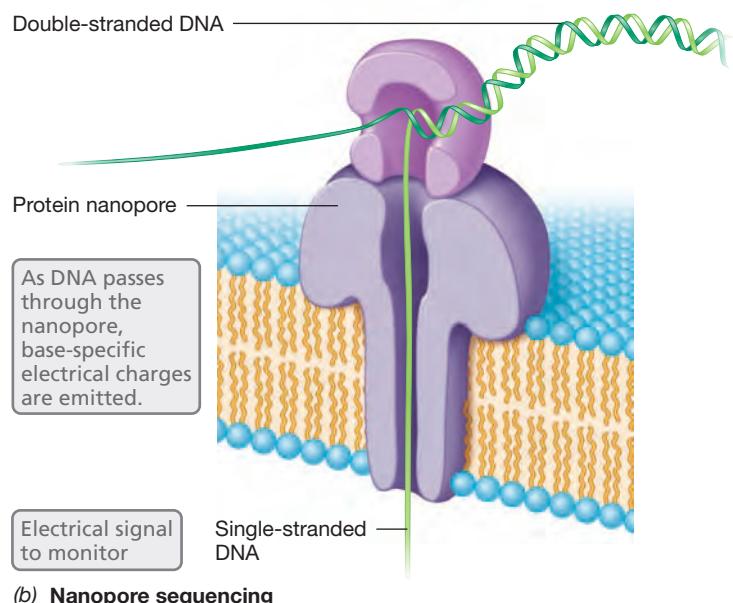

Figure 6.4 Fourth-generation sequencing. (a) The ion torrent semiconductor sequencing system is based on the release of protons (H⁺) each time a new deoxyribonucleotide is inserted into a growing strand of DNA. The resulting pH change is measured by an electrode. (b) In nanopore sequencing, a DNA double helix is converted to a single strand for passage through the pore. As the DNA transits the nanopore, it causes changes in electric charge that are base-specific.

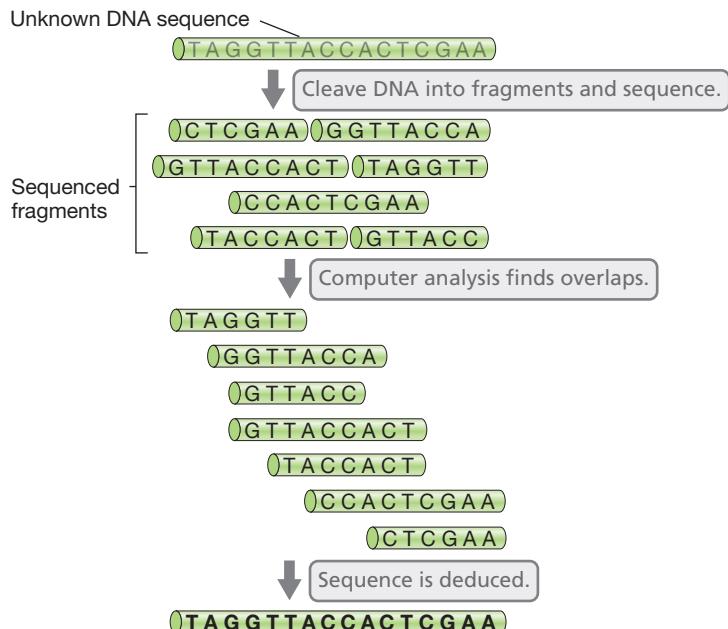

Figure 6.5 Computer assembly of DNA sequence. Most DNA sequencing methods generate vast numbers of short sequences (30 to several hundred bases) that must be assembled. The computer searches for overlaps in the short sequences and then arranges them to form a single overall sequence.

on a chip, upon which many long fragments of DNA can be sequenced simultaneously.

Genome Assembly

Regardless of how DNA is sequenced, the sequences must be assembled before they can be analyzed. Genome *assembly* consists of putting the fragments in the correct order and eliminating overlaps. In practice a computer examines many short DNA fragments that have been sequenced and deduces their order from the overlaps (Figure 6.5). Assembly generates a genome suitable for *annotation*, the process of identifying genes and other functional regions in the genome (discussed in the next section).

Sometimes sequencing and assembly does not yield a complete genome sequence and gaps in the genome remain. In such situations, a variety of approaches are used to obtain individual sequences that cover the gaps. Some genome projects have the goal of obtaining a *closed genome*, meaning that the entire genome sequence is determined. Other projects stop at the *draft stage*, dispensing with sequencing the small gaps. Because sequencing and assembly are heavily automated procedures, whereas gap closure is not, obtaining a closed genome is much more expensive and time consuming than a draft genome and typically needs much more human input to complete the job.

MINIQUIZ

- What is shotgun sequencing?
- What are the defining characteristics of third- and fourth-generation sequencing?
- What is accomplished during genome assembly?

6.3 Bioinformatics and Annotating Genomes

After sequencing and assembly, the next step is *genome annotation*, the conversion of raw sequence data into a list of the genes present and other functional sequences in the genome. **Bioinformatics** refers to the use of computers to store and analyze the sequences and structures of nucleic acids and proteins. Improved sequencing methods (Section 6.2) are now generating data faster than it can be properly analyzed. Thus, at present, annotation is the “bottleneck” in genomics.

Most genes encode proteins, and in most microbial genomes, especially those of prokaryotes, the great majority of the genome consists of coding sequences. Because genes in the genomes of microbial eukaryotes typically have fewer intervening sequences (introns, ↗ Section 4.9) than plant and animal genomes, and prokaryotes have almost none, microbial genomes essentially consist of a series of **open reading frames (ORFs)** separated by short regulatory regions and transcriptional terminators. Recall that an open reading frame is a sequence of DNA or RNA that can be translated to yield a polypeptide (↗ Section 4.11).

How Does the Computer Find an ORF?

A *functional ORF* is one that actually encodes a protein. The simplest way to find potential protein-encoding genes is to have a computer search the genome sequence for ORFs (Figure 6.6). Although any given gene is always transcribed from one strand, both strands are transcribed in some part of the genome (in all but the smallest plasmid or viral genomes). Thus, computer inspection of both strands of DNA is required.

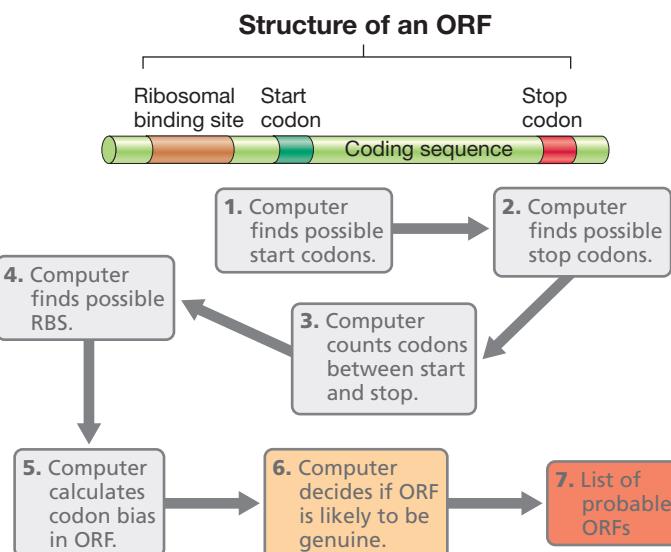

Figure 6.6 Computer identification of possible ORFs. The computer scans the DNA sequence looking first for start and stop codons. It then counts the number of codons in each uninterrupted reading frame and rejects those that are too short. The probability of a genuine ORF is made stronger if a likely ribosomal binding site (RBS) is found the correct distance in front of the reading frame. Codon bias calculations are used to test if an ORF complies with the codon usage of the organism being examined.

Table 6.3 Examples of codon bias

Arginine codon ^a	Usage of each arginine codon (%)		
	Escherichia coli	Fruit fly	Human
AGA	1	10	22
AGG	1	6	23
CGA	4	8	10
CGC	39	49	22
CGG	4	9	14
CGU	49	18	9

^aArginine has six codons; see Table 4.5.

The first step in finding an ORF is to locate *start* and *stop* codons in the sequence (☞ Section 4.11 and Table 4.5). However, in-frame start and stop codons appear randomly with reasonable frequency. Thus, further clues are needed. Most proteins contain 100 or more amino acids, so most functional ORFs are longer than 300 nucleotides (100 codons). However, ignoring ORFs shorter than 100 codons will miss some genuine but short genes. In *Bacteria*, translation begins at start codons located immediately downstream of a ribosome-binding sequence (Shine–Dalgarno site) on the mRNA (☞ Section 4.13). Thus, locating potential ribosome-binding sequences helps decide both whether an ORF is functional and which start codon is actually used.

More than one codon exists for many of the 20 common amino acids (☞ Table 4.5), and some codons are used more frequently than others. The latter is known as **codon bias** (codon usage) and differs greatly between organisms. For example, Table 6.3 shows the different usage of the six arginine codons in *Escherichia coli* compared to their usage in humans and fruit flies. If the codon bias in a given ORF differs greatly from the consensus for the organism containing it, that ORF may be nonfunctional or may be functional but obtained by horizontal gene transfer (Section 6.12).

An ORF is more likely to be functional if its sequence is similar to those of ORFs in the genomes of other organisms (regardless of whether they encode known proteins) or if the ORF includes a sequence known to encode a protein functional domain. This is because proteins with similar functions in different cells tend to share a common evolutionary origin and typically share sequence and structural features (Section 6.11). Computers can search for sequence similarities in databases such as GenBank. This database contains over 200 billion base pairs of sequence and is located at <http://www.ncbi.nlm.nih.gov/Genbank/>. The most widely used database search tool is *BLAST* (*Basic Local Alignment Search Tool*), which has several variants depending on whether nucleic acid or protein sequences are used for searching. For example, the tool BLASTn searches nucleic acid databases from a

nucleotide query, whereas BLASTp searches protein databases from a protein query.

Uncharacterized ORFs

Although there are differences among organisms, in most genomes the number of genes whose role can be clearly identified is approximately 70% of the total number of ORFs detected. Uncharacterized (or unknown) ORFs are said to encode *hypothetical proteins*, proteins that probably exist although their function is unknown. Uncharacterized ORFs have uninterrupted reading frames of reasonable length and the necessary start and stop codons (Figure 6.6). However, the proteins they encode lack sufficient amino acid sequence homology with any known protein to be identified.

As gene functions are identified in one organism, homologous ORFs in other organisms can be assigned functions. However, most genes for macromolecular synthesis and central metabolism essential for growth have been identified. Therefore most of the remaining ORFs will probably encode nonessential proteins.

Many of the unidentified genes in *E. coli* are predicted to encode regulatory or redundant proteins. These probably include proteins needed only under special conditions or “backups” for key enzymes. However, even in well-studied organisms such as *E. coli*, the precise functions of many genes are often unpredictable. Some gene identifications merely assign genes to a family or a general function (such as “transporter”). By contrast, other genes are completely unknown and have only been predicted using bioinformatics. Moreover, some annotations are actually incorrect. In fact, it has been estimated that as many as 10% of genes in databases are incorrectly annotated.

Noncoding RNA

In addition to protein-encoding genes, some genes encode RNA molecules that are not translated. Such genes therefore lack start codons and may well have multiple stop codons within the gene. In addition, these genes lack codon bias; consequently, they will not be recognized by programs that search for ORFs. Some non-coding RNAs are easy to detect because they are well characterized and are highly conserved. These include tRNAs and rRNAs. However, many noncoding regulatory RNA molecules (☞ Section 7.14) are conserved only in three-dimensional structure, with little sequence homology. Identifying these during genome annotation remains a challenge.

MINIQUIZ

- What is an open reading frame (ORF)? What is a hypothetical protein?
- How can protein homology assist in genome annotation?
- What is the major problem in identifying genes encoding nontranslated RNA?

II • Microbial Genomes

6.4 Genome Size and Content

Following sequencing, assembly, and annotation, comparative genomics can be used to compare genomes as to their size, orga-

nization, and gene content. The Microbes Online website (<http://www.microbesonline.org>) has nearly 4000 microbial genomes available for viewing.

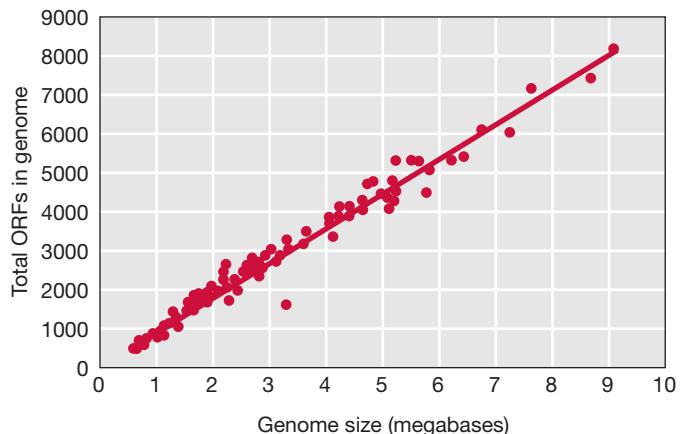

Figure 6.7 Correlation between genome size and ORF content in prokaryotes.

Analyses of 115 completed prokaryotic genomes including species of both *Bacteria* and *Archaea*. Data from *Proc. Natl. Acad. Sci. (USA)* 101: 3160–3165 (2004).

Size Range of Prokaryotic Genomes

Genomes of species of both *Bacteria* and *Archaea* show a strong correlation between genome size and open reading frame (ORF) content (Figure 6.7). Regardless of the organism, each megabase pair of DNA in a prokaryote encodes about 1000 ORFs. As the size of prokaryotic genomes increases, the gene number also increases proportionally. This contrasts markedly with the genomes of eukaryotes, in which noncoding DNA (introns, ↗ Section 4.9) may be a large fraction of the genome, especially in organisms with large genomes.

Analyzing genomic sequences can shed light on fundamental biological questions. For example, how many genes are necessary for a cell to exist? The record for the smallest genome for a free-living organism belongs to a species of *Bacteria* referred to as strain HTCC2181, whose genome contains 1,304,428 bp and 1354 genes. This undercuts the previous record holder, *Pelagibacter ubique*, a marine heterotroph, by a mere 4331 bp, suggesting that this is close to the practical limit for independent life. HTCC2181 is an as yet uncultured methylotrophic bacterium (methylotrophs are organisms that catabolize one-carbon compounds, such as methanol) that is common in marine coastal ecosystems.

Several other free-living *Bacteria* and *Archaea* are known that have genomes of around 1400 genes (Table 6.1). These organisms are extremely efficient in their use of DNA. They have few or no introns, inteins, or transposons and have very short intergenic spaces. The largest prokaryotic genomes contain over 10,000 genes and are primarily from soil bacteria, such as the myxobacteria, who undergo complex life cycles (↗ Section 14.19). Figure 6.8 shows five selected circular prokaryotic genomes drawn to scale to give a visual impression of how variable prokaryotic genomes can be.

Perhaps surprisingly, genomic analyses have shown that autotrophic organisms need only a few more genes than heterotrophs (↗ Section 3.3). For example, the methanogen *Methanocaldococcus jannaschii* (*Archaea*) is an autotroph whose genome contains only 1738 ORFs. This enables it to be not only free-living, but also to rely on CO₂ as its sole carbon source. *Aquifex aeolicus* (*Bacteria*) is also an autotroph and contains the smallest known

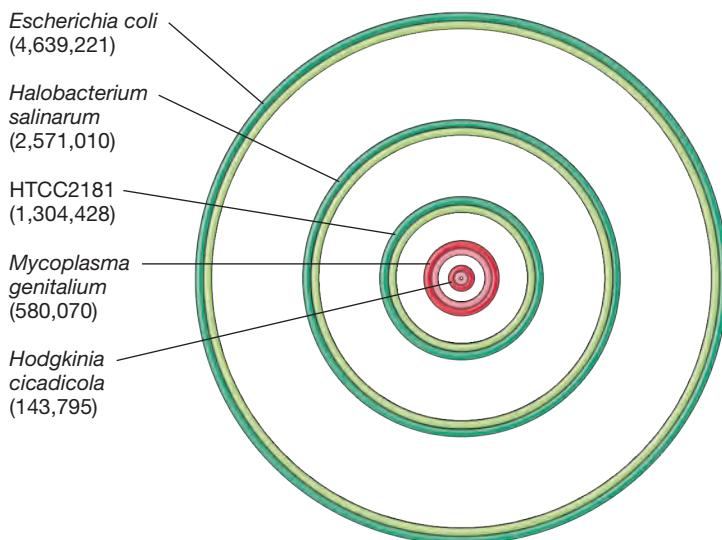

Figure 6.8 Genome size comparison. The circular genomes of several prokaryotes are shown drawn to scale. The number of nucleotides is shown next to the names. Green circles indicate free-living organisms whereas red circles indicate parasites (*Mycoplasma*) and insect symbionts (*Hodgkinia*).

genome of any autotroph at just 1.5 megabase pairs (Table 6.1). Both *Methanocaldococcus* and *Aquifex* are also hyperthermophiles, growing optimally at temperatures above 80°C. Thus, large genomes are not necessary to support autotrophic and extreme lifestyles.

Small Genomes

The smallest cellular genomes belong to prokaryotes that are parasitic or endosymbiotic (cells that live inside other cells). Genome sizes for obligately parasitic prokaryotes range from 490 kbp for *Nanoarchaeum equitans* (*Archaea*) to 4400 kbp for *Mycobacterium tuberculosis* (*Bacteria*). The genomes of several prokaryotes, including *N. equitans*, *Mycoplasma*, *Chlamydia*, and *Rickettsia*, are smaller than the largest known viral genome, that of *Mimivirus* with 1.2 Mbp (↗ Section 9.2). The degenerate cicada endosymbiont *Hodgkinia* has a tiny genome, less than 150 kbp (Figure 6.8; see also Figure 6.14).

Genomes smaller than 1.2 Mbp are all found in bacteria that are dependent on other cells for some aspect(s) of their existence. Mycoplasmas, with genomes of just over 500 kbp and just under 500 genes, have the smallest genomes among parasitic bacteria (Figure 6.8; see also Figure 6.14). Excluding endosymbionts, the smallest prokaryotic genome is that of *N. equitans*, which is some 90 kbp smaller than that of *Mycoplasma genitalium* (Table 6.1). Despite this, the genome of *N. equitans* actually contains more genes than *M. genitalium*. This is because the *N. equitans* genome is extremely compact with almost no noncoding DNA. *N. equitans* is a hyperthermophile and a parasite of another hyperthermophile, the archaeon *Ignicoccus* (↗ Section 16.7). *N. equitans* lacks virtually all genes that encode metabolic proteins and presumably depends on its host for most catabolic as well as anabolic functions.

Using *Mycoplasma*, which has around 500 genes, as a starting point, it has been estimated that around 250–300 genes are

the minimum number possible for a viable cell. These estimates rely partly on comparisons with other small genomes. In addition, systematic mutagenesis has been performed to identify essential genes. For example, experiments with *Escherichia coli* and *Bacillus subtilis*, both of which have about 4000 genes, indicated that approximately 300–400 genes are essential depending on the growth conditions. However, in these experiments the bacteria were provided with many nutrients, allowing them to survive without many genes that encode biosynthetic functions. Most of the “essential genes” identified are present in other bacteria as well and approximately 70% have also been found in *Archaea* and eukaryotes.

Large Genomes

Some prokaryotes have very large genomes that are as large as those of certain eukaryotic microorganisms. Because eukaryotes tend to have significant amounts of noncoding DNA and prokaryotes do not, some prokaryotic genomes actually have more genes than microbial eukaryotes, despite having less DNA. For example, the genome of *Bradyrhizobium japonicum*, a bacterium that forms nitrogen-fixing root nodules on leguminous plants such as soybeans, has 9.1 Mbp of DNA and 8300 ORFs, whereas the genome of the baker’s yeast *Saccharomyces cerevisiae*, a eukaryote, has 12.1 Mbp of DNA and only 5800 ORFs (see Table 6.5). The soil bacterium *Myxococcus xanthus* also has 9.1 Mbp of DNA, whereas many of its close relatives have genomes approximately half this size. It has been hypothesized that multiple duplications of substantial segments of genomic DNA might account for such very large genomes.

The largest prokaryotic genome known at present is that of *Sorangium cellulosum*, a species of the myxobacteria (► Section 14.19). With just over 13 Mbp on a single circular chromosome, its genome is roughly three times larger than that of *Escherichia coli*. The *Sorangium* genome has a relatively large proportion of noncoding DNA for a bacterium—14.5%—and consequently has fewer coding sequences than might have been expected—only 9400. Nonetheless, it has more DNA than several eukaryotes including yeast and the protozoans *Cryptosporidium* and *Giardia* (see Table 6.5). The complex regulation needed for the social lifestyle of *Sorangium* is seen in its massive number of eukaryotic-type protein kinases (enzymes that phosphorylate other proteins to control their activity). It has 317 kinases, over twice that of any other genome, including eukaryotes.

In contrast to *Bacteria*, the largest genomes found in *Archaea* thus far are around 5 Mbp (Table 6.1). Overall, prokaryotic genomes range in size from those of large viruses to those of eukaryotic microorganisms.

Gene Content of Bacterial Genomes

The complement of genes in a particular organism reveals its capabilities. Conversely, genomes are molded by adaptation to an organism’s lifestyle. Comparative analyses are useful when searching for genes that encode enzymes that probably exist because of the lifestyle of an organism. *Thermotoga maritima* (*Bacteria*), for example, is a hyperthermophile found in hot marine sediments, and laboratory studies have shown that it can catabolize a large

number of sugars. **Figure 6.9** summarizes some of the metabolic pathways and transport systems of *T. maritima* that were deduced from analysis of its genome. About 7% of its genes encode proteins for the metabolism of sugars. As expected, its genome is also rich in genes for transport, particularly for carbohydrates and amino acids. All this suggests that *T. maritima* exists in an environment rich in organic material.

One might imagine, for instance, that obligate parasites such as the spirochete *Treponema pallidum* (the agent of syphilis, ► Sections 14.20 and 29.12) would require relatively few genes for amino acid biosynthesis because amino acids can be supplied by their hosts. This is indeed the case, as the *T. pallidum* genome lacks recognizable genes for amino acid biosynthesis, although genes encoding several proteases, enzymes that can convert peptides taken up from the host into free amino acids, are found. In contrast, the free-living bacterium *Escherichia coli* has 131 genes for amino acid biosynthesis and metabolism and the soil bacterium *Bacillus subtilis* has over 200.

A functional analysis of genes and their activities in several bacteria is given in **Table 6.4**. Thus far, a distinct pattern of gene distribution in prokaryotes has emerged. Metabolic genes are typically the most abundant class in prokaryotic genomes, although genes for protein synthesis overtake metabolic genes on a percentage basis as genome size decreases (Table 6.4 and **Figure 6.10**). Although many genes can be dispensed with, genes that encode the protein-synthesizing apparatus cannot. Thus, the smaller the genome the greater the percentage of genes that encode translational processes. The vital functions of DNA replication and transcription are encoded by genes that make up only a minor fraction of a typical prokaryotic genome.

The percentage of an organism’s genes devoted to a particular function is to some degree a function of genome size. This is summarized for a large number of bacterial genomes in **Figure 6.10**. Core cellular processes, such as protein synthesis, DNA replication, and energy production, show only minor variations in gene number with genome size. Consequently, the relative percentage of such genes is large in organisms with small genomes. Conversely, large genomes contain more genes for regulation than small genomes. These extra regulatory systems allow the cell to adapt with more flexibility to diverse environmental situations.

Organisms with large genomes can also afford to encode many specialized metabolic genes. This likely makes these organisms more competitive in their habitats, which, for many prokaryotes with very large genomes, is soil. Here, carbon and energy sources vary greatly and are often scarce or available only intermittently (► Section 19.1). A cell with a large genome that encodes multiple metabolic options would thus be strongly selected for in such a habitat. As an example of this, all of the prokaryotes listed in Table 6.1 whose genomes are larger than 6 Mbp inhabit soil.

Analyses of gene categories have also been done for several *Archaea*. On average, *Archaea* devote a higher percentage of their genomes to energy and coenzyme production than do *Bacteria* (this result is undoubtedly skewed a bit due to the large number of novel coenzymes produced by methanogenic *Archaea* [► Section 13.20]). On the other hand, *Archaea* appear to contain fewer

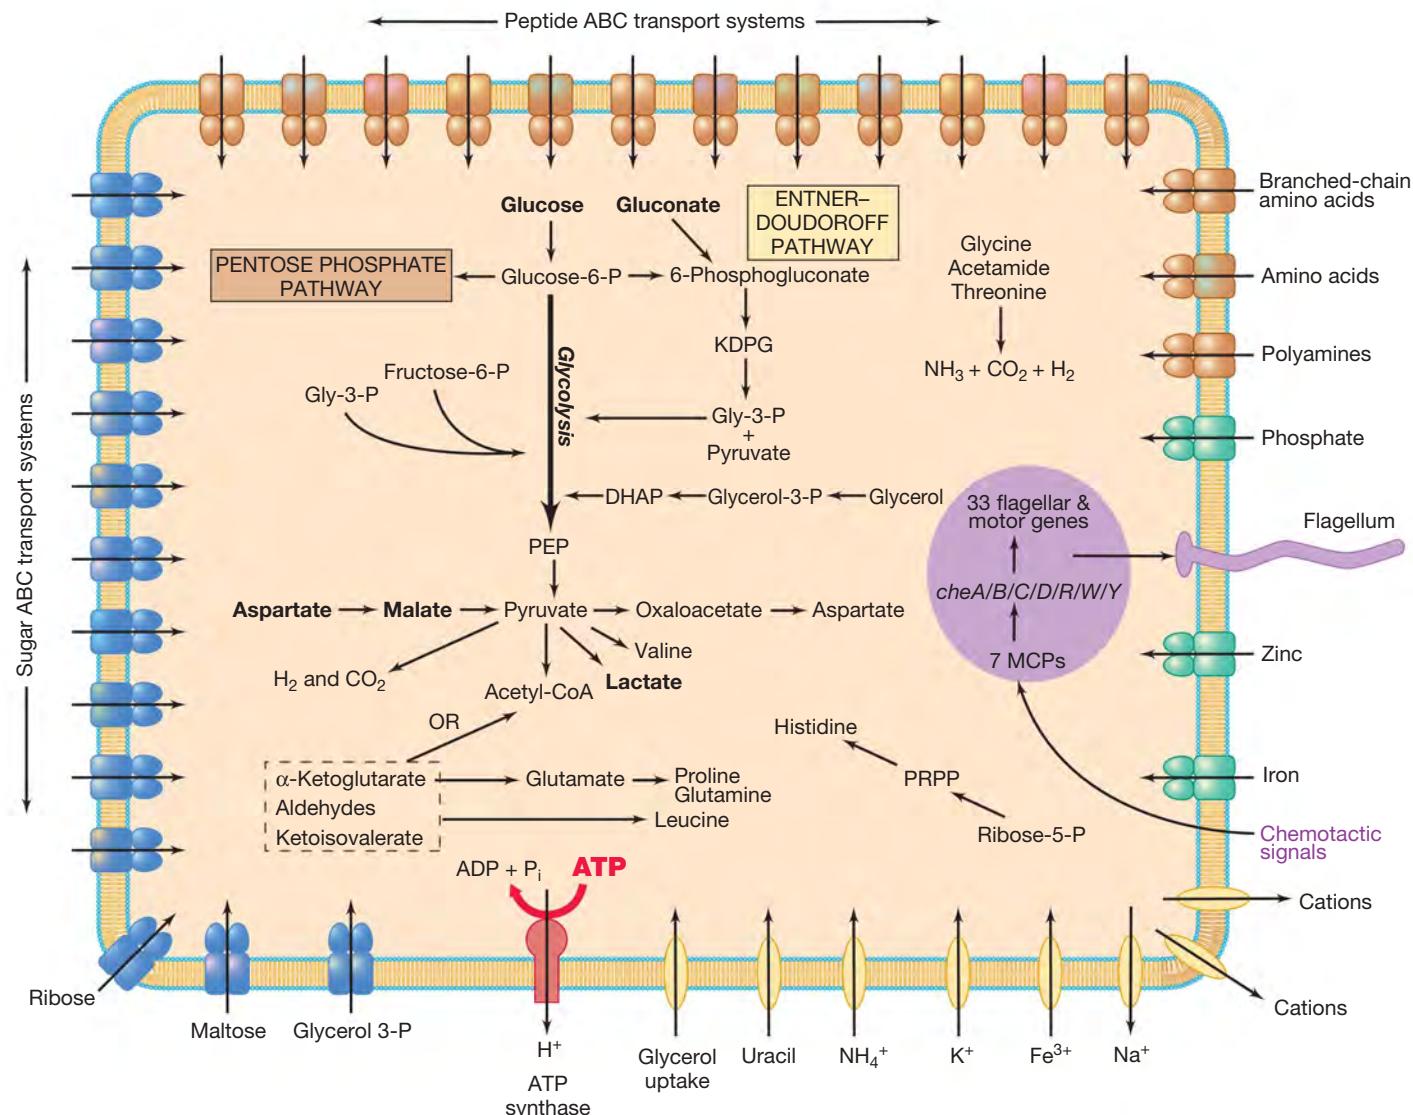

Figure 6.9 Overview of metabolism and transport in *Thermotoga maritima*. The figure summarizes the metabolic capabilities of this organism. These include some of the pathways for energy production and the metabolism of organic compounds, including transport proteins that were identified from analysis of the genomic sequence. Gene names are not shown. The genome contains several ABC-type transport systems, 12 for carbohydrates, 14 for peptides and amino acids, and still others for ions. These are shown as multi-subunit structures in the figure. Other types of transport proteins have also been identified and are shown as ovals. Chemotaxis and flagellar genes are highlighted in purple, and a few aspects of sugar metabolism are also shown. Data adapted from original figure published by The Institute for Genomic Research (TIGR, Rockville, MD).

genes for carbohydrate metabolism or membrane functions, such as transport and membrane biosynthesis, than do *Bacteria*. However, this conclusion is compromised because the corresponding pathways have been less studied in *Archaea* than in *Bacteria* and many of the relevant archaeal genes are probably still unidentified.

Both *Archaea* and *Bacteria* have relatively large numbers of genes whose functions are unknown or that encode only hypothetical proteins, although more uncertainty exists for the *Archaea* than the *Bacteria*. This may well be due to the fewer genome sequences available from species of *Archaea* than from *Bacteria*.

MINIQUIZ

- What lifestyle is typical of prokaryotes that have genomes smaller than those of certain viruses?
- Approximately how many protein-encoding genes will be found in a prokaryotic genome of 4 Mbp?
- Which is likely to have more genes, a prokaryote with 8 Mbp of DNA or a eukaryote with 10 Mbp? Explain.
- What category of genes do prokaryotes contain the most of on a percentage basis?

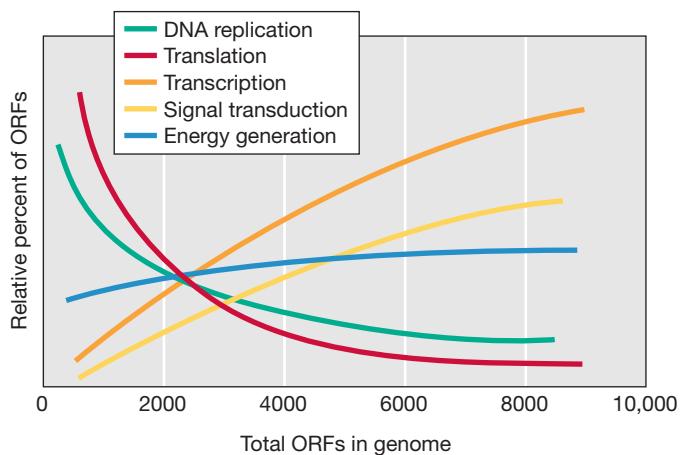

Figure 6.10 Functional category of genes as a percentage of the genome. The percentage of genes encoding products for translation or DNA replication is greater in organisms with small genomes, whereas the percentage of transcriptional regulatory genes is greater in organisms with large genomes. Data from *Proc. Natl. Acad. Sci. (USA)* 101: 3160–3165 (2004).

6.5 Genomes of Organelles

Mitochondria and chloroplasts are organelles derived from endosymbiotic bacteria that are found within eukaryotic cells (► Sections 2.21 and 17.1). Both contain small genomes that are bacterial in their fundamental properties. Moreover, both contain the machinery necessary for protein synthesis including ribosomes and transfer RNAs, plus the other components necessary to produce functional proteins. Again, these components are more closely related to those of *Bacteria* than to those found in the eukaryotic cytoplasm. Thus, organelles share many fundamental traits with the *Bacteria* to which they are phylogenetically related.

The Chloroplast Genome

Green plant cells contain chloroplasts, the organelles that perform photosynthesis (► Section 13.1). All known chloroplast genomes are circular DNA molecules, and each chloroplast contains several identical copies of the genome. The typical chloroplast genome is about 120–160 kbp and contains two inverted repeats of 6–76 kbp that each encode copies of the three rRNA

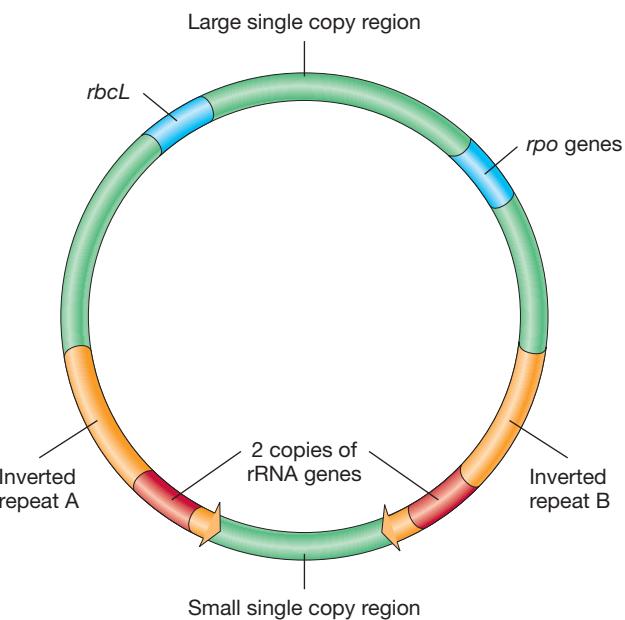

Figure 6.11 Map of a typical chloroplast genome. The inverted repeats each contain a copy of the three rRNAs (5S, 16S, and 23S) genes. The large subunit of RubisCO is encoded by *rbcL* and the chloroplast RNA polymerase by *rpo* genes.

genes (Figure 6.11). Many chloroplast genomes have been completely sequenced, and all are rather similar. The largest chloroplast genome so far sequenced is from the chlorophycean alga *Floydia terrestris*. It is just over 500 kbp and contains 97 conserved genes. About 80% of this genome consists of intergenic regions with many short repeats.

As might be expected, many chloroplast genes encode proteins for photosynthetic reactions and CO₂ fixation. The enzyme RubisCO catalyzes the key step in CO₂ fixation in the Calvin cycle (► Section 13.5). The *rbcL* gene encoding the large subunit of RubisCO is always present on the chloroplast genome (Figure 6.11), whereas the gene for the small subunit, *rbcS*, resides in the plant cell nucleus and its protein product must be imported from the cytoplasm into the chloroplast after synthesis.

The chloroplast genome also encodes rRNA used in chloroplast ribosomes, tRNA used in translation, several proteins used

Table 6.4 Gene function in bacterial genomes

Functional categories	Percentage of genes		
	Escherichia coli (4.64 Mbp) ^a	Haemophilus influenzae (1.83 Mbp) ^a	Mycoplasma genitalium (0.58 Mbp) ^a
Metabolism	21.0	19.0	14.6
Structure	5.5	4.7	3.6
Transport	10.0	7.0	7.3
Regulation	8.5	6.6	6.0

Transcription	1.3	1.5	2.6
Replication	2.7	4.9	6.8
Other, known	8.5	5.2	5.8
Unknown	38.1	43.0	32.0

^aChromosome size, in megabase pairs. Each organism listed contains only a single circular chromosome.

in transcription and translation, as well as some other proteins. Some proteins that function in the chloroplast are encoded by nuclear genes. These are thought to be genes that migrated to the nucleus as the chloroplast evolved from an endosymbiotic cell into a photosynthetic organelle. Introns (Section 4.9) are common in chloroplast genes and are primarily of the self-splicing type.

Mitochondrial Genomes and Proteomes

Mitochondria, the organelles that produce energy by respiration, are found in most eukaryotic organisms (Sections 2.21 and 17.1). Mitochondrial genomes primarily encode proteins for oxidative phosphorylation and, as for chloroplasts, also encode proteins, rRNAs, and tRNAs for protein synthesis. However, most mitochondrial genomes encode far fewer proteins than those of chloroplasts.

Several hundred mitochondrial genomes have been sequenced. The largest mitochondrial genome has 62 protein-encoding genes, but others encode as few as three proteins. The mitochondria of almost all mammals, including humans, encode only 13 proteins plus 22 tRNAs and 2 rRNAs. **Figure 6.12** shows a map of the 16,569-bp human mitochondrial genome. The mitochondrial genome of the yeast *Saccharomyces cerevisiae* is larger than that of humans (85,779 bp), but has only 8 protein-encoding genes. Besides the genes encoding the RNA and proteins, the genome of yeast mitochondria contains large stretches of adenine/thymine (AT)-rich DNA that has no apparent function.

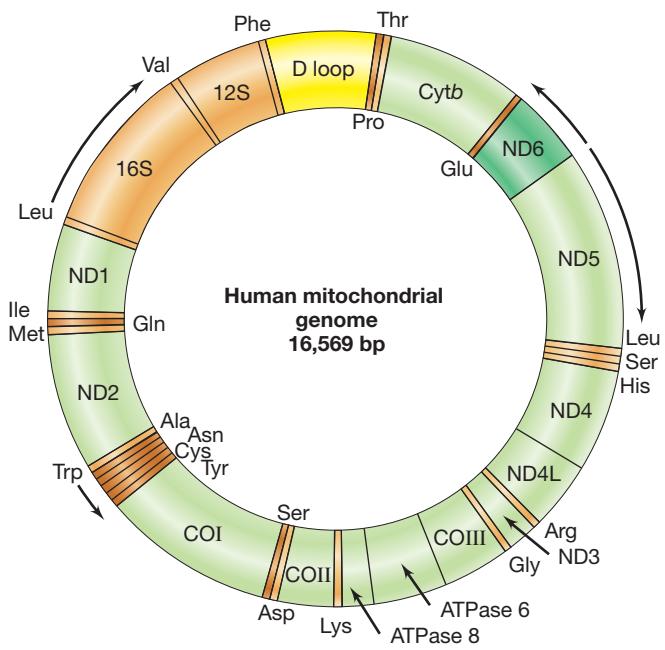

Figure 6.12 Map of the human mitochondrial genome. The genome encodes rRNAs, 22 tRNAs, and several proteins. Arrows show direction of transcription for genes of a given color, and the three-letter amino acid designations for tRNA genes are also shown. The 13 protein-encoding genes are in green. Cytb, cytochrome *b*; ND1–6, components of the NADH dehydrogenase complex; COI–III, subunits of the cytochrome oxidase complex; ATPase 6 and 8, polypeptides of the mitochondrial ATPase complex. The two promoters are in the region called the D loop, which is also involved in DNA replication.

The mitochondrial genomes of plants are much larger than those of animal cells, and mostly range from around 300 kbp to 2000 kbp. Despite this, they only have about 50 highly conserved genes, most of which encode components of the respiratory chain and translation apparatus. The variation in size is due to large amounts of noncoding DNA. The mitochondrial genomes of different species of the flowering plant genus *Silene* vary amazingly in size. The largest two are approximately 7 and 11 Mbp, making them larger than most bacterial genomes!

Unlike chloroplast genomes, which are all single, circular DNA molecules, the genomes of mitochondria are quite diverse. For example, some mitochondrial genomes are linear, including those of certain algae, protozoans, and fungi. In other cases, such as the yeast *S. cerevisiae*, genetic analysis implies that the mitochondrial genome is circular, but the physical form consists of large linear molecules containing multiple genome copies. (Certain viruses, such as bacteriophage T4, also have genomes that are genetically circular but physically linear; Section 8.6.) Finally, the mitochondria of many fungi and flowering plants contain small circular or linear plasmids in addition to the main mitochondrial genome.

Mitochondria require many more proteins than they encode. In particular, far more proteins are needed for translation than are encoded by the organelle genome. The proteins needed for many organelle functions are encoded by nuclear genes. The yeast mitochondrion contains as many as 800 different proteins (its proteome, Section 6.8). However, only eight of them are encoded by the yeast mitochondrial genome, the remaining proteins being encoded by nuclear genes (Figure 6.13). The genes for most organelle proteins are present in the nucleus, transcribed in the nucleus, and translated on the 80S ribosomes in the eukaryotic cytoplasm. The proteins are then transported into the organelles. The nuclear-encoded proteins required for translation and energy generation in mitochondria are more closely related to counterparts in the *Bacteria* than to those of the eukaryotic cytoplasm, consistent with the evolutionary history of the mitochondrion.

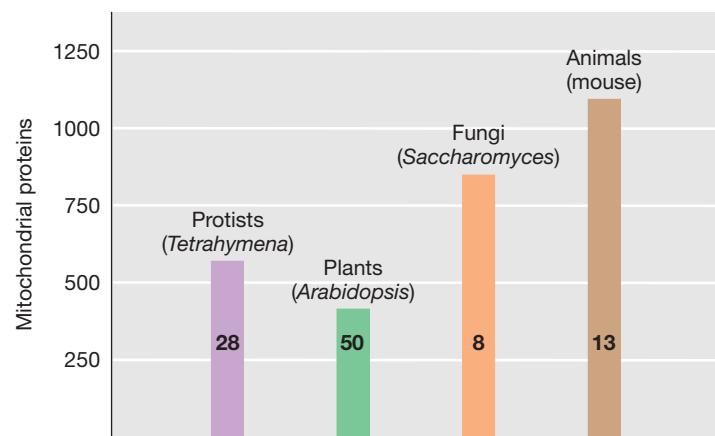

Figure 6.13 Mitochondrial proteomes. The number of proteins located in the mitochondria of different groups of model eukaryotes. The number is the best estimate because some proteins are present in very low amounts. The numbers in each colored bar are the number of proteins encoded on each organism's mitochondrial genome.

Variability in the Genetic Code

The original belief that all cells use the same genetic code led to the genetic code being regarded as universal (Figure 4.5). However, later discoveries showed that some mitochondria and a few cells use slight variations of the “universal” genetic code. Alternative genetic codes were first discovered in the genomes of animal mitochondria. These modified codes typically use stop codons as sense codons. For example, animal (but not plant) mitochondria use the codon UGA to encode tryptophan instead of using it as a stop codon. Yeast mitochondria also use UGA for tryptophan but in addition use the four CUN codons (N being any nucleotide) as threonine instead of leucine. These changes may have arisen from selection pressure for smaller genomes; for example, by inhabiting an environment where many necessary nutrients were already available. Thus, the 22 tRNAs produced in mitochondria are insufficient to read the universal genetic code, even when using wobble pairing (Figure 4.32). Therefore, base pairing between the anticodon and the codon is even more flexible in mitochondria than it is in cells.

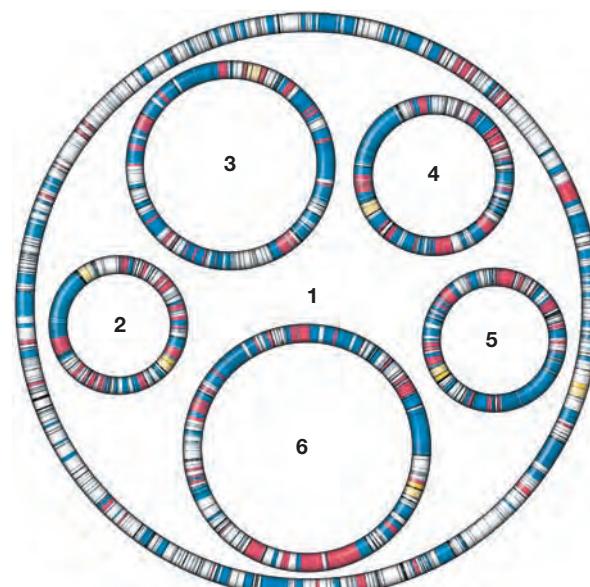

Several organisms are also known that use slightly different genetic codes. For example, in the genus *Mycoplasma* (Bacteria) and the genus *Paramecium* (Eukarya), certain stop codons encode amino acids. Consequently, these organisms have fewer stop codons. Certain fungi use the leucine codon CUG to encode serine. Curiously, however, these have become slightly ambiguous, as CUG is translated 97% of the time as serine and 3% of the time as leucine.

Symbionts and Organelles

Many insects and some other invertebrates, including certain nematodes and molluscs, contain symbiotic bacteria within their cells. Some of these bacterial symbionts are no longer capable of independent existence and show major reductions in the size of their genomes (Section 22.9). Symbiont genomes range from the same size as in free-living bacteria down to around 140 kbp for *Tremblaya* and *Hodgkinia* (Table 6.1 and Figure 6.8), the two smallest examples known (Figure 6.14). Thus, the genomes of some symbionts contain fewer genes than do some organelles and viruses. Such symbionts are totally dependent on their insect host cells for survival and nutrients. In turn, the symbionts provide the insect with essential amino acids and other nutrients that the insect cannot synthesize.

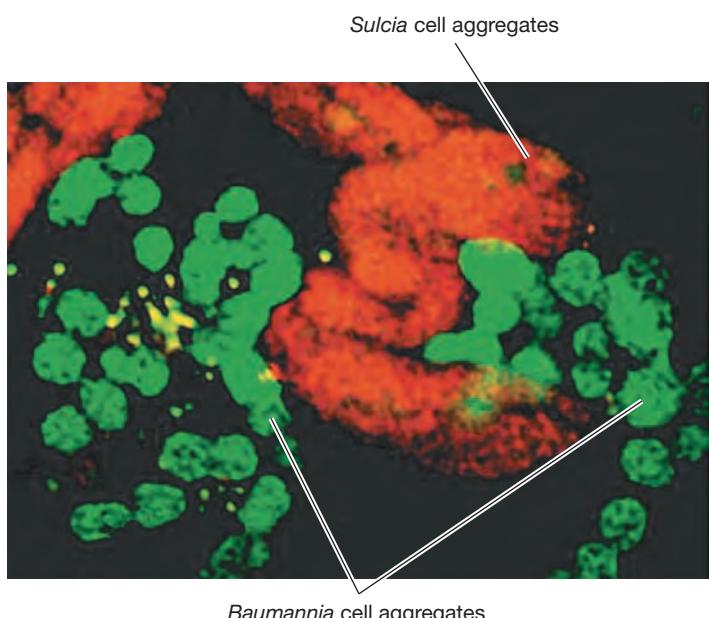

Some insects have two bacterial symbionts. For example, some leafhoppers contain both *Baumannia cicadellinicola*, which supplies vitamins and cofactors, plus *Sulcia muelleri*, which supplies many of the essential amino acids needed by the insect (Figure 6.15). Most symbionts are species of one of two major groups of the gram-negative bacterial phyla *Proteobacteria* and *Bacteroidetes*. Most of these greatly reduced genomes also have a strikingly high AT content, around 80%, except, paradoxically, for the two smallest, *Tremblaya* and *Hodgkinia*, which have around 40% AT. Some of these highly reduced genomes have apparently lost several genes regarded as essential for replication, such as the gene encoding the key cell division protein FtsZ (Section 5.2). So how these symbionts manage to replicate remains unknown.

The symbionts discussed differ from mitochondria and chloroplasts in several ways. Symbionts are restricted to a few tissues,

1. <i>Mycoplasma genitalium</i> (Mollicutes) 580.1 kbp GC: 31.7%	4. <i>Carsonella</i> (Gammaproteobacteria) 159.6 kbp GC: 16.6%
2. <i>Tremblaya</i> (Betaproteobacteria) 138.9 kbp GC: 58.8%	5. <i>Hodgkinia</i> (Alphaproteobacteria) 143.7 kbp GC: 58.4%
3. <i>Zinderia</i> (Betaproteobacteria) 208.5 kbp GC: 13.5%	6. <i>Sulcia</i> (Bacteroidetes) 245.5 kbp GC: 22.4%

Figure 6.14 Symbiont genomes. Five symbiont genomes are shown drawn to scale inside the circle representing the genome of a *Mycoplasma*. Blue: genes encoding genetic information processing; Red: genes encoding amino acid and vitamin biosyntheses; Yellow: rRNA genes; White: other genes; Gaps indicate noncoding DNA. Kbp, kilobase pairs.

Phat Tran and Nancy Moran

Figure 6.15 Two endosymbionts, *Sulcia* and *Baumannia*, both inhabit the same insect cells. Fluorescence in situ hybridizations were performed using probes that hybridize selectively to the rRNA of *Baumannia* (green) and of *Sulcia* (red).

even in a particular host organism. There is little evidence for transfer of symbiont genes to the host cell nucleus, and proteins made in the host cytoplasm do not enter the symbionts to perform vital functions. Nonetheless, some symbionts are absolutely required for host survival and cannot themselves survive outside the host. This leaves us with an important question to which there is presently no final answer: Where is the line between a symbiont and an organelle?

MINIQUIZ

- What is unusual about the genes that encode mitochondrial proteins?
- What do chloroplast genomes typically encode?
- What is unusual about the genomes of insect symbionts?

6.6 Eukaryotic Microbial Genomes

The genomes of many microbial eukaryotes have been sequenced (Table 6.5), and their size varies widely. Certain single-celled protozoans, including the free-living ciliate *Paramecium* (40,000 genes) and the pathogen *Trichomonas* (60,000 genes), have significantly more genes than do humans (Table 6.5). Indeed, *Trichomonas* pres-

ently holds the record for largest gene number of any organism. This is puzzling because *Trichomonas* is a human parasite, and such organisms typically have small genomes relative to comparable free-living organisms because parasites rely on their host for some or even many functions (Sections 6.3 and 6.5).

Genomes of Microbial Parasites

Apart from *Trichomonas*, parasitic eukaryotic microorganisms typically have genomes of 10–30 Mbp containing between 4000 and 11,000 genes. For example, *Trypanosoma brucei*, the agent of African sleeping sickness, has 11 chromosomes, 35 Mbp of DNA, and almost 11,000 genes. The most important eukaryotic parasite is *Plasmodium*, which causes malaria (► Section 17.5). The four species of *Plasmodium* that infect humans have genomes ranging from 23 to 27 Mbp, comprising 14 chromosomes with around 5500 genes. About half of these genes have introns and about a third encode conserved hypothetical proteins of unknown function. The free-living social amoeba *Dictyostelium* has about 12,500 genes (but note that *Dictyostelium* has both single-celled and multicellular phases in its life cycle, ► Section 17.8), and the pathogenic amoeba, *Entamoeba histolytica*, the causative agent of amebic dysentery, has approximately 10,000 genes.

Table 6.5 Some eukaryotic nuclear genomes^a

Organism	Comments	Lifestyle ^b	Genome size (Mbp)	Haploid chromosomes	ORFs
Nucleomorph of <i>Bigelowiella natans</i>	Degenerate endosymbiotic nucleus	E	0.37	3	331

^aAll data are for the haploid nuclear genomes of these organisms in megabase pairs. For most large genomes, both size and ORFs listed are best estimates due to large numbers of repetitive sequences and/or introns in the genomes.

^bE, endosymbiont; P, parasite; FL, free-living.

The smallest eukaryotic cellular genome known belongs to *Encephalitozoon cuniculi*, an intracellular pathogen of humans and other animals that causes lung infections. *E. cuniculi* lacks mitochondria, and although its haploid genome contains 11 chromosomes, the genome size is only 2.9 Mbp with approximately 2000 genes (Table 6.5); this is smaller than many prokaryotic genomes (Table 6.1). As for prokaryotes, the smallest eukaryotic genome belongs to an endosymbiont. Known as a *nucleomorph*, this is the degenerate remains of a eukaryotic endosymbiont found in certain green algae that have acquired photosynthesis by secondary endosymbiosis (Section 17.1). Nucleomorph genomes range from about 0.45 to 0.85 Mbp.

The Yeast Genome

Of single-celled eukaryotes, the yeast *Saccharomyces cerevisiae* is most widely used as a model organism and is also extensively used in both baking and brewing. The haploid yeast genome contains 16 chromosomes ranging in size from 220 kbp to 2352 kbp. The total yeast nuclear genome (excluding the mitochondria and some plasmid and virus-like genetic elements) is 13,400 kbp. Yeast chromosome XII contains a stretch of approximately 1260 kbp containing 100–200 repeats of yeast rRNA genes. In addition to multiple copies of the rRNA genes, the yeast nuclear genome has approximately 300 genes for tRNAs (only a few are identical) and nearly 100 genes for other types of noncoding RNA. Yeast has approximately 6000 ORFs, which is fewer than that of some genomes of *Bacteria* (Tables 6.1 and 6.5). About two-thirds of the yeast ORFs encode proteins whose functions are known.

How many yeast genes are actually essential? This question can be tackled by systematically inactivating each gene in turn with *knockout mutations* (mutations that completely inactivate genes, Section 11.5). Knockout mutations cannot normally be obtained in essential genes in a haploid organism. However, yeast can be grown in both diploid and haploid states (Section 17.13). By generating knockout mutations in diploid cells and then investigating whether they can also exist in haploid cells, it is possible to determine whether a particular gene is essential for cell viability. Using knockout mutations, it has been shown that around 900 yeast ORFs (17%) are essential. Note that this number of essential genes is much greater than the approximately 300 genes (Section 6.4) estimated to be the minimal number required in prokaryotes. Because eukaryotes are more complex than prokaryotes, a larger minimal gene complement would be expected.

III • Functional Genomics

Despite the major effort required to generate an annotated genome sequence, the net result is simply a “list of parts.” To understand how a cell functions, we need to know more than which genes are present. We must also investigate both gene expression (transcription) and the function of the final gene product. In analogy to the term “genome,” the entire complement of RNA produced under a given set of conditions is known as the **transcriptome**. Similar terminology is applied to the products

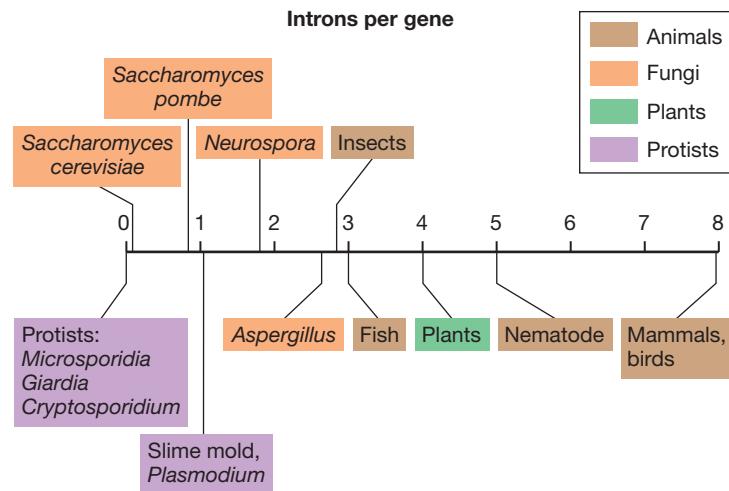

Figure 6.16 Intron frequency in different eukaryotes. The average number of introns per gene is shown for a range of eukaryotic organisms.

Being a eukaryote, the yeast genome contains introns (Section 4.9). However, the total number of introns in the protein-encoding genes of yeast is a mere 225. Most yeast genes with introns have only a single small intron near the 5' end of the gene. This situation differs greatly from that seen in more complex eukaryotes (Figure 6.16). For example, in the worm *Caenorhabditis elegans*, the average gene has five introns, and in the fruit fly *Drosophila*, the average gene has four. Introns are also common in the genes of plants, averaging around four per gene. The model higher plant *Arabidopsis* averages five introns per gene, and over 75% of *Arabidopsis* genes have introns. In humans almost all protein-encoding genes have introns, and it is common for a single gene to have 10 or more. Moreover, human introns are typically much longer than human exons, the DNA that actually encodes proteins. Indeed, exons make up only about 1% of the human genome, whereas introns account for 24%.

MINIQUIZ

- What is the size range of eukaryotic genomes?
- How does this compare with that of prokaryotes?
- How can you show whether a gene is essential?
- What is unusual about the genome of the eukaryote *Encephalitozoon*?

of translation, metabolism, and other related areas by adding the suffix “omic.” Table 6.6 summarizes the “omics” terminology used in this chapter.

6.7 Microarrays and the Transcriptome

Transcriptomics refers to the global study of transcription and is done by monitoring the total RNA generated under chosen

Table 6.6 Omics terminology

DNA	Genome the total complement of genetic information of a cell or a virus Metagenome the total genetic complement of all the cells present in a particular environment Epigenome the total number of possible epigenetic changes Methylome the total number of methylated sites on the DNA (whether epigenetic or not)
RNA	Transcriptome the total RNA produced in an organism under a specific set of conditions
Protein	Proteome the total set of proteins encoded by a genome Translatome the total set of proteins present under specified conditions Interactome the total set of interactions between proteins (or other macromolecules)
Metabolites	Metabolome the total complement of small molecules and metabolic intermediates Glycome the total complement of sugars and other carbohydrates
Organisms	Microbiome the total complement of microorganisms in an environment (including those associated with a higher organism) Virome the total complement of viruses in an environment Mycobiome the total complement of fungi in a natural environment

growth conditions. In the case of genes whose role is still unknown, discovering the conditions under which they are transcribed may yield clues to their function. Two main approaches are used: microarrays, which depend on RNA–DNA hybridization, and RNA-Seq, which depends on second-generation (or later) sequencing.

Microarrays and the DNA Chip

Microarrays are small solid supports to which genes or, more often, segments of genes are fixed and arrayed spatially in a known pattern; they are often called **gene chips** (Figure 6.17). Microarray technology requires RNA–DNA hybridization. When DNA is denatured (that is, the two strands are separated), the single strands can form hybrid double-stranded molecules with other single-stranded DNA or RNA molecules by complementary or almost complementary base pairing (☞ Section 11.2). This process is called *nucleic acid hybridization*, or **hybridization** for short, and is widely used in detecting, characterizing, and identifying segments of DNA or RNA. Segments of single-stranded nucleic acids whose identity is already known and that are used in hybridization are called **nucleic acid probes** or, simply, probes. To allow detection, probes are made radioactive or labeled with fluorescent dyes. By varying the conditions, it is possible to adjust the “stringency” of the hybridization such that complementary base pairing must be exact, or nearly so; this helps to avoid nonspecific pairing between sequences that are only partly complementary.

In a microarray, the gene segments may be synthesized by the polymerase chain reaction (PCR, ☞ Section 11.3), or alternatively, oligonucleotides are designed and synthesized for each gene based on the genomic sequence. Once attached to the solid support, the DNA segments can be hybridized with RNA from

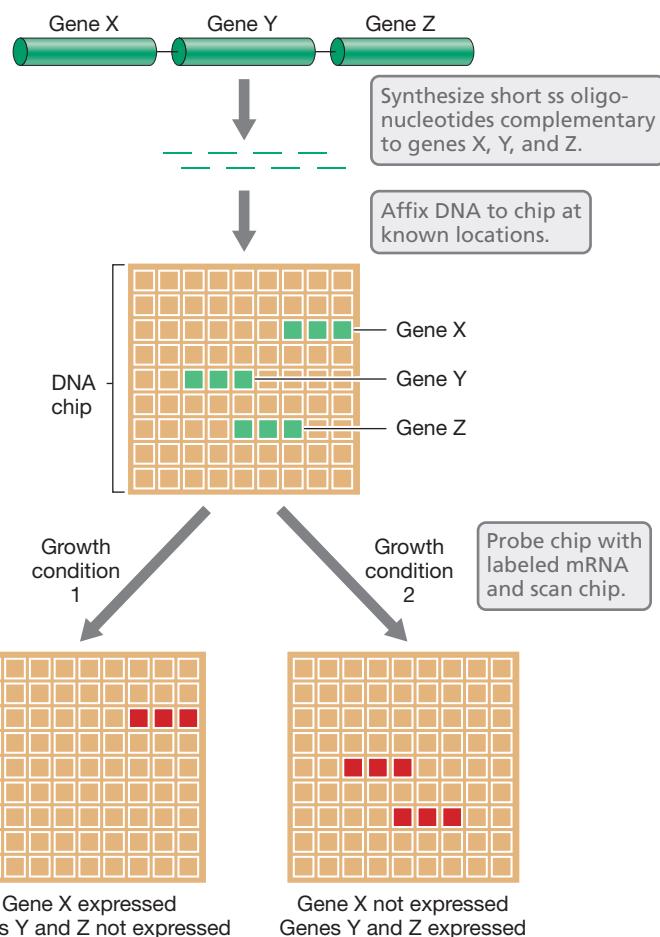

Figure 6.17 Making and using microarrays. Short single-stranded oligonucleotides corresponding to each gene in an organism are synthesized and affixed at known locations to make a microarray. The chip is assayed by hybridizing fluorescently labeled mRNA obtained from cells grown under a specific condition to the DNA probes on the chip and then scanning the chip with a laser.

cells grown under specific conditions and scanned and analyzed by computer. Hybridization between a specific RNA and a DNA segment on the chip indicates that the gene has been transcribed (Figure 6.17; see also Figure 6.18b). When studying protein-encoding genes, messenger RNA must be measured. In practice, mRNA is present at levels too low for direct use. Consequently, the mRNA sequences must first be amplified. This is done by using a modified version of PCR after converting the RNA to the *complementary DNA* (cDNA, ☞ Section 11.3).

Photolithography, a process used to produce computer chips, is also used to produce microarray chips. Chips are typically about 1 to 2 cm and are inserted into a plastic holder that can easily be manipulated (Figure 6.18a); each chip can hold thousands of different DNA fragments. In practice, each gene is usually represented more than once in the array to increase reliability. Whole genome arrays contain DNA segments that cover the entire genome of an organism. For example, a chip that covers the entire human genome (Figure 6.18a) can analyze over 47,000 human transcripts and has room for 6500 additional oligonucleotides for use in clinical diagnostics.

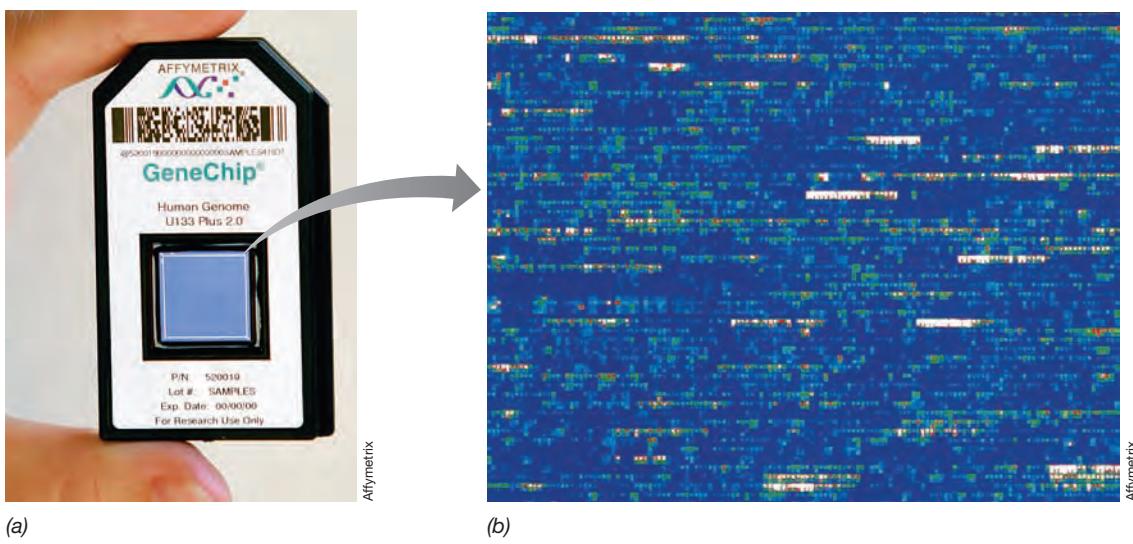

Figure 6.18 Using gene chips to assay gene expression. (a) The human genome chip contains over 40,000 gene fragments. Blowup from part a to part b indicates location of actual microarray. (b) A hybridized yeast chip shows fragments from a quarter of the genome of the baker's yeast, *Saccharomyces cerevisiae*. Each gene is present in several copies and has been probed with fluorescently labeled cDNA (derived from mRNA) from yeast cells grown under a specific condition. The background of the chip is blue. Locations where the cDNA has hybridized are indicated by a gradation of colors up to a maximum number of hybridizations, which shows as white. Because the location of each gene on the chip is known, when the chip is scanned, it reveals which genes were expressed.

Applications of Gene Chips: Gene Expression

Gene chips may be used in several ways depending on the genes affixed to the chip. Global gene expression is monitored by assembling an array of oligonucleotides complementary to each gene in the genome and then using the entire population of mRNA as the test sample. Figure 6.18b shows part of a chip used to assay gene expression in *Saccharomyces cerevisiae*. This chip easily holds the 6000 protein-encoding genes of *S. cerevisiae* (Table 6.5) such that global gene expression in this organism can be measured in a single experiment. To do this, the chip is hybridized with cRNA or cDNA derived from mRNA obtained from yeast cells grown under specific conditions. To visualize binding, the nucleic acids are tagged with a fluorescent dye, and the chip is scanned with a laser fluorescence detector. A distinct hybridization pattern is observed, depending upon which DNA sequences correspond to which mRNAs (Figure 6.18b). The fluorescence intensity measures gene expression in a quantitative manner that allows the computer to list which genes were expressed and at what level. This reveals the *transcriptome* of the target organism grown under specified conditions (Table 6.6).

The *S. cerevisiae* gene chip has been used to study metabolic control in this important industrial organism. Yeast can grow by fermentation or by respiration. Transcriptome analysis reveals which genes are shut down and which are turned on when yeast cells are switched from fermentative (anaerobic) to respiratory (aerobic) metabolism or vice versa. Such experiments show that yeast undergoes a major metabolic “reprogramming” during the switch from anaerobic to aerobic growth. Genes that control production of ethanol (a key fermentation product) are strongly repressed, whereas citric acid cycle functions (needed for aerobic growth) are strongly activated. Overall, over 700 genes are turned on and over 1000 turned off during this metabolic transition. Moreover, by using a microarray, the expression pattern of genes of unknown function is also revealed, yielding clues to their possible role.

Applications in Identification

Microarrays can also be used to identify microorganisms. In this case the array contains a set of characteristic DNA sequences

from each of a variety of organisms or viruses. Such an approach can be used to differentiate between different species or even closely related strains of the same species by differences in their hybridization patterns. This allows very rapid identification of pathogenic viruses or bacteria from clinical samples or detection of these organisms in other substances, such as food. For example, identification (ID) chips have been used in the food industry to detect specific pathogens, such as *Escherichia coli* O157:H7. A related use of DNA microarrays is to compare genes in closely related organisms. This can reveal how pathogenic bacteria may have evolved from their nonpathogenic relatives.

In environmental work, microarrays called *phylochips* have been used to assess microbial diversity. These contain oligonucleotides complementary to the 16S rRNA of different bacterial species, a molecule widely used in prokaryotic systematics (Chapter 12). After extracting bulk DNA or RNA from an environment, the presence or absence of each species can be assessed by the hybridization response on the chip (Section 18.6).

DNA chips can also be designed to identify higher organisms. A commercial chip, called the *FoodExpert-ID*, contains 88,000 gene segments from vertebrates and is used in the food industry to monitor food purity. This chip can confirm that the meat listed on a food label is as advertised, and can also detect foreign animal meats that may have been added as supplements to or substitutes for the stated ingredients. The *FoodExpert-ID* can also be used to detect vertebrate by-products in animal feed, a growing concern with the advent of prion-mediated infections such as mad cow disease (Section 9.13).

RNA-Seq Analysis

RNA-Seq analysis is a method in which all the RNA molecules from a cell are sequenced. Provided that the genome sequence is available for comparison, this will reveal not only which genes were transcribed but how many copies of each RNA were made. *RNA-Seq* is used both to measure expression of mRNA and to identify and characterize small noncoding RNAs. *RNA-Seq* requires high-throughput sequencing (second- or third-generation sequencing, Section 6.2) and is complicated by the fact that the

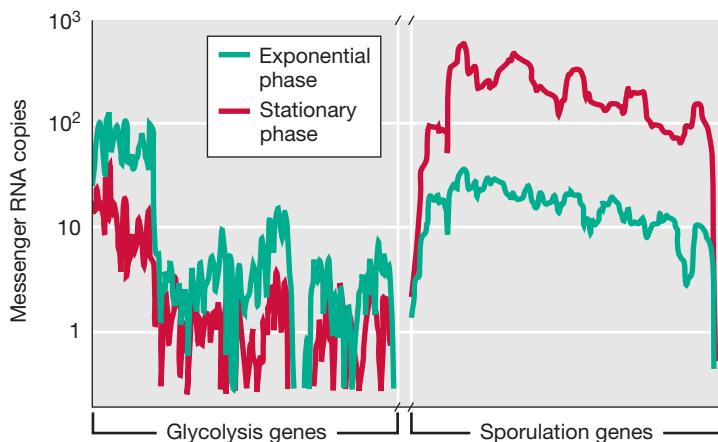

Figure 6.19 RNA-Seq analysis. The transcriptome of cultures of a *Clostridium* species grown for 4.5 h (cells in exponential phase) or 14 h (cells in stationary phase). Two genomic regions are shown: (1) ~5.4-kb segment surrounding the *gap-pgk-tpi* glycolytic operon, and (2) ~1.2-kb segment surrounding the *cotJC-cotJB* sporulation operon. Production of endospores is triggered by nutrient starvation (➡ Section 2.16). Data from Wang, Y., X. Li, Y. Mao, and H.P. Blaschek. 2011. Single-nucleotide resolution analysis of the transcriptome structure of *Clostridium beijerinckii* NCIMB 8052 using RNA-Seq. *BMC Genomics* 12: 479–489.

most abundant RNA in a cell is ribosomal RNA (rRNA). Nevertheless, methods are available to remove rRNA or enrich mRNA from a total RNA pool. In addition, recent improvements in sequencing technology may allow sequencing without needing to remove rRNA.

RNA-Seq is beginning to overtake microarray analysis as the method of choice for global studies of gene expression. For example, Figure 6.19 shows a comparison by RNA-Seq of cultures of a species of *Clostridium* in exponential and stationary phase. Clostridia are gram-positive rod-shaped bacteria that can produce endospores, the highly resistant and dormant stage of the cell's life cycle (➡ Section 2.16). As one might predict, transcription of genes of the glycolytic pathway (the major means by which the organism makes ATP) is elevated during exponential growth, whereas expression of sporulation genes increases in stationary phase, when nutrients become limiting. RNA-Seq is also being used for microbial community analysis and can provide information on relative transcription levels when a genome sequence is not available for comparison. In this case the sequences detected must be identified by homology with sequences present in data banks.

As we will see in Section 6.10, *metagenomics* is the genomic analysis of pooled DNA or RNA from an environment. Metagenomic analysis using RNA-Seq has been exploited for the laboratory culture of bacteria from natural samples that previously proved intractable to laboratory culture. This was done by using RNA-Seq to reveal which genes were being transcribed at high levels by a particular microbial community. Sequence analysis then identified the proteins corresponding to the most prevalent mRNAs. This allowed the researchers to deduce which nutrients the bacteria in the sample might be using given the most likely enzyme activities of these proteins. Culture media were then devised using this information as a guide and previously uncultured bacteria were successfully cultured.

MINIQUIZ

- Why is it useful to survey expression of the entire genome under particular conditions?
- What do microarrays tell you that studying gene expression by assaying individual enzymes cannot?
- What technological advances does RNA-Seq depend on?

6.8 Proteomics and the Interactome

The genome-wide study of the structure, function, and activity of an organism's *proteins* is called **proteomics**. The number and types of proteins present in a cell change in response to an organism's environment or other factors, such as developmental cycles. As a result, the term **proteome** has unfortunately become ambiguous. In its wider sense, a proteome refers to *all* the proteins encoded by an organism's genome. In its narrower sense, however, it refers to those proteins present in a cell *at any given time*. The term *translatome* is sometimes used for the latter situation, that is, to refer to every protein made under specific conditions.

Methods in Proteomics

The first major approach to proteomics began with the advent of two-dimensional (2D) polyacrylamide gel electrophoresis. This technique can separate, identify, and measure all the proteins present in a cell sample. A 2D gel separation of proteins from *Escherichia coli* is shown in Figure 6.20. In the first dimension (the horizontal dimension in Figure 6.20), the proteins are separated by differences in their isoelectric points, the pH at which the net charge on each protein reaches zero. In the second dimension, the proteins are denatured in a way that gives each amino acid residue a fixed charge. The proteins are then separated by size (in much the same way as for DNA molecules; ➡ Section 11.1).

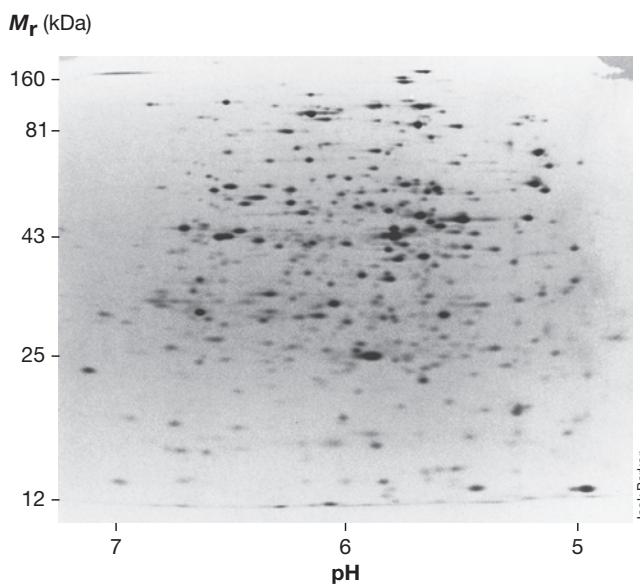

Figure 6.20 Two-dimensional polyacrylamide gel electrophoresis of proteins from *Escherichia coli*. Each spot on the gel is a different protein, radioactively labeled to allow for visualization and quantification. Denatured proteins were separated in the horizontal direction by isoelectric focusing and in the vertical direction by their mass (M_r ; in kilodaltons). The largest proteins are at the top of the gel.

In studies of *E. coli* and a few other organisms, hundreds of proteins separated in 2D gels have been identified by biochemical or genetic means, and their presence or absence has been studied under various growth conditions. Using 2D gels, the presence of a particular protein under different growth conditions can be measured and related to environmental conditions. One method of connecting an unknown protein with a particular gene using the 2D gel system is to elute the protein from the gel and sequence a portion of it, usually from its amino-terminal end. Alternatively, eluted proteins can be identified by a technique called *mass spectrometry* (Section 6.9), usually after preliminary digestion to give a characteristic set of peptides. The sequence information obtained by either technique may be sufficient to completely identify the protein. Alternatively, partial sequence data may allow the design of oligonucleotide probes or primers to locate the gene encoding the protein from genomic DNA by hybridization or PCR. Then, after sequencing of the DNA, the gene may be identified.

Today, liquid chromatography is increasingly used to separate protein mixtures. In high-pressure liquid chromatography (HPLC), the sample is dissolved in a suitable liquid and forced under pressure through a column packed with a stationary phase material that separates proteins by variations in their chemical properties, such as size, ionic charge, or hydrophobicity. As the mixture travels through the column, it is separated by interaction of the proteins with the stationary phase. Fractions are collected at the column exit. The proteins in each fraction are digested by proteases and the peptides identified by mass spectrometry.

Comparative Genomics and Proteomics

Although proteomics often requires intensive experimentation, computational techniques can also help. Once the sequence of an organism's genome is obtained, it can be compared to that of other organisms to find genes that are similar to those already known. The sequence that is most important here is the *amino acid sequence* of the encoded proteins. Because the genetic code is degenerate (see Section 4.11), differences in DNA sequence may not necessarily lead to differences in the amino acid sequence.

Proteins with greater than 50% sequence identity frequently have similar functions. Proteins with identities above 70% almost certainly have similar functions. Many proteins consist of distinct structural modules, called *protein domains*, each with characteristic functions. Such regions include metal-binding domains, nucleotide-binding domains, or domains for certain classes of enzyme activity, such as helicase or dehydrogenase. Identification of domains of known function in a protein may reveal much about its role, even in the absence of complete sequence homology. For example, many proteins contain the metal zinc as a cofactor. These are sometimes found at the active site of enzymes or in DNA-binding domains. **Figure 6.21** shows the distribution of zinc-containing proteins among prokaryotes and eukaryotes. Whereas both groups synthesize many zinc-containing enzymes, the use of zinc-containing transcription factors is predominantly a eukaryotic trait.

Structural proteomics refers to the proteome-wide determination of the three-dimensional (3D) structures of proteins. At

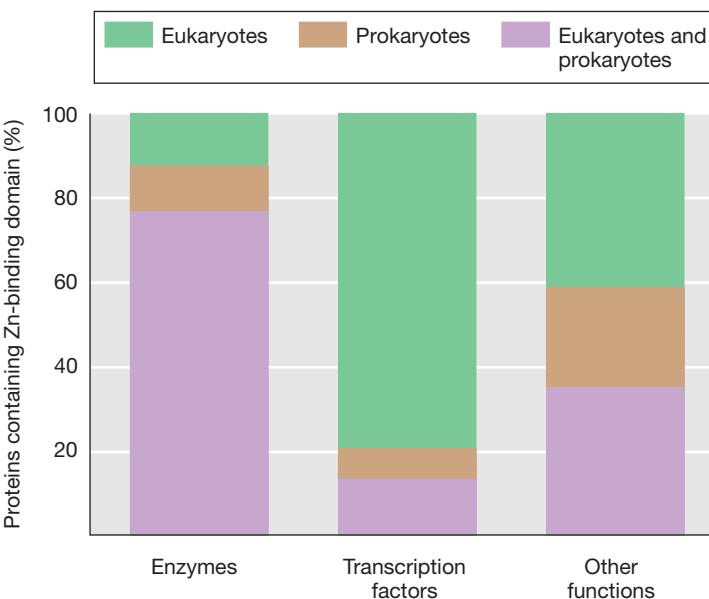

Figure 6.21 Comparative proteomics. The sequences of proteins containing zinc-binding-sequence domains from 40 *Bacteria*, 12 *Archaea*, and 5 eukaryotes were compared by functional category. Zinc-containing proteins comprise 5–6% of the total proteins in prokaryotes and 8–9% in eukaryotes and many are enzymes. Eukaryotes also contain many unique zinc-containing transcription factors.

present, it is not possible to predict the 3D structure of proteins directly from their amino acid sequences. However, structures of unknown proteins can often be modeled if the 3D structure is available for a protein with 30% or greater identity in amino acid sequence.

Coupling proteomics with genomics has yielded important clues about how gene expression in different organisms correlates with environmental stimuli. Not only does such information have important basic science benefits, but it also has potential applications. These include advances in medicine, environmental protection, and agriculture. In all of these areas, understanding the link between the genome and the proteome and how it is regulated can help in fighting disease and pollution as well as yield major benefits for agricultural productivity.

The Interactome

By analogy with the terms “genome” and “proteome,” the **interactome** is the complete set of *interactions* among the macromolecules within a cell (Figure 6.22). Originally, the term interactome applied to the interactions between proteins, many of which assemble into complexes. However, it is also possible to consider interactions between different classes of macromolecules, such as the protein–RNA interactome.

Interactome data are typically expressed in the form of network diagrams, with each node representing a protein and connecting lines representing the interactions. Diagrams of whole interactomes can be extremely complex and thus more focused interactomes, such as the motility protein network from the bacterium *Campylobacter jejuni* (Figure 6.22), are more instructive. This figure shows the core interactions between well-known components of the chemotaxis system (see Sections 2.19 and 7.8), including all other proteins that interact with these.

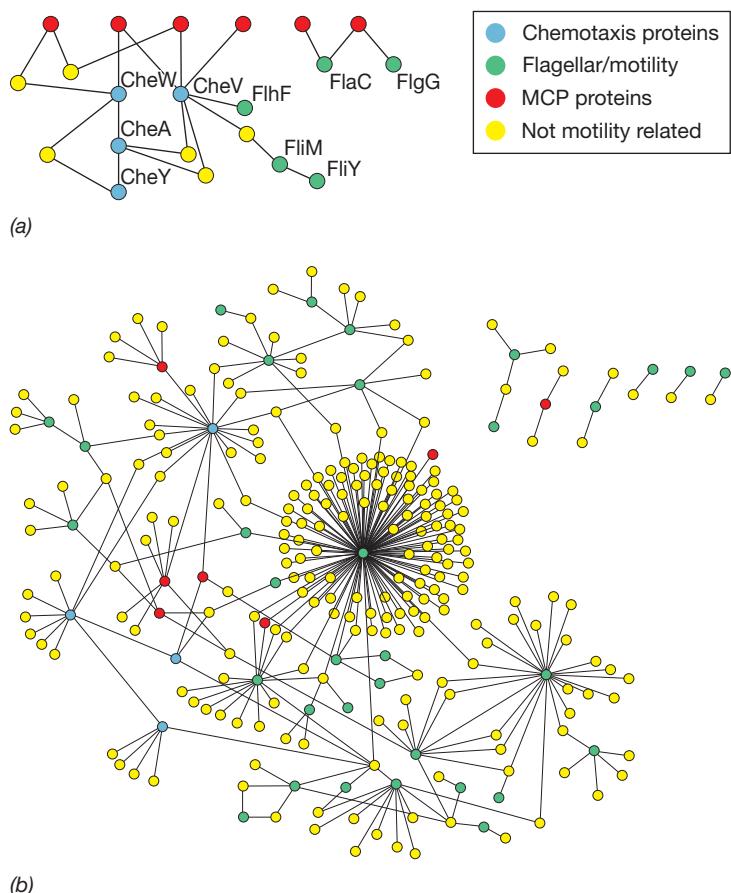

Figure 6.22 Motility protein interactome for *Campylobacter jejuni*. This network illustrates the way in which interactome data are depicted. (a) A subsection of the network highlighting the well-known proteins of the chemotaxis signal transduction pathway (CheW, CheA, and CheY) and their partners. MCP, methyl-accepting chemotaxis proteins (Section 7.8). (b) High-confidence interactions between all proteins known to have roles in motility. Note the six small networks that fall outside the single large network.

MINIQUIZ

- Why is the term “proteome” ambiguous, whereas the term “genome” is not?
- What are the most common experimental methods used to survey the proteome?
- What is the interactome?

6.9 Metabolomics and Systems Biology

The **metabolome** is the complete set of *metabolic intermediates* and other small molecules produced in an organism. Metabolomics has lagged behind other “omics” largely due to the immense chemical diversity of small metabolites that can be present in cells. This makes systematic screening technically challenging. Early attempts used nuclear magnetic resonance (NMR) analysis of extracts from cells labeled with ^{13}C -glucose (^{13}C is a heavy isotope of carbon, most of which is ^{12}C). However, this method is limited in sensitivity, and the number of compounds that can be simultaneously identified in a mixture is too low for resolution of complete cell extracts.

New Mass Spectrometry Techniques: MALDI-TOF

The most promising approach to metabolomics is the use of newly developed methods of mass spectrometry. This approach is not limited to particular classes of molecules and can be extremely sensitive. The mass of ^{12}C is defined as exactly 12 molecular mass units (daltons). However, the masses of other atoms, such as ^{14}N or ^{16}O , are not exact integers. Mass spectrometry using extremely high mass resolution allows the unambiguous determination of the molecular formula of any small molecule. Clearly, isomers will have the same molecular formula, but they can be distinguished by their different fragmentation patterns during mass spectrometry. The same approach is used to identify the peptide fragments from digested proteins during proteome analyses (Section 6.8). In this case, identifying several oligopeptides allows the identity of the parent protein to be deduced provided that its amino acid sequence is known.

In the MALDI (matrix-assisted laser desorption ionization) version of mass spectrometry, the sample is ionized and vaporized by a laser (Figure 6.23). The ions generated are accelerated along the column toward the detector by an electric field. The time of flight (TOF) for each ion depends on its mass/charge ratio—the smaller this ratio, the faster the ion moves. The detector measures the TOF for each ion and the computer calculates the mass and hence the molecular formula. The combination of these two techniques is known as *MALDI-TOF*.

Metabolome analysis is especially useful for the study of plant biochemistry, since plants produce several thousand different metabolites—more than for most other types of organism. These include many so-called *secondary metabolites*, chemicals such as scents, flavors, alkaloids, and pigments, many of which are commercially important. Metabolomic investigations have monitored the levels of several hundred metabolites in the model plant *Arabidopsis*, and significant changes were observed in the levels of many of these metabolites in response to changes in temperature. Future directions for metabolomics include assessing the effect of disease on the metabolome of various human organs and tissues. Such results may greatly improve our understanding of how the human body combats infectious and noninfectious disease and identify key compounds important in host defenses. Such compounds could possibly be developed as drugs for clinical treatment of particular diseases.

Systems Biology

The term **systems biology** has been widely used in recent years to refer to the integration of different fields of research to give an overview of an organism or cell or even entire species or ecosystems. Systems biology integrates all of the “omics” we have studied here: genomics, transcriptomics, proteomics, metabolomics, and so on (Figure 6.24). The ability to store and analyze large amounts of biological information by computer is essential to systems biology, and the understanding of entire biological systems is evolving in parallel with computer power and storage capabilities.

The basic strategy of systems biology is to compile a series of “omics” data and then build a computational model of the system under study (Figure 6.24). Such models may allow for the prediction of behavior or properties of a particular organism that were not

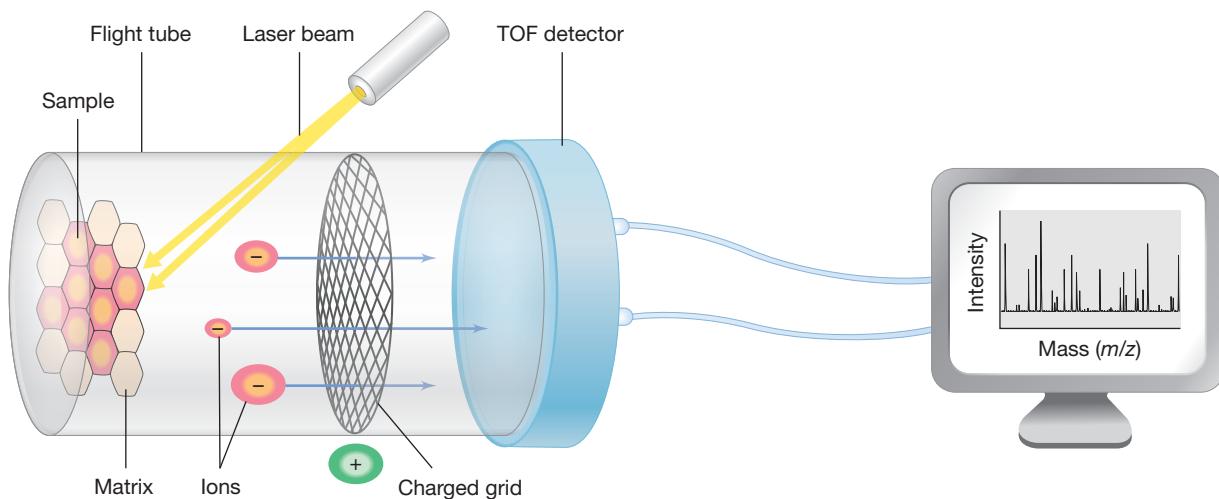

Figure 6.23 MALDI-TOF mass spectrometry. In matrix-assisted laser desorption ionization (MALDI) spectroscopy, the sample is ionized by a laser and the ions travel down the tube to the detector. The time of flight (TOF) depends on the mass/charge (m/z) ratio of the ion. The computer identifies the ions based on their time of flight; that is, the time it takes to reach the detector. MALDI-TOF has extremely high sensitivity and resolution.

obvious from the original observations. These are referred to as the *emergent properties* of an organism. It is predicted that an understanding of the emergent properties of an organism will provide much deeper insight into the overall biology of that organism than can any single “omics” study by itself.

MINIQUIZ

- What techniques are used to monitor the metabolome?
- What is a secondary metabolite?
- Why does systems biology depend on computing power? What is an “emergent property”?

6.10 Metagenomics

Microbial communities contain many species of *Bacteria* and *Archaea*, most of which have never been cultured or formally identified. **Metagenomics**, also called *environmental genomics*, analyzes pooled DNA or RNA from an environmental sample containing organisms that have not been isolated and identified. Just as the total gene content of an organism is its genome, so the

total gene content of the organisms inhabiting an environment is known as its **metagenome** (Table 6.6). In addition to metagenome analyses based on DNA sequencing, analyses based on RNA or proteins may be used to explore the patterns of gene expression in natural microbial communities. With today’s technology, these studies can even be done on individual cells (see Explore the Microbial World, “Genomics, One Cell at a Time”). Single-cell genomics is discussed further in Chapter 18.

Examples of Metagenomic Studies

Several environments have been surveyed by large-scale metagenomic sequencing projects. Extreme environments, such as acidic runoff waters from mines, tend to have low species diversity. Consequently it has been possible to isolate community DNA and assemble much of it into nearly complete individual genomes. Conversely, complex environments such as fertile soils or aquatic environments are much more challenging, and complete genome assemblies here are much more difficult. Nonetheless, a surprising finding that has emerged from metagenomic studies thus far is that most genes in the environment belong not to cellular organisms but to viruses. This is discussed further in Chapter 9 where we consider the genomics and phylogeny of viruses.

Even if complete genomes cannot be assembled, much useful information can be derived from metagenomic surveys. For example, environments can be analyzed for the presence and distribution of different taxonomic groups of bacteria. These vary greatly in relative abundance in different environments and Figure 6.25 illustrates this for major subgroups of *Proteobacteria* (Chapter 15) at a sampling site close to Hawaii in the Pacific Ocean. Light, oxygen, nutrients, and temperature all change with depth, and these factors can be correlated with which proteobacterial subgroups are most competitive at each depth (Figure 6.25). One curious observation that has emerged from such metagenomic studies is that much cellular DNA in natural habitats does not belong to living cells. For example, about 50–60% of the DNA in the oceans is extracellular DNA found in deep-sea sediments. Presumably this is DNA deposited when dead organisms from the upper layers of the ocean sink to the bottom and eventually lyse. Because nucleic acids are major repositories of phosphate, this DNA is a major contributor to the global phosphorus cycle.

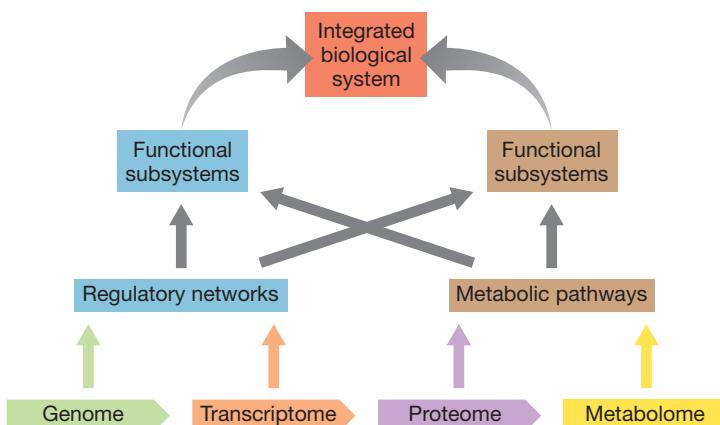

Figure 6.24 The components of systems biology. The results of various “omics” analyses are combined and successively integrated into higher-level views of the entire biology of an organism.

EXPLORE THE MICROBIAL WORLD

Genomics, One Cell at a Time

Modern genome analysis has been driven by scaling up the number of samples run simultaneously and also by scaling down the sample size. The reduction in sample size needed to do genomics has led to the capability of analyzing even single cells—a technique called *single-cell genomics*—and some amazing results have emerged.

Single cells can be isolated by using various physical techniques and then subjected to genomics procedures (Figure 1). Genome sequencing and transcriptome and proteome analyses have all been performed with single bacterial cells. Sequencing DNA from single cells relies on a highly modified version of PCR known as *multiple displacement amplification* (MDA) (Section 18.11 and Figure 18.32). This technique amplifies the femtogram (10^{-15} g) quantities of DNA present in a single bacterial cell into the micrograms of DNA required for sequencing (a billionfold amplification). Likewise, RNA can be analyzed by RNA-Seq or following amplification by a modified version of PCR. Single-cell proteomic analyses are more tricky, but analyses that employ very sensitive fluorescence methods are available for this purpose.

Single cells have been isolated from soil and various other habitats and their DNA sequenced. Using single-cell genomics, metabolic genes present in an environment can be not only identified but actually assigned to particular species. Thus, single-cell genomics can reveal which organisms in a microbial community are degrading which nutrients. For example, single-cell genomics has been used to analyze hydrocarbon degradation by bacteria in polluted environments, leading to a better understanding of which organisms are

doing what in the overall process. Similarly, plasmids and viruses can be allocated to their correct host when a single cell is sequenced.

A surprising finding in single-cell studies has been that protein and transcript levels vary greatly from cell to cell in an actively growing pure culture of a bacterium, presumably as a result of transcription and translation occurring in bursts, rather than smoothly. This is especially true for proteins expressed at low levels. Consequently and counterintuitively, for individual genes in a single cell there is little correlation between copy numbers of an mRNA and its corresponding protein at any given time point. This is partly due to the difference in the average lifetime of protein and mRNA molecules. Whereas most proteins survive longer than a cell generation, mRNA in bacteria is generally degraded within two or three minutes of its synthesis. Thus, mRNA levels at any given time are determined by the transcription rate in the preceding few minutes, whereas protein levels reflect synthesis over the course of an hour or so.

Single-cell genomics has a bright future for probing many important facets of an organism's biology on an individual cell rather than a cell population basis. The method has already challenged previous assumptions about the biochemical uniformity of cells in exponential-phase cultures, and it is likely that many other questions will emerge for which single-cell omics technologies will be ideally suited to yield answers not obtainable with mass cultures. Single-cell genomics is also an excellent example of how scientific methods designed with one goal in mind (that is, the genomic analysis of a population of cells) can be modified by creative scientists to ask scientific questions never before thought possible.

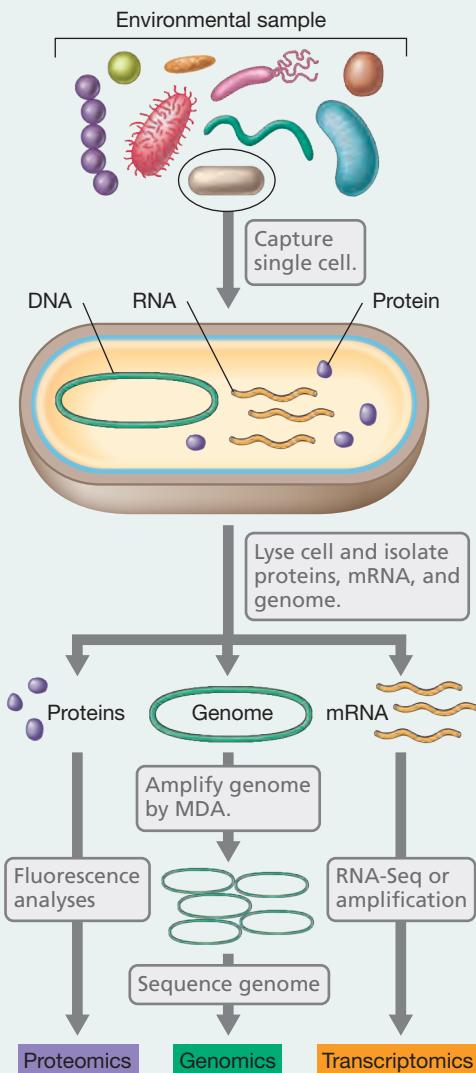

Figure 1 Single-cell genomics. A single cell isolated from an environmental sample can be the source of a diversified “omics” study.

Metagenomics and “Biome” Studies

The human body is estimated to contain about 10 trillion (10^{13}) cells, but each of us also carries around ten times more prokaryotic cells than human ones. This collection of prokaryotic cells is called the human *microbiome*. Most of these prokaryotes inhabit the gut and the majority belong to two bacterial groups, the *Bacteroidetes* and the *Firmicutes* (Chapter 15). A fascinating finding is that the composition of the gut microbiome correlates with obesity in both humans and experimental mouse models. The higher the proportion of *Firmicutes* (mostly *Clostridium* and relatives),

the fatter the human or mouse. A suggested mechanism is that species of *Firmicutes* convert more dietary fiber into short-chain fatty acids that can be absorbed by the host. Hence, the host gets more fat from the same amount of food. Moreover, although an important model organism in biology, the bacterium *Escherichia coli* comprises only about 1% of the total gut bacterial population.

Recent surveys of the human and mouse gut microbiome have also revealed several species of fungi (Figure 6.26), previously undetected; these make up what is called the *mycobiome* (the prefix “myco” means “fungal”). Many of these are common yeasts, such as

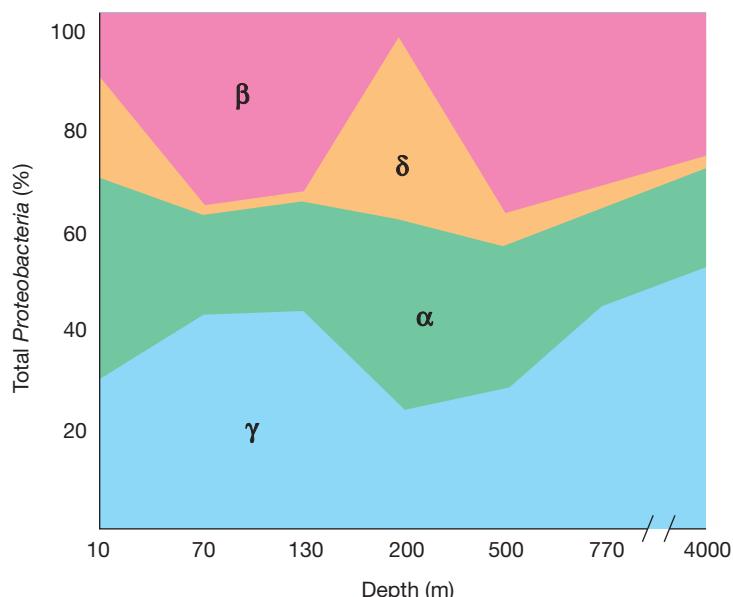

Figure 6.25 Metagenomics of *Proteobacteria* in the ocean. The distribution with depth of the major subgroups (alpha α , beta β , gamma γ , and delta δ) of *Proteobacteria* in the Pacific Ocean is shown. Many other types of bacteria are also present (not shown). Data adapted from Kembel, S.W., J.A. Eisen, K.S. Pollard, and J.L. Green. 2011. *PLoS One* 6: e23214.

Saccharomyces and *Candida*, although some of the gut fungi detected, such as *Aspergillus* and *Trichosporon*, are potential serious pathogens (Figure 6.26). Moreover, although gut fungi constitute less than 1% of the microbiome, it is known that certain conditions such as inflammatory bowel disease correlate strongly

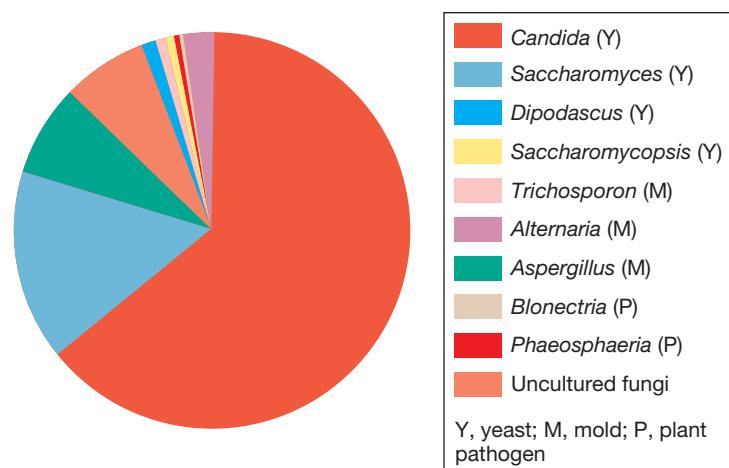

Figure 6.26 The mouse mycobiome. The data shown are for the fungal population of the mouse intestine. The pie chart shows the most common fungi present are yeasts. M, mold; Y, yeast; P, plant pathogen. Data adapted from Iliev, I.D., et al. *Science* 336: 1314–1317 (2012).

with specific fungal populations. Thus metagenomics holds great promise for probing possible connections between specific microbial populations and specific diseases in humans and other animals.

MINIQUIZ

- What is a metagenome?
- How is a metagenome analyzed?
- How do the human microbiome and mycobiome differ?

IV • The Evolution of Genomes

In addition to revealing how genes function and how organisms interact with the environment, comparative genomics can illuminate evolutionary relationships between organisms. Reconstructing evolutionary trees from genome sequences helps to distinguish between primitive and derived characteristics and can resolve ambiguities in phylogenetic trees based on analyses of a single gene, such as an rRNA gene (☞ Section 12.4). Genomics is also a link to understanding early life forms and may eventually help answer the most fundamental of all questions in biology: How did life originate?

6.11 Gene Families, Duplications, and Deletions

Genomes from both prokaryotic and eukaryotic sources often contain multiple copies of genes that are related in sequence due to shared evolutionary ancestry; such genes are called *homologous genes*, or **homologs**. Groups of gene homologs are called **gene families**. Not surprisingly, larger genomes tend to contain more individual members from a particular gene family.

Paralogs and Orthologs

Comparative genomics shows that many genes have arisen by *duplication* of other genes. Such homologs may be subdivided, depending on their origins. Genes whose similarity is the result of gene duplication at some time in the evolution of an organism are called **paralogs**. Genes found in one organism that are similar to genes in another organism because of descent from a common ancestor are called **orthologs** (Figure 6.27). Orthologs are often not identical because of divergent evolution in lineages following speciation. An example of paralogous genes are those encoding several variant lactate dehydrogenase (LDH) enzymes in humans. These variants, called *isoenzymes*, are structurally distinct yet all highly related and carry out the same enzymatic reaction. By contrast, the corresponding LDH from the lactic acid bacterium, *Lactobacillus*, is orthologous to all of the human LDH isoenzymes. Thus, gene families contain both paralogs and orthologs.

Gene Duplication

It is widely thought that gene duplication is the mechanism by which most new genes evolve. If a segment of duplicated DNA

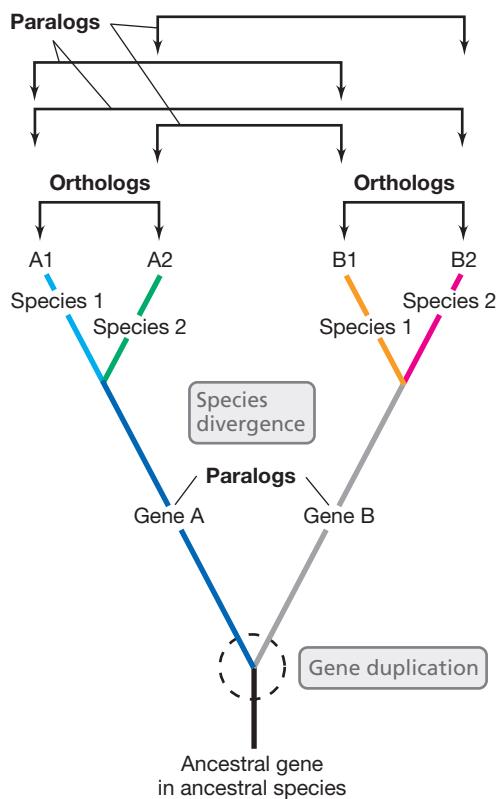

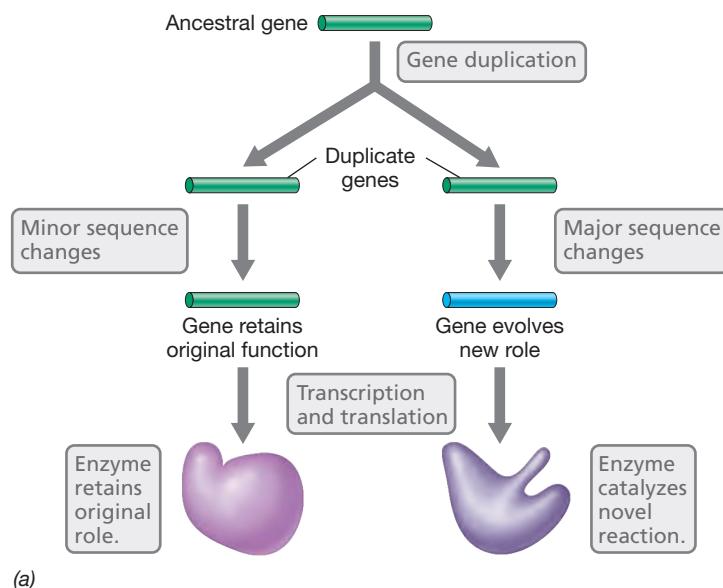

Figure 6.27 Orthologs and paralogs. This family tree depicts an ancestral gene that duplicated and diverged into two paralogous genes, A and B. Later, the ancestral species diverged into species 1 and species 2, both of which have genes for A and B (designated A1 and B1 and A2 and B2, respectively). Each such pair are paralogs. However, because species 1 and 2 are now separate species, A1 is an ortholog of A2 and B1 is an ortholog of B2.

is long enough to include an entire gene or group of genes, the organism with the duplication has multiple copies of these particular genes. After duplication, one of the duplicates is free to evolve while the other copy continues to supply the cell with the original function (Figure 6.28a). In this way, evolution can “experiment” with one copy of the gene. Such gene duplication events, followed by diversification of one copy, are thought to be the major events that fuel microbial evolution. Genomic analyses have revealed many examples of protein-encoding genes that were clearly derived from gene duplication. Figure 6.28b shows this for the enzyme RubisCO, a key enzyme of autotrophic metabolism (Section 13.5). Here an ancestral gene gave rise to enzymes with different related catalytic activities.

Duplications of genetic material may include just a handful of bases or even whole genomes. For example, comparison of the genomes of the yeast *Saccharomyces cerevisiae* and other fungi suggests that the ancestor of *Saccharomyces* duplicated its entire genome. This was followed by extensive deletions that eliminated much of the duplicated genetic material. Analysis of the genome of the model plant *Arabidopsis* suggests that there were one or more whole genome duplications in the ancestor of the flowering plants, as well.

Did bacterial genomes evolve by whole genome duplication? The distribution of duplicated genes and gene families in the genomes of bacteria suggests that many frequent but relatively small duplications have occurred. For example, the soil bacterium *Myxococcus* has a genome of 9.1 Mbp. This is approximately twice that of the genomes of its close relatives. Among a group of gram-negative bacteria called the *Alphaproteobacteria*, genome sizes range from 1.1–1.5 Mbp for parasitic species to 4 Mbp for free-living *Caulobacter*, and up to 7–9 Mbp for plant-associated bacteria

(a)

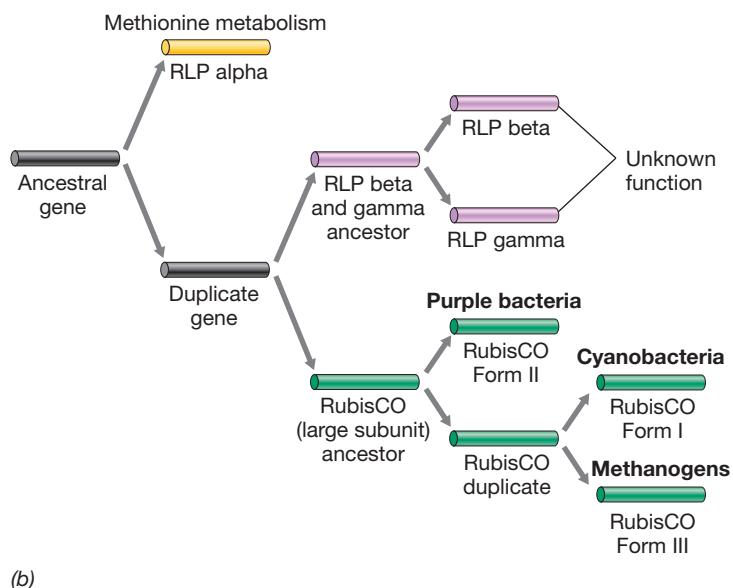

Figure 6.28 Evolution by gene duplication. (a) The principle of gene duplication. After duplication, the “spare” copy of a gene is free to evolve a new function. (b) The RubisCO (*rbcL*) family of genes. The large subunit of the enzyme RubisCO that fixes CO₂ during photosynthesis has split into three closely related forms (I, II, and III) that all retain the original function (green bars). However, RubisCO is in turn derived from an ancestral gene (black bars) of unknown function that divided to produce a gene encoding an enzyme in methionine metabolism (yellow bar) and several genes whose function is still unknown (purple bars). RLP, RubisCO-like protein.

such as *Rhizobium* (Table 6.1). However, in all of these cases gene distribution analysis points to frequent small-scale gene duplications rather than entire genome duplications. Conversely, in bacteria that are parasitic, frequent successive deletions have eliminated genes no longer needed for a parasitic lifestyle, leading to their unusually small genomes (Section 6.4, Table 6.1, and Figures 6.8 and 6.14).

Gene Analysis in Different Domains

The comparison of genes and gene families is a major task in comparative genomics. Because chromosomes from many different microorganisms have already been sequenced, such comparisons can be easily done, and the results are often surprising. For instance, genes in *Archaea* that are active in DNA replication, transcription, and translation are more similar to those in *Eukarya* than to those in *Bacteria*. Unexpectedly however, many other genes in *Archaea*, for example, those encoding metabolic functions other than information processing, are more similar to those in *Bacteria* than those in *Eukarya*. The analytical tools of bioinformatics allow genetic relationships between any organisms to be deduced quickly and at the single gene, gene group, or entire genome level. The results obtained thus far generally support the phylogenetic picture of life deduced originally by comparing rRNA sequences (Section 12.4) and suggest that many genes in all organisms have common evolutionary roots. However, these analyses have also revealed instances of horizontal gene transfer, an important issue to which we now turn.

MINIQUIZ

- What is a homologous gene?
- What is a gene family?
- Contrast gene paralogs with gene orthologs.

6.12 Horizontal Gene Transfer and Genome Stability

Evolution dictates the transfer of genetic traits from one generation to the next. However, in prokaryotes, **horizontal gene transfer** (sometimes called *lateral gene transfer*) also occurs, and this can complicate the analysis of genomes.

Horizontal gene transfer refers to transfer from one cell to another by means other than the usual (vertical) inheritance process in which the genome is transferred from mother cell to daughter cell (Figure 6.29). In prokaryotes, at least three mechanisms for horizontal gene transfer are known: *transformation*, *transduction*, and *conjugation* (Chapter 10). Horizontal gene flow may be extensive in nature and may sometimes cross even phylogenetic domain boundaries. However, for horizontal gene transfer to be detectable by comparative genomics, the difference between the organisms must be rather large. For example, several eukaryotic genes have been found in *Chlamydia* and *Rickettsia*, both bacterial pathogens of humans. In particular, two genes encoding histone H1-like proteins have been found in the *Chlamydia trachomatis* genome, suggesting horizontal transfer from a eukaryotic source, possibly even its human host. Note that this is the reverse

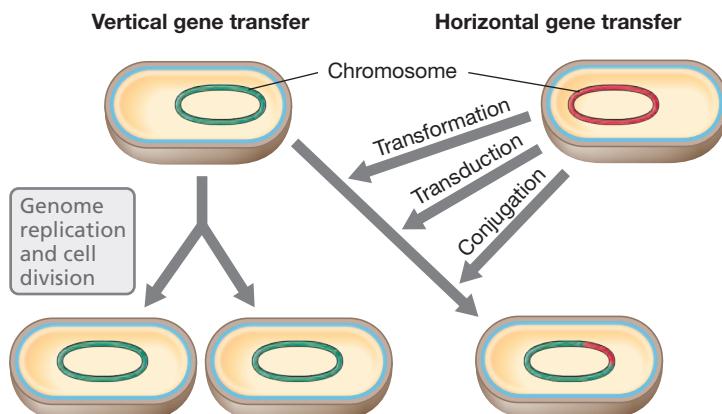

Figure 6.29 Vertical versus horizontal gene transfer. Vertical gene transfer occurs when cells divide. Horizontal gene transfer occurs when a donor cell contributes genes to a recipient cell. In prokaryotes, horizontal transfer occurs through one of the three mechanisms: transformation, transduction, and conjugation.

of the situation with the mitochondrion in which genes from the ancestor of the mitochondrion were transferred to the eukaryotic nucleus (Section 6.5).

Detecting Horizontal Gene Flow

Horizontal gene transfers can be detected in genomes once the genes have been annotated (Section 6.3). The presence of genes that encode proteins typically found only in distantly related species is one signal that the genes originated from horizontal transfer. However, another clue to horizontally transferred genes is the presence of a stretch of DNA whose guanosine/cytosine (GC) content or codon bias differs significantly from the rest of the genome (Figure 6.29). With these clues, many likely examples of horizontal transfer have been documented in the genomes of various prokaryotes. A classic example exists with the organism *Thermotoga maritima*, a species of *Bacteria*, which was shown to contain over 400 genes (greater than 20% of its genome) of archaeal origin. Of these genes, 81 were found in discrete clusters. This strongly suggests that they were obtained by horizontal gene transfer, presumably from thermophilic *Archaea* that share the hot environments inhabited by *Thermotoga*.

Horizontally transferred genes typically encode metabolic functions distinct from the core molecular processes of DNA replication, transcription, and translation, and may account for the previously mentioned similarities of metabolic genes in *Archaea* and *Bacteria* (Section 6.4). In addition, there are several examples of virulence genes of pathogens that have been transferred by horizontal means. It is apparent that prokaryotes are actively exchanging genes in nature, and the process likely functions to "fine-tune" an organism's genome to a particular situation or habitat. Nevertheless, it is necessary to be cautious when invoking horizontal gene transfer to explain the distribution of genes in a given organism. For example, when the human genome was first sequenced, over 200 genes were identified as being horizontal transfers from prokaryotes. However, when more eukaryotic genomes became available for comparison, homologs were found for most of these genes in many eukaryotic lineages. Consequently, it now seems that most of these genes are in fact of eukaryotic

origin. Only about a dozen human genes are now accepted as strong candidates for having relatively recent prokaryotic origins. The phrase “relatively recent” here refers to genes transferred from prokaryotes after separation of the major eukaryotic lineages (☞ Section 12.4), not to genes of possible ancient prokaryotic origin that are shared by eukaryotes as a whole.

Genome Evolution and Mobile Elements

The term “mobile DNA” refers to segments of DNA that move from one location to another within host DNA molecules (☞ Section 10.11). Most mobile DNA consists of *transposable elements*, but insertion sequences and integrated virus genomes are also common. Such mobile elements can play important roles in genome evolution (Figure 6.30).

Transposons are common forms of mobile DNA that move between different host DNA molecules, including chromosomes, plasmids, and viruses, by the activity of an enzyme called *transposase* (☞ Section 10.11). In doing so they may pick up and horizontally transfer genes for various characteristics, including resistance to antibiotics and production of toxins. However, transposons may also mediate a variety of large-scale chromosomal changes (Figure 6.30). Bacteria that are undergoing rapid evolutionary change often contain relatively large numbers of mobile elements, especially insertion sequences, simple transposable elements whose genes encode only transposition. Recombination among identical elements generates chromosomal rearrangements such as deletions,

inversions, or translocations, and these provide a source of genomic diversity upon which natural selection can act. Thus, chromosomal rearrangements that accumulate in bacteria during stressful growth conditions are often flanked by repeats or insertion sequences.

Conversely, once a species settles into a stable evolutionary niche, most mobile elements are apparently lost. For example, genomes of species of *Sulfolobus* (*Archaea*) have unusually high numbers of insertion sequences and show a high frequency of gene translocations. By contrast, *Pyrococcus* (*Archaea*) shows an almost complete lack of insertion sequences and a correspondingly low number of gene translocations. This suggests that for whatever reason(s), perhaps because of fluctuations in conditions in their habitats, the genomes of *Sulfolobus* species are more dynamic than the more stable genome of *Pyrococcus*.

Chromosomal rearrangements due to insertion sequences have apparently contributed to the evolution of several bacterial pathogens. In *Bordetella*, *Yersinia*, and *Shigella*, the more highly pathogenic species show a much greater frequency of insertion sequences. For example, *Bordetella bronchiseptica* has a genome of 5.3 Mbp but carries no known insertion sequences. Its more pathogenic relative, *Bordetella pertussis*, the causative agent of whooping cough (☞ Section 29.3), has a smaller genome (4.1 Mbp) but has more than 260 insertion sequences. Comparison of these genomes suggests that the insertion sequences are responsible for major genome rearrangements, including the deletions that reduced the genome size in *B. pertussis*.

Insertion sequences also play a role in assembling genetic modules to generate novel plasmids. For example, 46% of the 220-kbp virulence megaplasmid of the pathogenic bacterium *Shigella flexneri* consists of insertion sequence DNA. In addition to full-length insertion sequences, there are also many fragments in this plasmid that imply multiple ancestral rearrangements.

MINIQUIZ

- Which class of genes is rarely transferred horizontally? Why?
- List the major mechanisms by which horizontal gene transfer occurs in prokaryotes.
- How might transposons be especially important in the evolution of pathogenic bacteria?

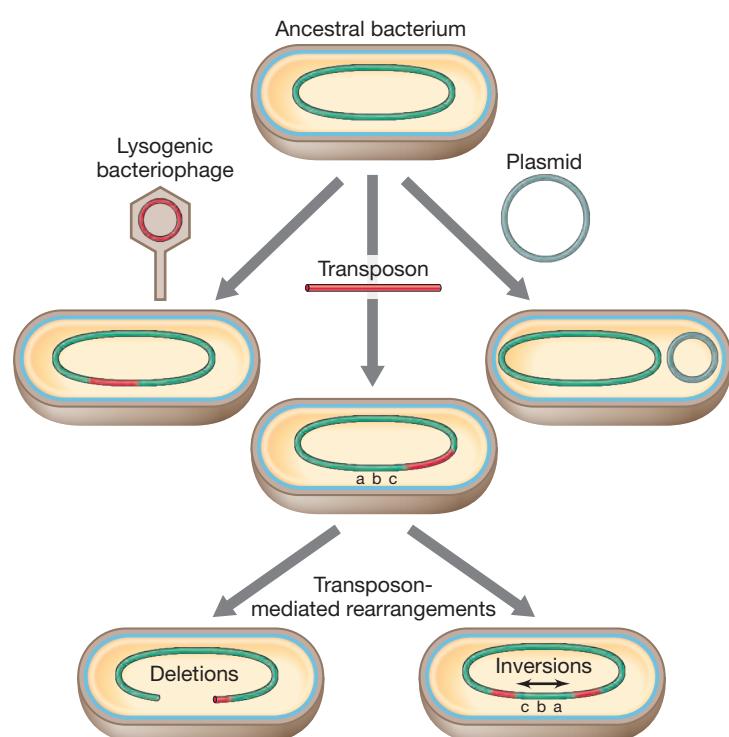

Figure 6.30 Mobile elements promote genome evolution. A variety of mobile genetic elements can move from one organism to another, thus adding genes to the genome of the recipient. The most common of these are plasmids, bacteriophages, and transposons. In the latter case, chromosomal rearrangements, such as deletions and inversions of DNA neighboring the transposon, may be mediated by the activity of the transposase.

6.13 Core Genome versus Pan Genome

One of the most important concepts to emerge from comparing the genome sequences of multiple strains of the same species is the distinction between the **pan genome** and the **core genome**. The *core genome* is that shared by all strains of a given species, whereas the *pan genome* includes the core plus all of the optional extras present in one or more strains but not all strains of that species (Figure 6.31). As we have seen, horizontal gene transfer of entire genetic elements such as plasmids, viruses, or transposable elements is possible. Consequently, there may be major differences in the total amount of DNA and the suite of accessory capabilities (virulence, symbiosis, or biodegradation) between strains of a single bacterial species. In other words, one could say that the *core genome* is typical of the species as a whole, whereas the other components of the *pan genome*, frequently

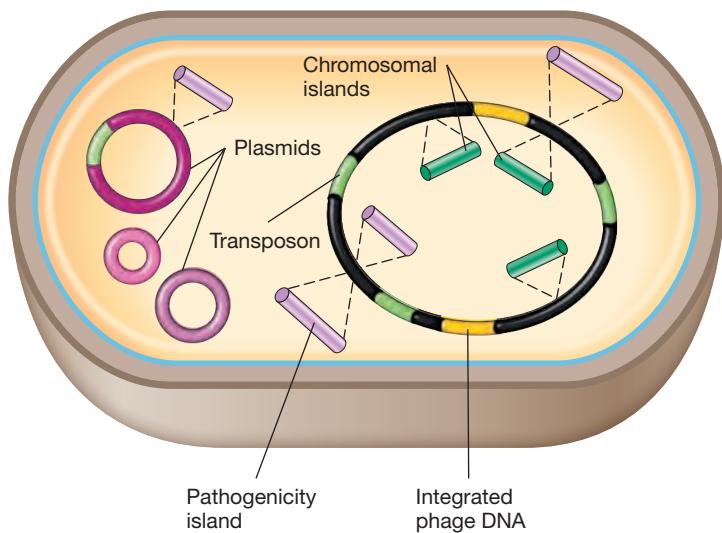

Figure 6.31 Pan genome versus core genome. The core genome is represented by the black regions of the chromosome and is present in all strains of a species. The pan genome includes elements that are present in one or more strains but not in all strains. Each colored wedge indicates a single insertion. Where two wedges emerge from the same location, they represent alternative islands that can insert at that site. However, only one insertion can be present at a given location. Plasmids, like the chromosome, may have insertions that are not present in all strains.

including mobile elements, are restricted to particular strains within a species.

It is difficult to define the size of the pan genome precisely because it increases as the genomes of more strains of a species are sequenced. In some cases, such as the enteric bacteria *Escherichia coli* and *Salmonella enterica*, many different isolates have been found that carry a wide range of different plasmids, transposons, and the like. Consequently the pan genome is extremely large. **Figure 6.32** illustrates the pan genome for serovars (strains) of the important human pathogen *Salmonella enterica* depicted in a “flowerplot” schematic.

Chromosomal Islands

Comparison of the core and pan genomes of particular bacteria or of genomes of particular species with their close relatives sometimes reveals extra blocks of genetic material that are part of the chromosome, rather than being plasmids or integrated viruses. These so-called **chromosomal islands** contain clusters of genes for specialized functions that are not needed for simple survival (Figure 6.31). Consequently, two strains of the same bacterial species may show significant differences in genome size.

Not surprisingly, chromosomal islands in pathogenic bacteria have drawn the most attention. However, chromosomal islands are also known that encode the biodegradation of pollutants such as aromatic hydrocarbons and herbicides. In addition, many of the genes essential for the symbiotic relationship of rhizobia with the root nodules of plants (Section 22.3) are carried in chromosomal islands. Perhaps the most unique chromosomal island is the magnetosome island of the bacterium *Magnetospirillum*; this DNA fragment carries genes that encode the formation of magnetosomes, intracellular magnetic particles used to orient the organism in a magnetic field and influence the direction of its movement (Section 2.14).

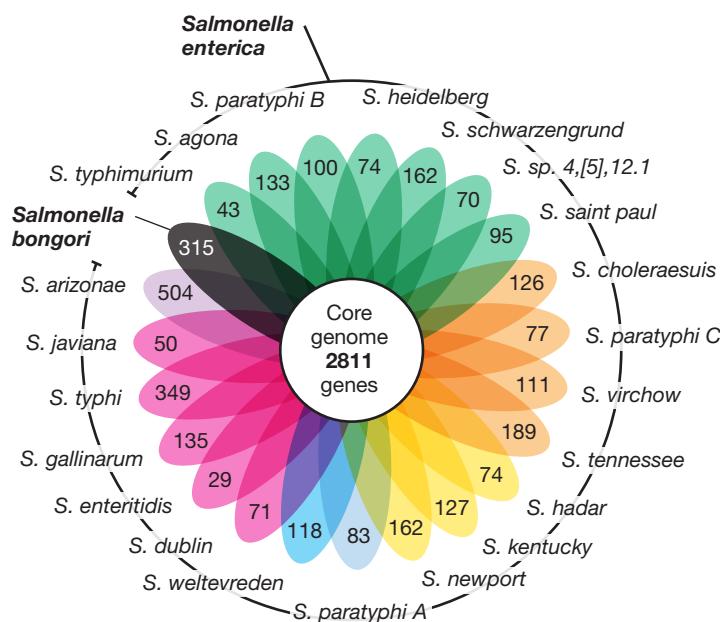

Figure 6.32 Flowerplot of the *Salmonella enterica* pan genome. A “flowerplot” of gene families in serovars (strains) of the gram-negative pathogenic bacterium *Salmonella enterica* (the names surrounding the flowerplot are immunologically unique serovars [S.] of *S. enterica*). The figure presents the average number of gene families found in each genome as being unique to each serovar. *Salmonella bongori* is a species distinct from *S. enterica*. Serovar 4,[5],12.i is recently identified and not yet named. Data from Jacobsen, A., R.S. Hendriksen, F.M. Aarestrup, D.W. Ussery, and C. Friis. 2011. The *Salmonella enterica* pan-genome. *Microb Ecol* 62: 487–504.

Chromosomal islands are presumed to have a “foreign” origin based on several observations. First, these extra regions are often flanked by inverted repeats, implying that the whole region was inserted into the chromosome by transposition (Section 6.12) at some period in the recent evolutionary past. Second, the base composition and codon bias (Table 6.3) in chromosomal islands often differ significantly from that of the genome proper. Third, chromosomal islands are found in some strains of a particular species but not in others.

Some chromosomal islands carry a gene encoding an integrase enzyme and are thought to move in a manner similar to conjugative transposons (Section 6.12). Chromosomal islands are typically inserted into a gene for a tRNA; however, because the target site is duplicated upon insertion, an intact tRNA gene is regenerated during the insertion process. In a few cases, transfer of a whole chromosomal island between related bacteria has been demonstrated in the laboratory; transfer can presumably occur by any of the mechanisms of horizontal transfer: transformation, transduction, and conjugation (Figure 6.29). It is thought that after insertion into the genome of a new host cell, chromosomal islands gradually accumulate mutations, and hence, over many generations, chromosomal islands tend to lose their ability to move.

Pathogenicity Islands and the Evolution of Virulence

Comparison of the genomes of pathogenic bacteria with those of their harmless relatives often reveals chromosomal islands that encode **virulence factors**, special proteins or other molecules or structures that help initiate disease (Chapter 23). Some virulence genes

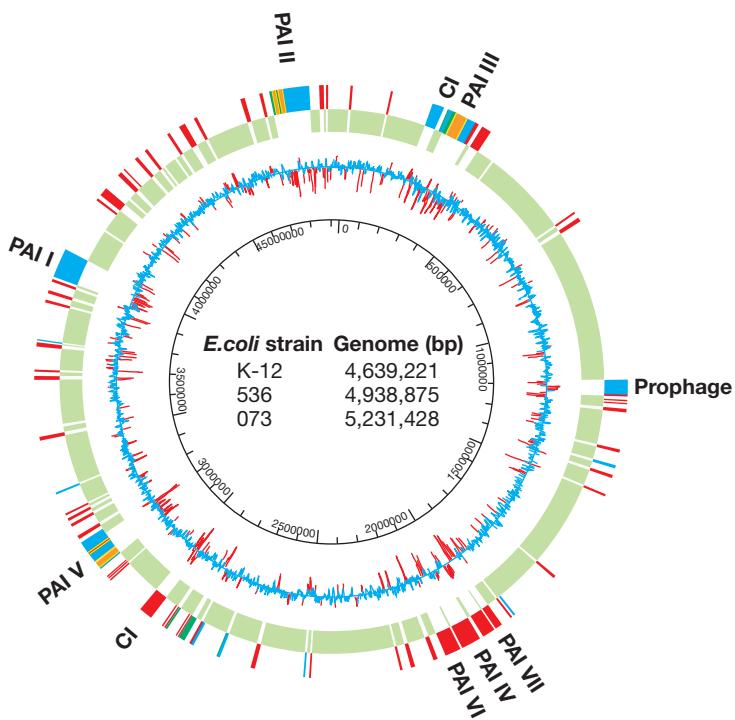

Figure 6.33 Pathogenicity islands in *Escherichia coli*. Genetic map of *E. coli* strain 536, a urinary tract pathogen, compared with a second pathogenic strain (073) and the nonpathogenic strain K-12. The pathogenic strains contain pathogenicity islands, and thus their chromosomes are larger than that of K-12. Inner circle, nucleotide base pairs. Jagged circle, DNA GC distribution; regions where GC content varies dramatically from the genome average are in red. Outermost circle, three-way genomic comparison: green, genes common to all strains; red, genes present in the pathogenic strains only; blue, genes found only in strain 536; orange, genes of strain 536 present in a different location in strain 073. Some very small inserts deleted for clarity. PAI, pathogenicity island; CI, chromosomal island. Prophage, DNA from a temperate bacteriophage. Note the correlation between genomic islands and skewed GC content. Data adapted from *Proc. Natl. Acad. Sci. (USA)* 103: 12879–12884 (2006).

are carried on plasmids or lysogenic bacteriophages (► Sections 8.8 and 10.7); however, many others are clustered in chromosomal regions called **pathogenicity islands** (Figure 6.31 and **Figure 6.33**).

Pathogenicity islands are the best known of the chromosomal islands. Although pathogenicity islands are regarded as a subclass of chromosomal islands, genetically related islands that share homologous genes for integration and conjugation may carry virulence genes in some bacteria but biodegradation genes in others. For example, the identity and chromosomal location of most genes of pathogenic strains of *Escherichia coli* correspond to those of the harmless laboratory strain *E. coli* strain K-12, as would be expected. However, most pathogenic strains contain pathogenicity islands of considerable size that are not present in the *E. coli* K-12 chromosome (Figure 6.33). Consequently, two strains of the same bacterial species may show significant differences in genome size due to the presence or absence of the island. Thus, as shown in Table 6.1, the enterohemorrhagic strain *E. coli* O157:H7 contains 20% more DNA and genes than *E. coli* K-12.

Small pathogenicity islands that encode a series of virulence factors are present in certain strains of the gram-positive pathogenic bacterium *Staphylococcus aureus* and can be moved between cells by temperate bacteriophages (► Section 10.7). The islands are smaller than the phage genome, and when the islands excise from the chromosome and replicate, they induce the formation of defective phage particles that carry the genes for the islands but are too small to carry the phage genome. In this way, strains of *S. aureus* that lack the islands can quickly obtain them and become more effective pathogens.

MINIQUIZ

- What is the difference between core genome and pan genome?
- What is a chromosomal island and how can one be identified as being of foreign origin?
- What is a pathogenicity island and how does one move between bacterial species?

BIG IDEAS

6.1 • Small viruses were the first organisms whose genomes were sequenced, but now many prokaryotic and eukaryotic cellular genomes have been sequenced.

6.2 • DNA sequencing technology is advancing very quickly. The original Sanger method is rarely used and there are now four successive generations of sequencing technology. Advances in technology have greatly increased the speed of DNA sequencing. Shotgun techniques employ random cloning and sequencing of small genome fragments followed by computer-generated assembly of the genome.

6.3 • Computer analysis of sequencing data is a vital part of genomics. Computational tools are used to store and analyze the sequences and the structures of biological macromolecules.

6.4 • Sequenced prokaryotic genomes range in size from 0.15 to 13 Mbp. The smallest prokaryotic genomes are smaller than those of the largest viruses, whereas the largest have more genes than some eukaryotes. Gene content in prokaryotes is typically proportional to genome size. Many genes can be identified by their sequence similarity to genes found in other organisms. However, a significant percentage of sequenced genes are of unknown function.

6.5 • Virtually all eukaryotic cells contain mitochondria, and in addition, plant cells contain chloroplasts. Both organelles contain circular DNA genomes that encode rRNAs, tRNAs, and a few proteins needed for energy metabolism. Although the genomes of the organelles are independent of the nuclear genome, the organelles themselves are not. Many genes in the nucleus encode proteins required for organelle function.

6.6 • The complete genomic sequence of many microbial eukaryotes has been determined. The genome of the yeast *Saccharomyces cerevisiae* encodes about 6000 proteins, of which only about 900 appear essential. Relatively few of the protein-encoding genes of yeast contain introns. The number of genes in microbial eukaryotes ranges from 2000 (less than many prokaryotes) to 60,000 (more than twice as many as humans).

6.7 • Microarrays consist of genes or gene fragments attached to a solid support in a known pattern; mRNA is then hybridized with the DNA to determine patterns of gene

expression. The arrays are large enough for the transcription pattern of an entire genome (the transcriptome) to be analyzed. RNA-Seq requires massive sequencing of cDNA for transcriptomic analyses and requires third- or fourth-generation sequencing technology.

6.8 • Proteomics is the analysis of all the proteins present in an organism. The ultimate aim of proteomics is to understand the structure, function, and regulation of these proteins. The interactome is the total set of interactions between macromolecules inside the cell.

6.9 • The metabolome is the complete set of metabolic intermediates produced by an organism. Systems biology uses data from genomics, transcriptomics, and other omics to build computer models of molecular activities and interactions in cells.

6.10 • Most microorganisms in the environment have never been cultured. Nonetheless, analysis of DNA samples has revealed enormous sequence diversity in most habitats. The concept of the metagenome embraces the total genetic content of all the organisms in a particular habitat.

6.11 • Genomics can be used to study the evolutionary history of an organism. Organisms contain gene families, genes with related sequences. If these arose because of gene duplication, the genes are said to be paralogs; if they arose by speciation, they are called orthologs.

6.12 • Organisms may acquire genes from other organisms in their environment by horizontal gene transfer, and such transfer may even cross phylogenetic domain boundaries. Mobile DNA elements, including transposons, integrons, and viruses, are important in genome evolution and often carry genes encoding antibiotic resistance or virulence factors.

6.13 • Comparison of the genomes of multiple strains of the same bacterial species shows a conserved component (the core genome) plus many variable genetic modules only present in certain members of the species (the pan genome). Many bacteria contain relatively large inserts of foreign origin known as chromosomal islands. These contain clusters of genes that encode specialized metabolic functions or pathogenesis and virulence factors (pathogenicity islands).

REVIEW OF KEY TERMS

Bioinformatics the use of computational tools to acquire, analyze, store, and access DNA and protein sequences

Chromosomal island a bacterial chromosome region of foreign origin that contains clustered genes for some extra property such as virulence or symbiosis

Codon bias the relative proportions of different codons encoding the same amino acid; it varies in different organisms. Same as codon usage

Core genome the part of a genome shared by all strains of a species

Gene chip small solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern (also called microarrays)

Gene family genes related in sequence to each other because of common evolutionary origin

Genome the total complement of genetic information of a cell or a virus

Genomic library a collection of cloned DNA fragments that cover an entire genome

Genomics the discipline that maps, sequences, analyzes, and compares genomes

Homologs genes related in sequence to an extent that implies common genetic ancestry; includes both orthologs and paralogs

Horizontal gene transfer the transfer of genetic information between organisms as opposed to transfer from parent to offspring

Hybridization the joining of two single-stranded nucleic acid molecules by complementary

base pairing to form a double-stranded hybrid DNA or DNA–RNA molecule

Interactome the total set of interactions between proteins (or other macromolecules) in an organism

Metabolome the total complement of small molecules and metabolic intermediates of a cell or organism

Metagenome the total genetic complement of all the cells present in a particular environment

Metagenomics the genomic analysis of pooled DNA or RNA from an environmental sample containing organisms that have not been isolated; same as environmental genomics

Microarray small, solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern (also called gene chips)

Nucleic acid probe a labeled strand of nucleic acid that can be used to hybridize with a complementary strand of nucleic acid in a mixture

Open reading frame (ORF) a sequence of DNA or RNA that could be translated to give a polypeptide

Ortholog a gene in one organism that is similar to a gene in another organism because of descent from a common ancestor (see also *paralog*)

Pan genome the totality of the genes present in the different strains of a species

Paralog a gene whose similarity to one or more other genes in the same organism is the result of gene duplication (see also *ortholog*)

Pathogenicity island a bacterial chromosome region of foreign origin that contains clustered genes for virulence

Primer an oligonucleotide to which DNA polymerase attaches the first deoxyribonucleotide during DNA synthesis

Proteome the total set of proteins encoded by a genome or the total protein complement of an organism

Proteomics the genome-wide study of the structure, function, and regulation of the proteins of an organism

Sequencing deducing the order of nucleotides in a DNA or RNA molecule by a series of chemical reactions

Shotgun sequencing sequencing of DNA from previously cloned small fragments of a genome in a random fashion; shotgun sequencing is followed by computational methods to reconstruct the entire genome sequence

Systems biology the integration of data from genomics and other “omics” areas to build an overall picture of a biological system

Transcriptome the complement of all RNA produced in an organism under a specific set of conditions

18. What are pathogenicity islands and why are they important? (Section 6.13)

APPLICATION QUESTIONS

1. Apart from genome size, what factors make complete assembly of a eukaryotic genome more difficult than assembly of a prokaryotic genome?
2. Describe how one might determine which proteins in *Escherichia coli* are repressed when a culture is shifted from a minimal medium (containing only a single carbon source) to a rich medium containing many amino acids, bases, and vitamins. How might one study which genes are expressed during each growth condition?
3. The gene encoding the beta subunit of RNA polymerase from *Escherichia coli* is said to be orthologous to the *rpoB* gene of *Bacillus subtilis*. What does that mean about the relationship between the two genes? What protein do you suppose the *rpoB* gene of *B. subtilis* encodes? The genes for the different sigma factors of *E. coli* are paralogous. What does that say about the relationship among these genes?

7 • Metabolic Regulation

microbiologynow

Luminescence or Lethality?

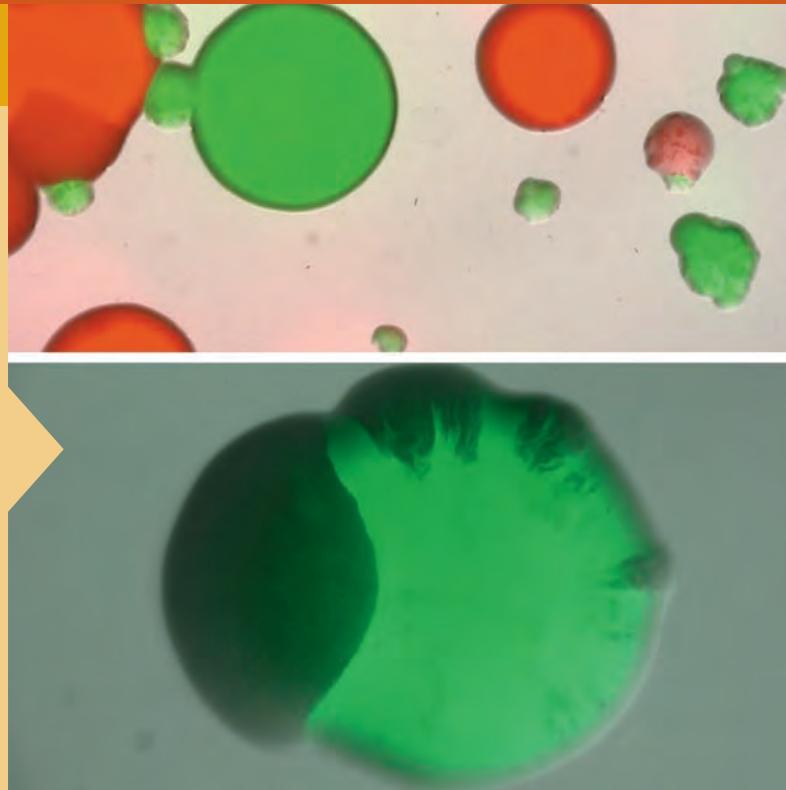

All human cells contain the same genetic blueprint, but what makes a brain cell different from a liver cell? This cellular differentiation is controlled by the elegant manner in which a cell deploys its genome—what is commonly known as *regulation of gene expression*. While cellular differentiation is primarily associated with multicellular organisms, some prokaryotes are also able to change their morphology or switch from benign to pathogenic forms by altering gene expression.

Photobacterium luminescens, a bioluminescent bacterium that colonizes the gut of a worm, provides an astonishing example of this pathogenic switch. While one might assume that colonization by *Photobacterium* would be detrimental to the worm, the relationship between these two organisms is strikingly beneficial. In the nonpathogenic stage, the bacteria reside harmlessly in the worm intestine. When the worm prepares to reproduce, it enters a host insect and regurgitates its intestinal bacteria. Through altered gene expression, some *Photobacterium* cells then switch to the pathogenic mode and secrete insecticidal toxins that kill the host insect and enzymes that dissolve its body, releasing nutrients for both the worm and the bacterium.

Using fluorescent gene reporters, microbiologists have been able to visualize this elegant switch in a pure culture of *Photobacterium*.¹ Cells that are in the beneficial colonization mode tend to form smaller colonies (top photo, green), whereas colonies of pathogenic cells containing the insecticidal toxins are larger (red). Researchers have also shown that both phenotypes can be exhibited within a single isolated colony! This is seen as black sectors within the large green colony in the bottom photo.

Research with *Photobacterium* thus clearly illustrates how a simple change in gene expression can trigger a major switch in the phenotype of a bacterium, dramatically changing its lifestyle.

¹Somvanshi, V.S., et al. 2012. A single promoter inversion switches *Photobacterium* between pathogenic and mutualistic states. *Science* 337: 88–92.

To efficiently orchestrate the numerous reactions that occur in a cell and to maximally use available resources, cells must *regulate* the types, amounts, and activities of proteins and other macromolecules they make. Regulation occurs at all molecular levels in the cell. After DNA is transcribed into RNA, the information is

translated to yield specific protein. Collectively, these processes are called **gene expression**. Once proteins have been translated, additional mechanisms can be used to regulate their activity. This chapter focuses on the systems that control gene expression and the activity of proteins.

I • Overview of Regulation

Some proteins and RNA molecules are needed in the cell at about the same level under all growth conditions. The expression of these molecules is said to be *constitutive*. However, more often a particular protein or RNA is needed under some conditions but not others. For instance, enzymes required for using the sugar lactose are useful only if lactose is available to the cell. Microbial genomes encode many more proteins than are actually present in the cell under any particular growth condition (Chapter 6). Thus, regulation is a major process in all cells and helps to conserve energy and resources.

Cells use two major approaches to regulate protein function. One controls the *activity* of a preformed enzyme or other protein, and the second controls the *amount* of an enzyme or other

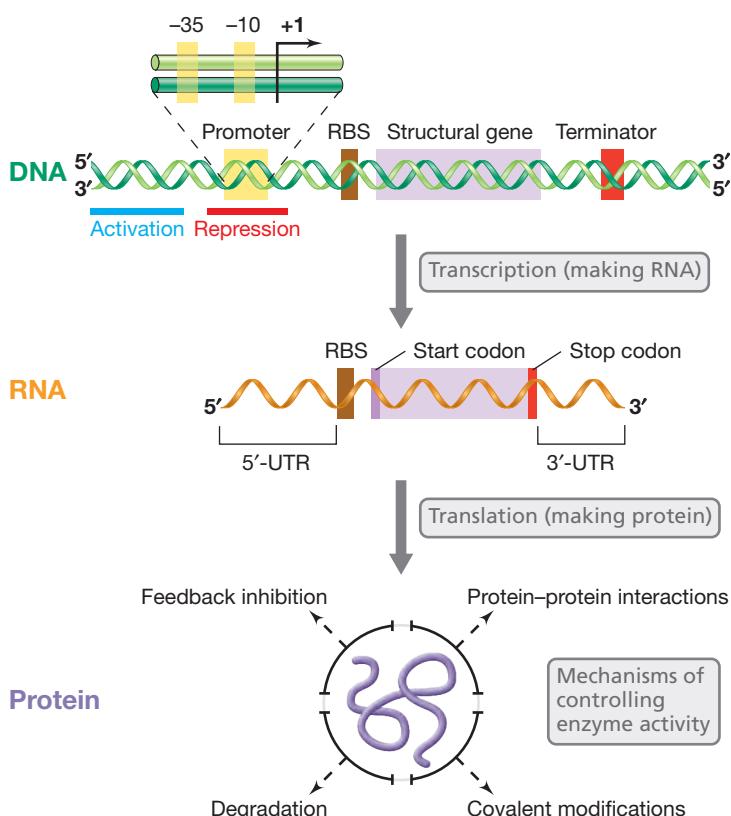

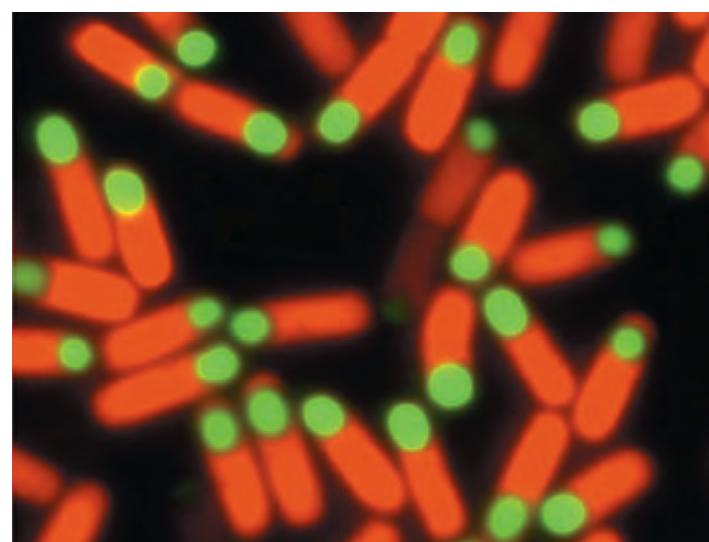

Figure 7.1 Gene expression and regulation of protein activity. The promoter and terminator as well as regions involved in transcriptional activation and repression are indicated. The 5' untranslated region (5'-UTR) is a short region between the start of transcription and the start of translation, while the 3' untranslated region (3'-UTR) is a short region between the stop codon and the transcription terminator. These are the regions where translational regulation often occurs. Mechanisms for regulating protein activity after translation are shown at the bottom.

protein. The activity of a protein can be regulated only after it has been synthesized (that is, post-translationally). Regulating the activity of an enzyme in the cell is typically very rapid (taking seconds or less), whereas synthesizing an enzyme is relatively slow (taking several minutes). After synthesis of an enzyme begins, it takes some time before it is present in amounts sufficient to affect metabolism. Conversely, after synthesis of an enzyme stops, a considerable time may elapse before the enzyme is sufficiently diluted that it no longer affects metabolism. However, working together, regulation of enzyme activity and of enzyme synthesis efficiently controls cell metabolism.

7.1 Major Modes of Regulation

Most bacterial genes are transcribed into messenger RNA (mRNA), which in turn is translated into protein, as we discussed in Chapter 4. The components of a typical gene and the points within the flow of genetic information where the amount of a specific gene product (RNA or protein) and its corresponding activity can be controlled are summarized in **Figure 7.1**. The amount of protein synthesized can be regulated at either the level of transcription, by varying the amount of mRNA made, or

T. Doan, R. Losick, and D. Rudner

Figure 7.2 Gene expression in *Bacillus* during sporulation using the green fluorescent protein (GFP). During endospore formation, alternative sigma factors are localized to specific regions of the cell (Section 7.11). σ F linked to GFP indicates expression and activity of the protein in the developing endospore (at one end of each cell). σ E linked to a reporter protein that fluoresces red indicates expression and activity of the protein throughout the mother cell prior to endospore formation. Regions correspond to the model depicted in Figure 7.25b.

at the level of translation, by translating or not translating the mRNA. The structural gene encodes the gene product and its expression is controlled by sequences in the upstream region (☞ Section 4.7). Note that the sequences that determine the beginning and end of transcription are distinct from those that determine the beginning and end of translation. They are separated by small spacer regions, the 5' and 3' *untranslated regions* (5'-UTR and 3'-UTR). After translation, other regulatory processes such as feedback inhibition, covalent modifications, degradation, and interactions with other proteins can further regulate the activity of some proteins.

To monitor gene expression levels corresponding to specific proteins, *reporter genes* can be employed (☞ Section 11.6; Figure 7.2). Reporter genes encode a protein product that is easy to detect and assay and thus can be fused to other genes or regulatory elements to monitor gene expression. The **green fluorescent protein (GFP)**, which fluoresces bright green when exposed to a specific wavelength of light, is commonly used for monitoring gene expression. If the open-reading frame for GFP is linked directly to a regulatory region or fused to the end of a separate

gene of interest, the level of fluorescence can be correlated to the level of gene expression. Figure 7.2 illustrates the use of GFP and its derivatives to monitor expression of the alternative sigma factors necessary for sporulation in *Bacillus* (Section 7.11). The use of fluorescent proteins fused to the promoter of two separate sigma factors allows the cellular location of each sigma factor to be determined. Expression of σF , as indicated by green fluorescence, is localized at the end of the cell where endospore development occurs. The expression of σE , which is necessary to activate gene transcription throughout the mother cell, can be seen as red fluorescence throughout the rest of the cell (Figure 7.2).

MINIQUIZ

- What steps in the synthesis of protein might be subject to regulation?
- Which is likely to be more rapid, the regulation of activity or the regulation of synthesis? Why?
- What mechanisms can be used to regulate the activity of some proteins?

II • DNA-Binding Proteins and Transcriptional Regulation

As we have said, the amount of a protein present in a cell may be controlled at the level of transcription, at the level of translation, or, occasionally, by protein degradation. Our discussion begins with control at the level of transcription because this is the major means of regulation in prokaryotes.

7.2 DNA-Binding Proteins

For a gene to be transcribed, RNA polymerase must recognize a specific promoter on the DNA and begin its activity (☞ Section 4.7). Small molecules often take part in regulating this process. However, they rarely do so directly. Instead, they typically influence the binding of certain proteins, called *regulatory proteins*, to specific sites on the DNA. This event regulates gene expression by turning transcription either on or off.

Interaction of Proteins with Nucleic Acids

Interactions between proteins and nucleic acids are central to replication, transcription, and translation, and also to the regulation of these processes. Protein–nucleic acid interactions may be specific or nonspecific, depending on whether the protein attaches anywhere along the nucleic acid or binds to a specific site. Most DNA-binding proteins interact with DNA in a sequence-specific manner. Specificity is provided by interactions between specific amino acid side chains of the proteins and specific chemical groups on the nitrogenous bases and the sugar–phosphate backbone of the DNA. Because of its size, the *major groove* of DNA is the main site of protein binding, and Figure 4.2 identified atoms of the bases in the major groove that are known to interact with proteins. To achieve high specificity, the binding protein must interact simultaneously with several nucleotides.

We have already described a structure in DNA called an *inverted repeat* (☞ Figure 4.23a). Such inverted repeats are

frequently the locations at which regulatory proteins bind specifically to DNA (Figure 7.3). Note that this interaction does not require the formation of stem–loop structures in the DNA. DNA-binding proteins are often homodimeric, meaning they are composed of two identical polypeptide subunits, each subdivided into **domains**—regions of the protein with a specific structure and

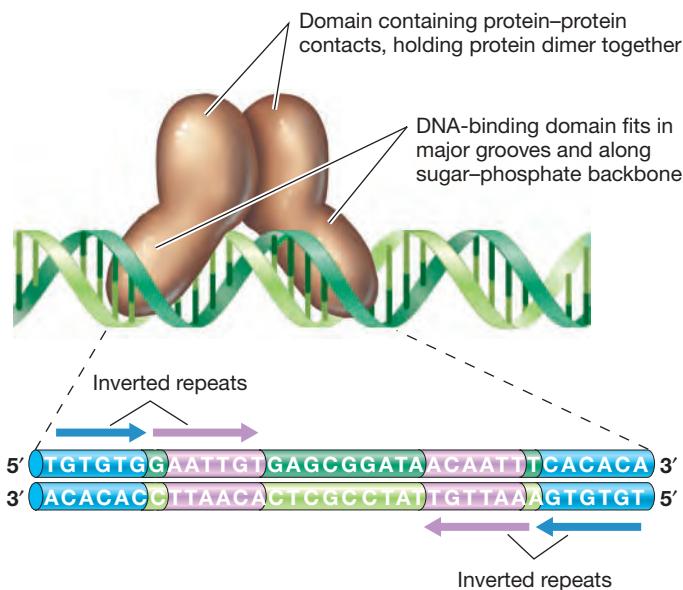

Figure 7.3 DNA-binding proteins. Many DNA-binding proteins are dimers that combine specifically with two sites on the DNA. The specific DNA sequences that interact with the protein are inverted repeats. The nucleotide sequence of the operator gene of the lactose operon (Section 7.3) is shown, and the inverted repeats, which are sites at which the *lac* repressor makes contact with the DNA, are shown in purple and blue boxes.

function. Each subunit has a domain that interacts specifically with a region of DNA in the major groove. When protein dimers interact with inverted repeats on DNA, each subunit binds to one of the inverted repeats. The dimer as a whole thus binds to both DNA strands (Figure 7.3).

Structure of DNA-Binding Proteins

DNA-binding proteins in both prokaryotes and eukaryotes possess several classes of protein domains that are critical for proper binding to DNA. One of the most common is the *helix-turn-helix* structure (Figure 7.4a). This consists of two segments of polypeptide chain that have α -helix secondary structure connected by a short sequence forming the “turn.” The first helix is the *recognition helix* that interacts specifically with DNA. The second helix, the *stabilizing helix*, stabilizes the first helix by interacting with it by way of hydrophobic interactions. The turn linking the two helices consists of three amino acid residues, the first of which is typically a glycine. Sequences are recognized by noncovalent interactions, including hydrogen bonds and van der Waals contacts, between the recognition helix of the protein and specific chemical groups in the sequence of base pairs on the DNA.

Many different DNA-binding proteins from *Bacteria* contain the helix-turn-helix structure. These include many repressor

proteins, such as the *lac* and *trp* repressors of *Escherichia coli* (Section 7.3 and see Figure 7.4), and some proteins of bacterial viruses, such as the bacteriophage lambda repressor (Figure 7.4b). Indeed, over 250 different proteins with this motif bind to DNA to regulate transcription in *E. coli*. Two other types of protein domains are commonly found in DNA-binding proteins. One of these, the *zinc finger*, is frequently found in regulatory proteins in eukaryotes and, as its name implies, binds a zinc ion. The other protein domain commonly found in DNA-binding proteins is the *leucine zipper*, which contains regularly spaced leucine residues that function to hold two recognition helices in the correct orientation to bind DNA.

Once a protein binds at a specific site on the DNA, various outcomes are possible. Some DNA-binding proteins are enzymes that catalyze a specific reaction on the DNA, such as transcription. In other cases, however, the binding event either blocks transcription (*negative regulation*, Section 7.3) or activates it (*positive regulation*, Section 7.4).

MINIQUIZ

- What is a protein domain?
- Why are most DNA-binding proteins specific to certain chemical groups within the DNA?

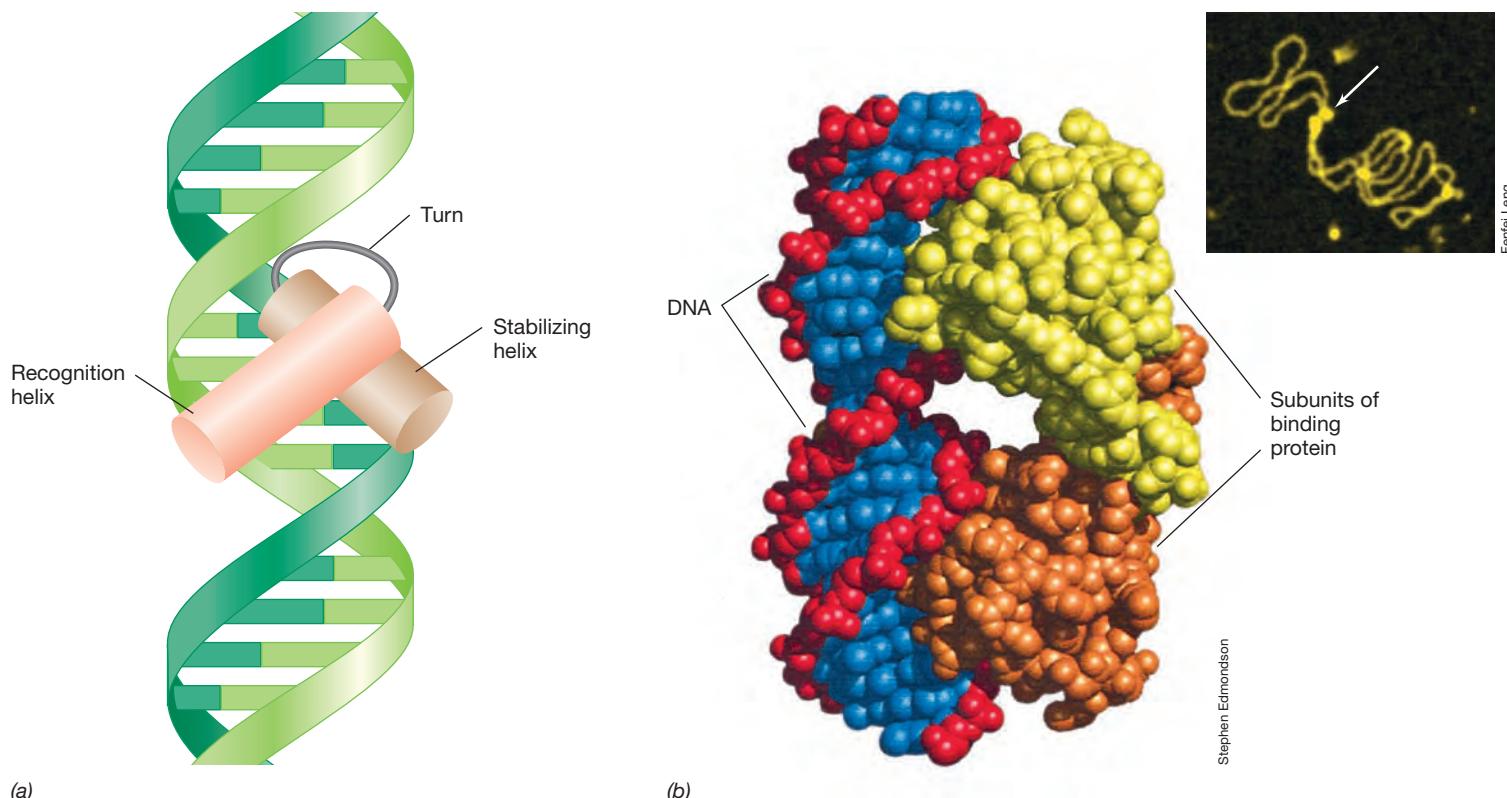

Figure 7.4 The helix-turn-helix structure of some DNA-binding proteins. (a) A simple model of the helix-turn-helix structure within a single protein subunit. (b) A computer model of both subunits of the bacteriophage lambda repressor bound to its operator. The DNA is red and blue. One subunit of the dimeric repressor is shown in brown and the other in yellow. Each subunit contains a helix-turn-helix structure. The coordinates used to generate this image were downloaded from the Protein Data Base (<http://www.pdb.org>). Inset: Atomic force microscopy showing copies of the LacI repressor protein (arrow) bound to multiple operator sites on a DNA molecule.

7.3 Negative Control: Repression and Induction

Transcription is the first step in biological information flow; because of this, it is simple and efficient to control gene expression at this point. If one gene is transcribed more frequently than another, there will be more of its mRNA available for translation and therefore a greater amount of its protein product in the cell. We begin with the processes of repression and induction, simple forms of regulation that govern gene expression at the level of transcription. Here we deal with **negative control** of transcription, control that *prevents* transcription.

Enzyme Repression and Induction

Often the enzymes that catalyze the synthesis of a specific product are not made if the product is already present in the medium in sufficient amounts. For example, in *Escherichia coli* and many other *Bacteria*, the enzymes needed to synthesize the amino acid arginine are made only when arginine is absent from the culture medium; an excess of arginine decreases the synthesis of these enzymes. This is called enzyme **repression**.

As can be seen in **Figure 7.5**, if arginine is added to a culture growing exponentially in a medium devoid of arginine, growth continues at the previous rate, but production of the enzymes for arginine synthesis stops. Note that this is a *specific* effect, as the synthesis of all other enzymes in the cell continues at the previous rate. This is because the enzymes affected by a particular repression event make up only a tiny fraction of the entire complement of proteins in the cell. Enzyme repression is widespread in bacteria as a means of controlling the synthesis of enzymes required for the production of amino acids and the nucleotide precursors purines and pyrimidines. In most cases, the final product of a particular biosynthetic pathway represses the enzymes of the pathway. This ensures that the organism does not waste energy and nutrients synthesizing unneeded enzymes.

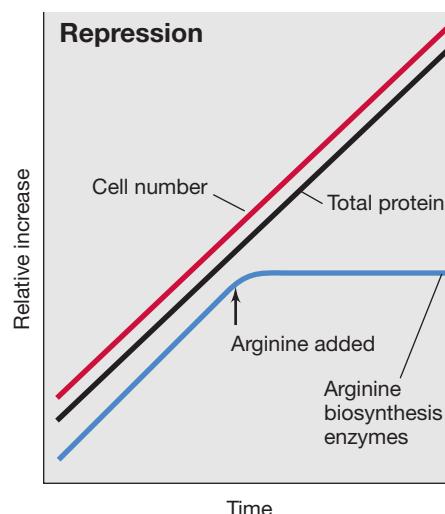

Figure 7.5 Enzyme repression. In a growing bacterial culture, the addition of arginine to the medium specifically represses production of enzymes needed to make arginine. Net protein synthesis is unaffected.

Enzyme **induction** is conceptually the opposite of enzyme repression. In enzyme induction, an enzyme is made only when its substrate is *present*. Enzyme repression typically affects biosynthetic (anabolic) enzymes. In contrast, enzyme induction usually affects degradative (catabolic) enzymes. To illustrate induction, consider the utilization of the sugar lactose as a carbon and energy source by *Escherichia coli*, the enzymes for which are encoded by the *lac* operon (► Section 4.3). **Figure 7.6** shows the induction of β -galactosidase, the enzyme that cleaves lactose into glucose and galactose. This enzyme is required for *E. coli* to grow on lactose. If lactose is absent, the enzyme is not made, but synthesis begins almost immediately after lactose is added. The three genes in the *lac* operon encode three proteins, including β -galactosidase, that are induced simultaneously upon adding lactose. This type of control mechanism ensures that specific enzymes are synthesized only when needed.

Inducers and Corepressors

The substance that induces enzyme synthesis is called an *inducer* and a substance that represses enzyme synthesis is called a *corepressor*. These substances, which are normally small molecules, are collectively called *effectors*. Interestingly, not all inducers and corepressors are actual substrates or end products of the enzymes involved. For example, structural analogs may induce or repress even though they are not substrates of the enzyme. Isopropylthiogalactoside (IPTG), for instance, is an inducer of β -galactosidase even though IPTG cannot be hydrolyzed by this enzyme. In nature, however, inducers and corepressors are probably normal cell metabolites. Detailed studies of lactose utilization in *E. coli* have shown that the actual inducer of β -galactosidase is not lactose, but its isomer allolactose, which is made from lactose.

Mechanism of Repression and Induction

How can inducers and corepressors affect transcription in such a specific manner? They do this indirectly by binding to specific

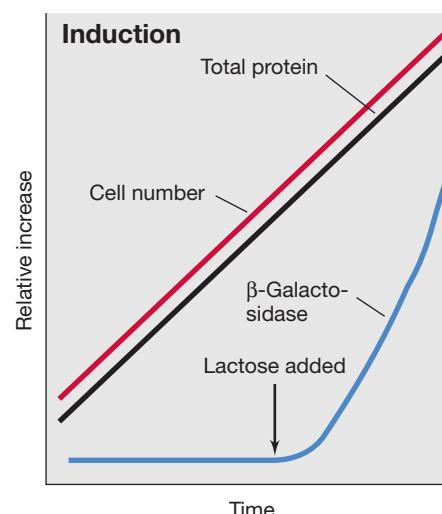

Figure 7.6 Enzyme induction. In a growing bacterial culture, the addition of lactose to the medium specifically induces synthesis of the enzyme β -galactosidase. Net protein synthesis is unaffected.

DNA-binding proteins, which, in turn, affect transcription. For an example of a repressible enzyme, we consider the arginine operon (Figure 7.5). **Figure 7.7a** shows transcription of the arginine genes, which proceeds when the cell needs arginine. However, when arginine is plentiful, it acts as a corepressor. As Figure 7.7b shows, arginine binds to a specific **repressor protein**, the *arginine repressor*, present in the cell. The repressor protein is **allosteric**; that is, its conformation is altered when the effector molecule binds to it (Section 7.17).

By binding its effector, the repressor protein is *activated* and can then bind to a specific region of the DNA near the promoter of the gene called the *operator*. This region gave its name to the **operon**, a cluster of consecutive genes whose expression is under the control of a single operator (► Section 4.3). All of the genes in an operon are transcribed as a single unit yielding a single mRNA (► Section 4.8). The operator is located downstream of the promoter where synthesis of mRNA is initiated (Figure 7.7). If the repressor binds to the operator, transcription is physically blocked because RNA polymerase can neither bind nor proceed. Hence, the polypeptides encoded by the genes in the operon cannot be synthesized. If the mRNA is polycistronic (► Section 4.8), all the polypeptides encoded by this mRNA will be repressed.

Enzyme induction may also be controlled by a repressor. In this case, the repressor protein is *active* in the absence of the inducer, completely blocking transcription. When the inducer is added, it combines with the repressor protein and inactivates it; inhibition is overcome and transcription can proceed (**Figure 7.8**).

All regulatory systems employing repressors have the same underlying mechanism: prevention of mRNA synthesis by the activity of specific repressor proteins that are themselves under the control of specific small effector molecules. And, as previously noted, because the repressor's role is to stop transcription, regulation by repressors is called *negative control*. One point to note is that genes are not turned on and off completely like light switches. DNA-binding proteins vary in concentration and affinity and thus control is quantitative. Even

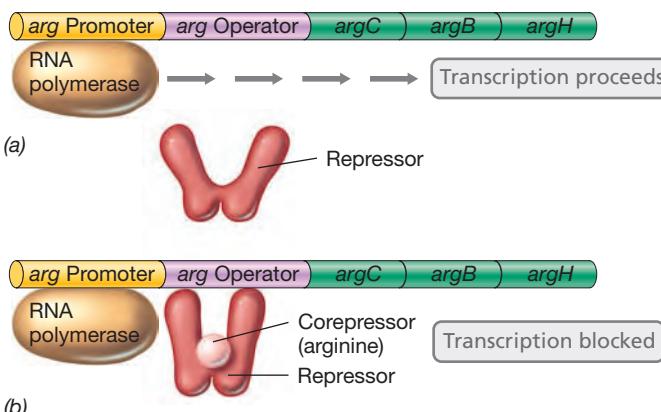

Figure 7.7 Enzyme repression in the arginine operon. (a) The operon is transcribed because the repressor is unable to bind to the operator. (b) After a corepressor (small molecule) binds to the repressor, the repressor binds to the operator and blocks transcription; mRNA and the proteins it encodes are not made. For the *argCBH* operon, the amino acid arginine is the corepressor that binds to the arginine repressor.

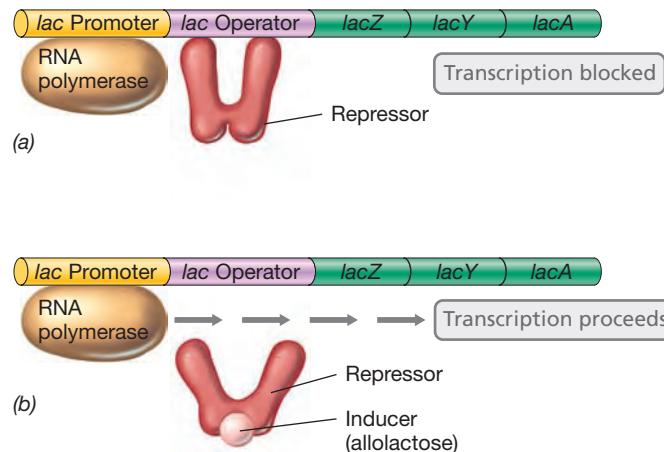

Figure 7.8 Enzyme induction in the lactose operon. (a) A repressor protein blocks the binding of RNA polymerase. (b) An inducer molecule binds to the repressor and inactivates it so that it no longer can bind to the operator. RNA polymerase then transcribes the DNA and makes an mRNA for that operon. For the *lac* operon, the sugar allolactose is the inducer that binds to the lactose repressor.

when a gene is “fully repressed” there is often a very low level of basal transcription.

MINIQUIZ

- Why is “negative control” so named?
- How does a repressor inhibit the synthesis of a specific mRNA?

7.4 Positive Control: Activation

Negative control relies on a protein (the repressor) to repress mRNA synthesis. By contrast, in **positive control** of transcription the regulatory protein is an *activator* that activates the binding of RNA polymerase to DNA. An example of positive regulation is the catabolism of the disaccharide sugar maltose in *Escherichia coli*.

Maltose Catabolism in *Escherichia coli*

The enzymes for maltose catabolism in *E. coli* are synthesized only after the addition of maltose to the medium. The expression of these enzymes thus follows the pattern shown for β -galactosidase in Figure 7.6 except that maltose rather than lactose is required to induce gene expression. However, the synthesis of maltose-degrading enzymes is not under negative control, as in the *lac* operon, but under positive control; transcription requires the binding of an **activator protein** to the DNA.

The maltose activator protein cannot bind to the DNA unless it first binds maltose, the inducer. When the maltose activator protein binds to DNA, it allows RNA polymerase to begin transcription (**Figure 7.9**). Like repressor proteins, activator proteins bind specifically to certain chemical groups within the DNA. However, the region on the DNA that is the binding site of the activator is not called an operator (Figures 7.7 and 7.8), but instead an *activator-binding site* (Figure 7.9). Nevertheless, the genes controlled by this activator-binding site are still called an operon.

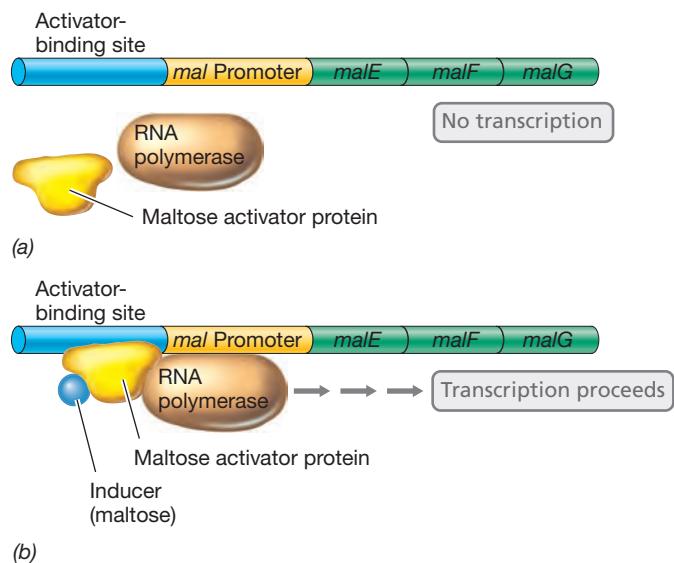

Figure 7.9 Positive control of enzyme induction in the maltose operon.

(a) In the absence of an inducer, neither the activator protein nor the RNA polymerase can bind to the DNA. (b) An inducer molecule (for the *malEF*G operon it is the sugar maltose) binds to the activator protein (MalT), which in turn binds to the activator-binding site. This recruits RNA polymerase to bind to the promoter and begin transcription.

Binding of Activator Proteins

The promoters of positively controlled operons have nucleotide sequences that bind RNA polymerase weakly and are poor matches to the consensus sequence (Section 4.7). Thus, even with the correct sigma (σ) factor, the RNA polymerase has difficulty binding to these promoters. The role of the activator protein is to help the RNA polymerase recognize the promoter and begin transcription. For example, the activator protein may modify the structure of the DNA by bending it (Figure 7.10), allowing the RNA polymerase to make necessary contacts with nucleotides in the

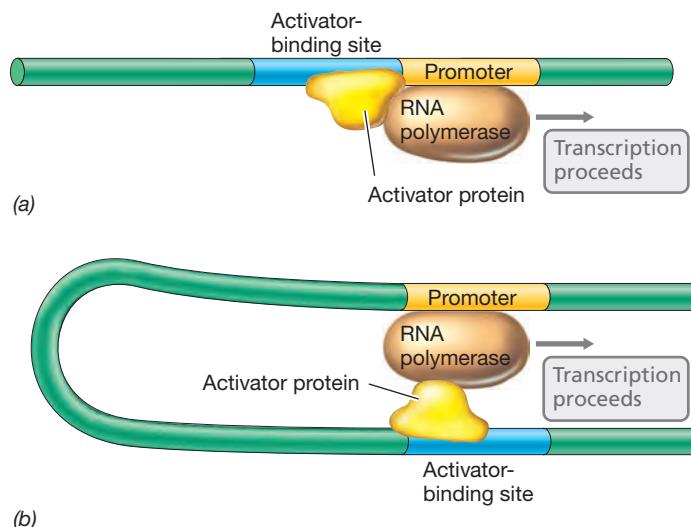

Figure 7.11 Activator protein interactions with RNA polymerase. (a) The activator-binding site is near the promoter. (b) The activator-binding site is several hundred base pairs from the promoter. In this case, the DNA must be looped to allow the activator and the RNA polymerase to contact.

promoter region to begin transcription. Alternatively, the activator protein may interact directly with the RNA polymerase. This can happen either when the activator-binding site is close to the promoter (Figure 7.11a) or when it is several hundred base pairs away from the promoter, a situation in which DNA looping is required to make the necessary contacts between protein and nucleic acid (Figure 7.11b).

Many genes in *E. coli* have promoters under positive control and many have promoters under negative control. In addition, many operons have promoters with multiple types of control and some have more than one promoter, each with its own control system! Thus, the simple picture outlined above does not hold for all operons. Multiple control features are common in the operons of virtually all prokaryotes, and thus their overall regulation may require a network of interactions.

Operons versus Regulons

In *E. coli*, the genes required for maltose utilization are spread out over the chromosome in several operons, each of which has an activator-binding site to which a copy of the maltose activator protein can bind (Figure 7.12). Therefore, the maltose activator protein actually controls the transcription of more than one operon. When more than one operon is under the control of a single regulatory protein, these operons are collectively called a **regulon**. Therefore, the enzymes for maltose utilization are encoded by the maltose regulon.

Regulons are known for operons under negative control as well. For example, the arginine biosynthetic enzymes (Section 7.3) are encoded by the arginine regulon, whose operons are all under the control of the arginine repressor protein (only one of the arginine operons was shown in Figure 7.7). In regulon control, a specific DNA-binding protein binds only at those operons it controls regardless of whether it is functioning as an activator or repressor; other operons are not affected.

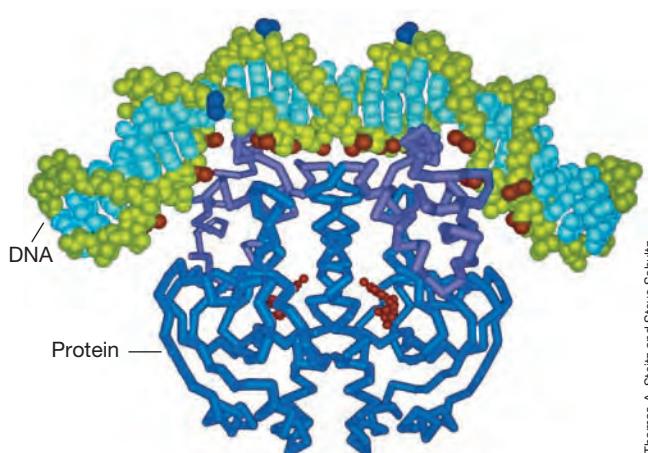

Figure 7.10 Computer model of a positive regulatory protein interacting with DNA. This model shows the cyclic AMP receptor protein (CRP), a regulatory protein that controls several operons. The α -carbon backbone of this protein is shown in blue and purple. The protein is binding to a DNA double helix (green and light blue). Note that binding of the CRP protein to DNA has bent the DNA.

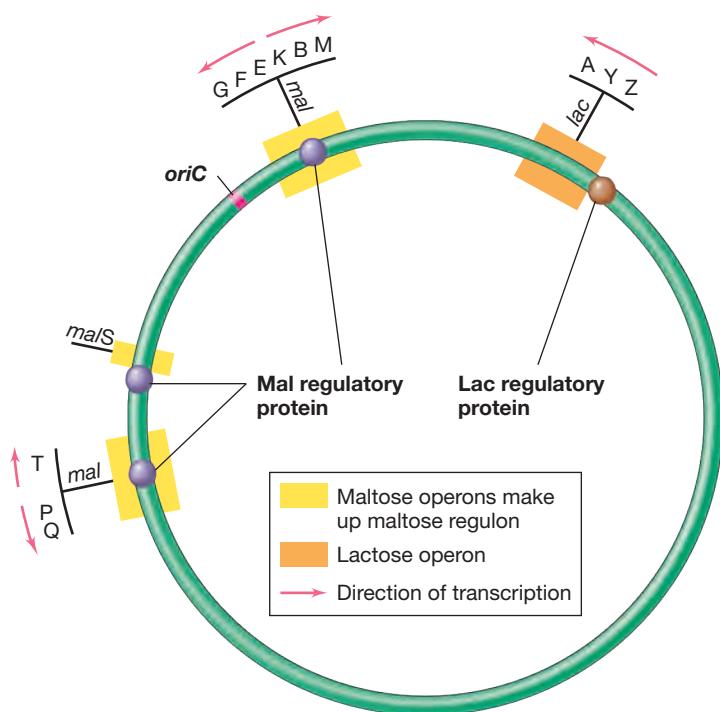

Figure 7.12 Maltose regulon of *Escherichia coli*. The genes and operons required for maltose utilization (*mal*) are dispersed throughout the *E. coli* genome and regulated by the same maltose regulatory protein. Note that the Lac repressor protein binds only to the *lac* operon, which is only located at one position on the chromosome, while the Mal repressor protein binds to multiple operons (the *mal* regulon).

MINIQUIZ

- Compare and contrast the activities of an activator protein and a repressor protein.
- Distinguish between an operon and a regulon.

7.5 Global Control and the *lac* Operon

An organism often needs to regulate many unrelated genes simultaneously in response to a change in its environment. Regulatory mechanisms that respond to environmental signals by regulating the expression of many different genes are called *global control systems*. Both the lactose operon and the maltose regulon respond to global controls in addition to their own controls discussed in Sections 7.3 and 7.4. We begin our consideration of global regulation by revisiting the *lac* operon and seeing how cells respond when given more than one sugar.

Catabolite Repression

We have not yet considered the possibility that bacteria might be confronted with several different utilizable carbon sources. For example, *Escherichia coli* can use many different sugars. When given several sugars, including glucose, do cells of *E. coli* use them simultaneously or one at a time? The answer is that *glucose is always used first*. It would be wasteful to induce enzymes for using other sugars when glucose is available, because *E. coli* grows faster on glucose than on other carbon

sources. **Catabolite repression** is a mechanism of global control that controls the use of carbon sources if more than one is present.

When cells of *E. coli* are grown in a medium that contains glucose, the synthesis of enzymes needed for the breakdown of other carbon sources (such as lactose or maltose) is repressed, even if those other carbon sources are present. Thus, the presence of a favored carbon source represses the induction of pathways that catabolize other carbon sources. Catabolite repression is sometimes called the “glucose effect” because glucose was the first substance shown to cause this response. But catabolite repression is not always linked to glucose; the key point is that the favored substrate is a better carbon and energy source than other available carbon sources. Thus, catabolite repression ensures that the organism uses the *best* carbon and energy source first.

Why is catabolite repression called *global* control? In *E. coli* and other organisms for which glucose is the best energy source, catabolite repression prevents expression of most other catabolic operons as long as glucose is present. Dozens of catabolic operons are affected, including those for lactose, maltose, a host of other sugars, and most other commonly used carbon and energy sources for *E. coli*. In addition, genes for the synthesis of flagella are controlled by catabolite repression because if bacteria have a good carbon source available, there is no need to swim around in search of nutrients.

One consequence of catabolite repression is that it may lead to two exponential growth phases, a situation called *diauxic growth*. If two usable energy sources are available, the cells grow first on the better energy source. Growth stops when the better source is depleted, but then following a lag period, it resumes on the other energy source. Diauxic growth is illustrated in Figure 7.13 for a culture of *E. coli* grown on a mixture of glucose and lactose. The cells grow more rapidly on glucose than on lactose. Although glucose and lactose are both excellent energy sources for *E. coli*, glucose is superior, and growth is faster.

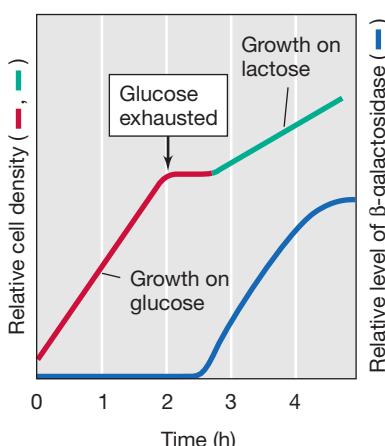

Figure 7.13 Diauxic growth of *Escherichia coli* on a mixture of glucose and lactose. The presence of glucose represses the synthesis of β -galactosidase, the enzyme that cleaves lactose into glucose and galactose. After glucose is depleted, there is a lag during which β -galactosidase is synthesized. Growth then resumes on lactose but at a slower rate, as indicated by the green line.

The proteins of the *lac* operon, including the enzyme β -galactosidase, are required for using lactose and are induced in its presence (Figures 7.6 and 7.8). But the synthesis of these proteins is also subject to catabolite repression. As long as glucose is present, the *lac* operon is not expressed and lactose is not used. However, when glucose is depleted, catabolite repression is abolished, the *lac* operon is expressed, and the cells grow on lactose.

Cyclic AMP and Cyclic AMP Receptor Protein

Despite its name, catabolite repression relies on an activator protein and is actually a form of positive control (Section 7.4). The activator protein is called the *cyclic AMP receptor protein* (CRP). A gene that encodes a catabolite-repressible enzyme is expressed only if CRP binds to DNA in the promoter region. This allows RNA polymerase to bind to the promoter. CRP is an allosteric protein and binds to DNA only if it has first bound a small molecule called *cyclic adenosine monophosphate* (*cyclic AMP* or *cAMP*) (Figure 7.14). Like many DNA-binding proteins (Section 7.2), CRP binds to DNA as a dimer.

Cyclic AMP is a key molecule in many metabolic control systems, both in prokaryotes and eukaryotes. Because it is derived from a nucleic acid precursor, it is a **regulatory nucleotide**. Other regulatory nucleotides include cyclic guanosine monophosphate (cyclic GMP; important mostly in eukaryotes), cyclic di-GMP (important in biofilm formation; Section 7.9), and guanosine tetraphosphate (ppGpp; important in the stringent response). Cyclic AMP is synthesized from ATP by an enzyme called *adenylate cyclase*. However, glucose inhibits the synthesis of cyclic AMP and also stimulates cyclic AMP transport out of the cell. When glucose enters the cell, the cyclic AMP level is lowered, CRP cannot bind DNA, and RNA polymerase fails to bind to the promoters of operons subject to catabolite repression.

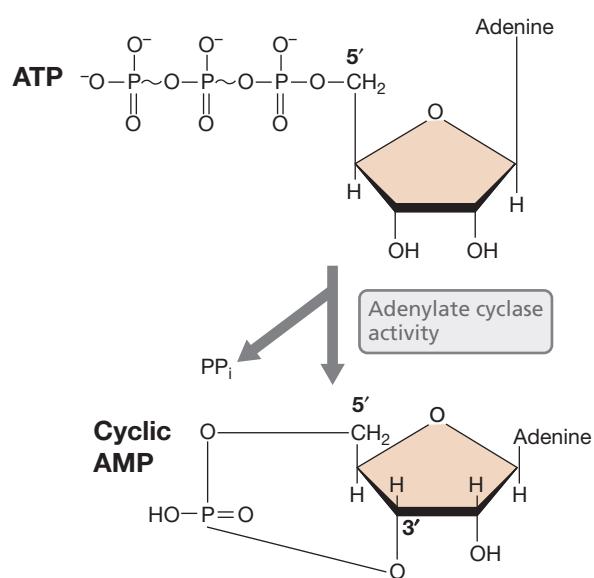

Figure 7.14 Cyclic AMP. Cyclic adenosine monophosphate (cyclic AMP) is made from ATP by the enzyme adenylate cyclase.

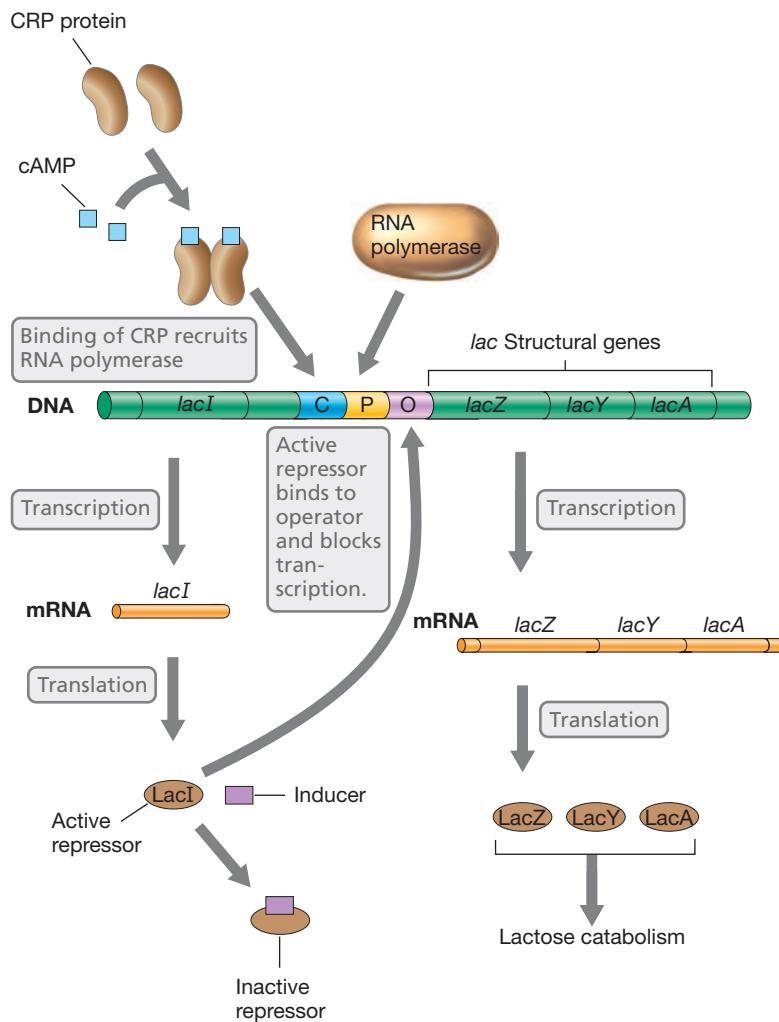

Figure 7.15 Overall regulation of the *lac* system. The *lac* operon consists of *lacZ*, encoding β -galactosidase, *lacY*, encoding lactose permease, and *lacA*, encoding lactose acetylase. The LacI repressor protein is encoded by a separate gene, *lacI*. LacI binds to the operator (O) unless the inducer is present. CRP binds to the C site when activated by cyclic AMP and recruits RNA polymerase to bind to the promoter (P). For the *lac* operon to be transcribed by RNA polymerase, the LacI repressor must be absent (that is, inducer must be present) and cyclic AMP levels must be high (due to the absence of glucose), thus allowing CRP to bind.

sion. Thus, catabolite repression is an indirect result of the presence of a better energy source (glucose); the direct cause of catabolite repression is a low level of cyclic AMP.

Let us return to the *lac* operon and include catabolite repression. The entire regulatory region of the *lac* operon is diagrammed in Figure 7.15. For *lac* genes to be transcribed, two requirements must be met: (1) The level of cyclic AMP must be high enough for the CRP protein to bind to the CRP-binding site (positive control), and (2) lactose or another suitable inducer must be present so that the lactose repressor (LacI protein) does not block transcription by binding to the operator (negative control). If these two conditions are met, the cell is signaled that glucose is absent and lactose is present; then and only then does transcription of the *lac* operon begin.

MINIQUIZ

- Explain how catabolite repression depends on an activator protein.
- What role does cyclic AMP play in glucose regulation?
- Explain how the *lac* operon is both positively and negatively controlled.

7.6 Transcription Controls in Archaea

There are two alternative approaches to regulating the activity of RNA polymerase. One strategy, common in *Bacteria*, is to use DNA-binding proteins that either block RNA polymerase activity (repressor proteins) or stimulate RNA polymerase activity (activator proteins). The alternative, common in eukaryotes, is to coordinate numerous DNA-binding proteins known as *transcription factors* to interact with RNA polymerase. Given the greater overall similarity between the mechanism of transcription in *Archaea* and *Eukarya* (Chapter 4), it is perhaps surprising that the regulation of transcription in *Archaea* more closely resembles that of *Bacteria*.

Few repressor or activator proteins from *Archaea* have yet been characterized in detail, but it is clear that *Archaea* have both types of regulatory proteins. Archaeal repressor proteins either block the binding of RNA polymerase itself or block the binding of TBP (TATA-binding protein) and TFB (transcription factor B), proteins that are required for RNA polymerase to bind to the promoter in *Archaea* (☞ Section 4.9). At least some archaeal activator proteins function in just the opposite way, by recruiting TBP to the promoter, thereby facilitating transcription.

Control of Nitrogen Assimilation in Archaea

A good example of an archaeal repressor is the NrpR protein from the methanogen *Methanococcus maripaludis*. NrpR represses genes encoding nitrogen assimilation functions (Figure 7.16), such as those for nitrogen fixation (☞ Section 3.17) and glutamine synthesis (☞ Section 3.15). When organic nitrogen is plentiful in the *M. maripaludis* cell, NrpR represses nitrogen assimilation genes. However, if the level of nitrogen becomes limiting, α -ketoglutarate accumulates to high levels. This occurs because α -ketoglutarate, a citric acid cycle intermediate, is also a major acceptor of ammonia during nitrogen assimilation.

When levels of α -ketoglutarate rise, this signals the cell that ammonia is limiting and that additional pathways need to be activated for obtaining ammonia, such as nitrogen fixation or the high-affinity nitrogen assimilation enzyme glutamine synthetase. Elevated levels of α -ketoglutarate function as an inducer by binding to the NrpR protein. In this state, NrpR loses its affinity for the promoter regions of its target genes and no longer blocks transcription from promoters. In this respect, the NrpR protein resembles the LacI repressor and similar proteins of *Bacteria* (Section 7.3).

Positive Archaeal Regulatory Systems

Other archaeal proteins regulate transcription in a positive manner. Thus their binding in the promoter region increases transcription. Some of these transcription activators are related

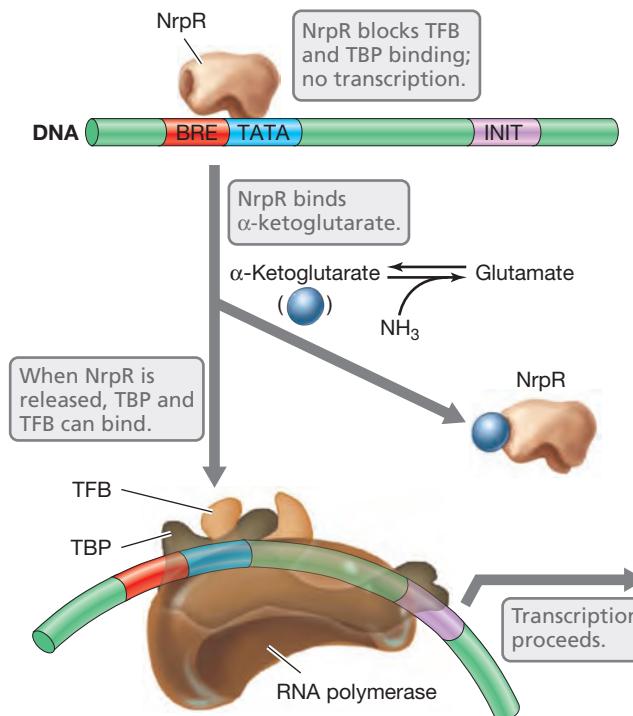

Figure 7.16 Repression of genes for nitrogen metabolism in *Archaea*. The NrpR protein of *Methanococcus maripaludis* acts as a repressor. It blocks the binding of the TFB and TBP proteins, which are required for promoter recognition, to the BRE site and TATA box, respectively. If there is a shortage of ammonia, α -ketoglutarate is not converted to glutamate. The α -ketoglutarate accumulates and binds to NrpR, releasing it from the DNA. Now TBP and TFB can bind. This in turn allows RNA polymerase to bind and transcribe the operon.

to bacterial proteins, whereas others appear to be unique to the *Archaea*. The SurR protein of the hyperthermophilic archaeon *Pyrococcus furiosus* is an example of a regulatory protein that functions either as an activator or as a repressor, depending on the location of its binding site within the promoter region. SurR controls the metabolic shift of *P. furiosus* from fermentation and production of H₂ to sulfur (S⁰) reduction (a form of anaerobic respiration) and production of H₂S. When S⁰ is absent, SurR activates genes necessary for hydrogenase production so that *P. furiosus* can grow by fermentation. At the same time, SurR functions as a repressor to prevent transcription of genes encoding proteins that participate in sulfur metabolism. However, when S⁰ is present, SurR is no longer able to bind to DNA due to the oxidation of cysteine residues within the DNA-binding motif of this regulatory protein. The release of SurR from regulatory regions both promotes expression of genes that participate in S⁰ metabolism and represses the expression of hydrogenase genes required for fermentation.

MINIQUIZ

- What is the major difference between transcriptional regulation in *Archaea* and eukaryotes?
- How do transcriptional activators in *Archaea* often differ in mechanism from those in *Bacteria*?

III • Sensing and Signal Transduction

Prokaryotes regulate cell metabolism in response to many different environmental fluctuations, including changes in temperature, pH, oxygen or nutrient availability, and even changes in the number of other cells present. Therefore, there must be mechanisms by which cells receive signals from the environment and transmit them to the specific target to be regulated. Some of those signals are small molecules that enter the cell and function as effectors. However, in many cases the external signal is not transmitted directly to the regulatory protein but instead is detected by a sensor that transmits it to the rest of the regulatory machinery, a process called **signal transduction**.

7.7 Two-Component Regulatory Systems

Because most signal transduction systems contain two parts, they are called **two-component regulatory systems**. Characteristically, such systems consist of a specific **sensor kinase protein** usually located in the cytoplasmic membrane, and a **response regulator protein**, present in the cytoplasm.

A kinase is an enzyme that phosphorylates compounds, typically using phosphate from ATP. Sensor kinases detect a signal from the environment and phosphorylate themselves (a process called auto-phosphorylation) at a specific histidine residue (Figure 7.17). Sensor

kinases thus belong to the class of enzymes called *histidine kinases*. The phosphate is then transferred from the sensor to another protein inside the cell, the response regulator. The latter is typically a DNA-binding protein that regulates transcription in either a positive or a negative fashion. In the example shown in Figure 7.17, regulation is negative; the phosphorylated response regulator functions as a repressor that binds DNA, thereby blocking transcription. Once dephosphorylated, the response regulator is released and transcription is permitted.

A balanced regulatory system must have a *feedback loop*, that is, a way to complete the regulatory circuit and terminate the response. This resets the system for another cycle. This feedback loop employs a phosphatase, an enzyme that removes the phosphate from the response regulator at a constant rate. The response regulator itself often catalyzes this reaction, although in some cases separate proteins are needed (Figure 7.17). Phosphatase activity is typically slower than phosphorylation. However, if phosphorylation ceases due to reduced sensor kinase activity, phosphatase activity eventually returns the response regulator to the fully nonphosphorylated state and the system is reset.

Examples of Two-Component Regulatory Systems

Two-component systems regulate a large number of genes in many different bacteria. Interestingly, two-component systems are either extremely rare or absent in *Archaea* and in *Bacteria* that live as parasites of higher organisms. A few key examples of two-component systems include those that respond to phosphate limitation, nitrogen limitation, and osmotic pressure.

In *Escherichia coli* almost 50 different two-component systems are present, and several are listed in Table 7.1. In one example, the osmolarity of the environment controls the relative levels of the proteins OmpC and OmpF in the *E. coli* outer membrane. OmpC and OmpF are *porins*, proteins that allow metabolites to cross the outer membrane of gram-negative bacteria (Section 2.11). If osmotic pressure is *low*, the synthesis of OmpF, a porin with a larger pore, increases; if osmotic pressure is *high*, OmpC, a porin with a smaller pore, is made in larger amounts. EnvZ, a cytoplasmic membrane sensor histidine kinase, detects changes in osmotic pressure. When a shift occurs, EnvZ autophosphorylates itself and transfers its phosphate group to OmpR, the response regulator of this system (Figure 7.18). Under conditions of *low* osmotic pressure, phosphorylated OmpR (OmpR-P) *activates* transcription of the *ompF* gene. Conversely, when osmotic pressure is *high*, OmpR-P *represses* transcription of *ompF* gene and activates transcription of *ompC* instead (Figure 7.18). The expression of *ompF* is also regulated by an additional control mechanism: regulatory RNA, and we discuss this in Section 7.14.

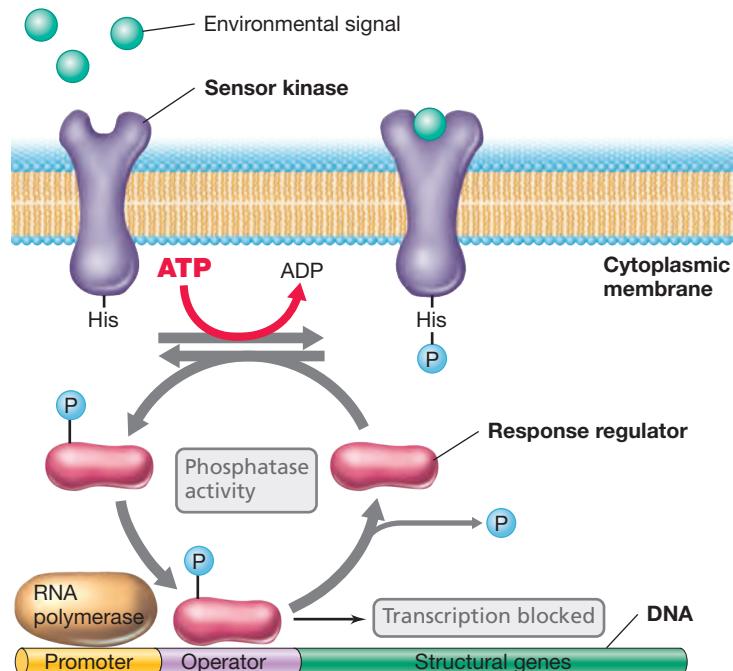

Figure 7.17 The control of gene expression by a two-component regulatory system. One component is a sensor kinase in the cytoplasmic membrane that phosphorylates itself in response to an environmental signal. The phosphoryl group is then transferred to the second component, a response regulator. The phosphorylated form of the response regulator then binds to DNA. In the system shown here, the phosphorylated response regulator is a repressor protein. The phosphatase activity of the response regulator slowly releases the phosphate from the response regulator and resets the system.

Two-Component Systems with Multiple Regulators

Some signal transduction systems have more than one regulatory element and their activities can quickly become quite complex. For instance, in the Ntr regulatory system, which regulates nitrogen assimilation in many *Bacteria*, the response regulator is an activator called *nitrogen regulator I* (*NRI*). *NRI* activates

Table 7.1 Examples of two-component systems that regulate transcription in *Escherichia coli*

System	Environmental signal	Sensor kinase	Response regulator	Activity of response regulator ^a
Arc system	Oxygen	ArcB	ArcA	Repressor/activator
Nitrate and nitrite respiration (Nar)	Nitrate and nitrite	NarX	NarL	Activator/repressor
		NarQ	NarP	Activator/repressor
Nitrogen utilization (Ntr)	Shortage of organic nitrogen	NRII (= GlnL)	NRI (= GlnG)	Activator of promoters requiring RpoN/ σ^{54}
Pho regulon	Inorganic phosphate	PhoR	PhoB	Activator
Porin regulation	Osmotic pressure	EnvZ	OmpR	Activator/repressor

^aNote that many response regulator proteins act as both activators and repressors depending on the genes being regulated. Although ArcA can function as either an activator or a repressor, it functions as a repressor on most operons that it regulates.

transcription from promoters recognized by RNA polymerase using the alternative sigma factor σ^{54} (RpoN) (► Section 4.7). The sensor kinase in the Ntr system is a protein called *nitrogen regulator II* (NRII), which functions as both a kinase and a phosphatase. The activity of NRII is in turn regulated by another protein called PII, whose own activity is regulated by the addition or removal of uridine monophosphate (UMP) groups. Under nitrogen starvation conditions, UMP is added to PII, and

the resulting PII–UMP complex promotes the kinase activity of NRII and results in the phosphorylation of NRI. Conversely, removal of UMP from PII promotes the phosphatase activity of NRII.

The *Nar regulatory system* (Table 7.1) is another example of a two-component regulatory system with multiple regulators; this system controls a set of genes that allow the use of nitrate (NO_3^-) or nitrite (NO_2^-) (or both) as alternative electron acceptors during anaerobic respiration (► Section 13.17). The Nar system contains two different sensor kinases and two different response regulators. In addition, all of the genes regulated by this system are in turn controlled by the FNR protein (fumarate nitrite regulator), which is a global regulator for genes of anaerobic respiration (see Table 7.2). This type of regulation in which a hierarchy of systems act in cascading fashion is common for systems of central importance to cellular metabolism.

Two-component systems closely related to those in *Bacteria* are also present in microbial eukaryotes, such as the yeast *Saccharomyces cerevisiae*, and even in plants. However, most eukaryotic signal transduction pathways rely on phosphorylation of serine, threonine, and tyrosine residues of proteins that are unrelated to those of the bacterial two-component systems that phosphorylate histidine residues (Figures 7.17 and 7.18).

MINIQUIZ

- What are kinases and what is their role in two-component regulatory systems?
- What are phosphatases and what is their role in two-component regulatory systems?

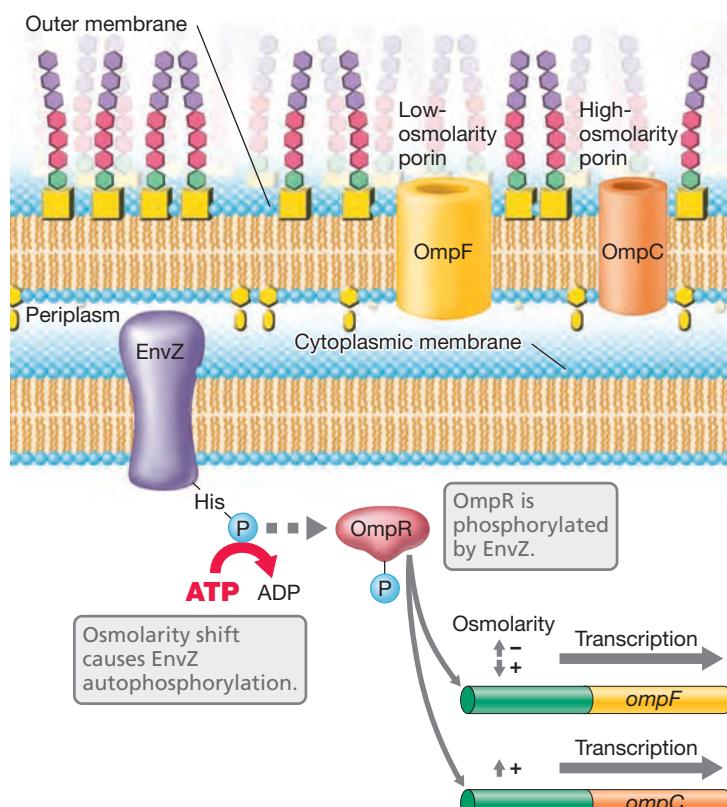

Figure 7.18 Regulation of outer membrane proteins in *Escherichia coli*. The inner membrane histidine kinase EnvZ autophosphorylates itself under osmotic pressure changes and then activates the transcriptional regulator OmpR by phosphorylation. OmpR-P binds upstream of the *ompF* gene and activates transcription under low osmotic pressure, but conversely represses transcription of *ompF* under high osmotic pressure. OmpR-P only activates transcription of the *ompC* gene under conditions of high osmolarity.

7.8 Regulation of Chemotaxis

We have previously seen that some prokaryotes can move toward attractants and away from repellents, a behavior called *chemotaxis* (► Section 2.19). We noted that prokaryotes are too small to sense spatial gradients of a chemical, but they can respond to temporal gradients. That is, they can sense the *change* in concentration of a chemical over time rather than the absolute concentration of the chemical stimulus. Prokaryotes use a modified two-component system to sense temporal changes in attractants or repellents and process this information to regulate flagellar rotation. Note that chemotaxis uses a two-component

system to regulate the activity of preexisting flagella rather than to control the transcription of genes encoding flagella.

Response to Signal

The mechanism of chemotaxis depends upon a signal cascade of multiple proteins. Several sensory proteins reside in the cytoplasmic membrane and sense the presence of attractants and repellents. These sensor proteins are not themselves sensor kinases but interact with cytoplasmic sensor kinases. These sensory proteins allow the cell to monitor the concentration of various substances over time.

The sensory proteins are called *methyl-accepting chemotaxis proteins* (MCPs). *Escherichia coli* possesses five different transmembrane protein MCPs, each specific for certain compounds. For example, the Tar MCP of *E. coli* senses the attractants aspartate and maltose and the repellents cobalt and nickel. MCPs bind attractants or repellents directly or in some cases indirectly through interactions with periplasmic binding proteins. Binding of an attractant or repellent triggers interactions with cytoplasmic proteins that eventually affect flagellar rotation.

MCPs make contact with the cytoplasmic proteins CheA and CheW (Figure 7.19). CheA is the sensor kinase for chemotaxis. When an MCP binds a chemical, it changes conformation and, with help from CheW, leads to the autophosphorylation of CheA.

to form CheA-P. Attractants *decrease* the rate of autophosphorylation, whereas repellents *increase* this rate. CheA-P then passes the phosphate to CheY (forming CheY-P); this is the response regulator that controls flagellar rotation. CheA-P can also transfer the phosphate to CheB, which plays a role in adaptation described later.

Controlling Flagellar Rotation

CheY is a central protein in the system because it governs the direction of rotation of the flagellum. Recall that if rotation of the flagellum is counterclockwise, the cell will continue to move in a run, whereas if the flagellum rotates clockwise, the cell will tumble (Section 2.19). Once CheY is phosphorylated, CheY-P interacts with the flagellar motor to induce clockwise flagellar rotation, which causes tumbling (Figure 7.19). When unphosphorylated, CheY cannot bind to the flagellar motor and the flagellum rotates counterclockwise; this causes the cell to run. Another protein, CheZ, dephosphorylates CheY, returning it to the form that allows runs instead of tumbles. Because repellents increase the level of CheY-P, they lead to tumbling, whereas attractants lead to a lower level of CheY-P and smooth swimming (runs).

Adaptation

Once an organism has successfully responded to a stimulus, it must stop responding and reset the sensory system to await further signals. This is known as *adaptation*. During adaptation of the chemotaxis system, a feedback loop resets the system. This relies on the response regulator CheB, mentioned earlier.

As their name implies, MCPs can be methylated. When MCPs are fully methylated they no longer respond to attractants, but are more sensitive to repellents. Conversely, when MCPs are unmethylated they respond highly to attractants, but are insensitive to repellents. Varying the methylation level thus allows adaptation to sensory signals. This is accomplished by methylation and demethylation of the MCPs by CheR and phosphorylated CheB (CheB-P), respectively (Figure 7.19).

If the level of an attractant remains high, the rate of CheA autophosphorylation is low. This leads to unphosphorylated CheY and CheB. Consequently, the cell swims smoothly. Methylation of the MCPs increases during this period because CheB-P is not present to rapidly demethylate them. However, MCPs no longer respond to the attractant when they become fully methylated. Therefore, if the level of attractant remains high but constant, the cell begins to tumble. Eventually, CheB becomes phosphorylated and CheB-P demethylates the MCPs. This resets the receptors and they can once again respond to further increases or decreases in level of attractants. Therefore the cell stops swimming if the attractant concentration is constant. It only continues to swim if even higher levels of attractant are encountered.

The course of events is just the opposite for repellents. Fully methylated MCPs respond best to an increasing gradient of repellents and send a signal for cell tumbling to begin. The cell then moves off in a random direction while MCPs are slowly demethylated. With this mechanism for adaptation, chemotaxis successfully achieves the ability to monitor small changes in the concentrations of both attractants and repellents over time.

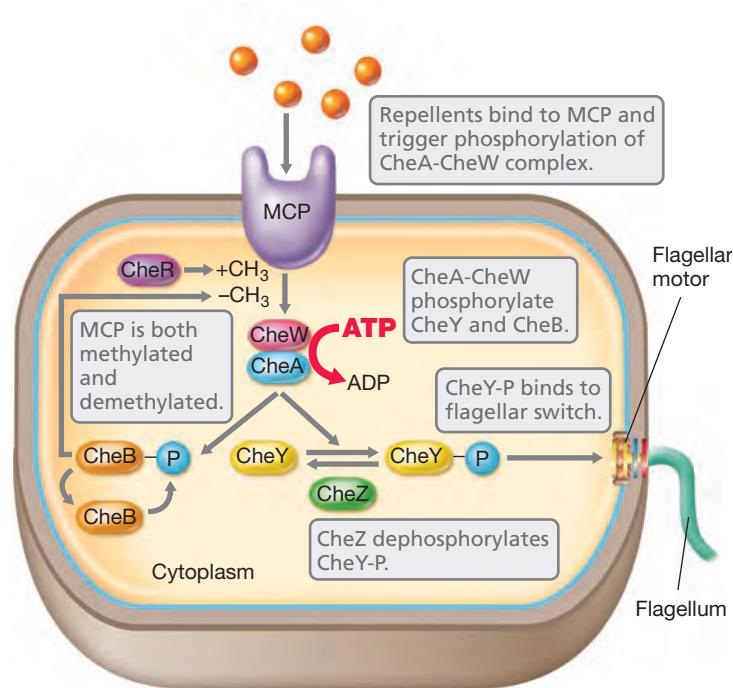

Figure 7.19 Interactions of MCPs, Che proteins, and the flagellar motor in bacterial chemotaxis. The methyl-accepting chemotaxis protein (MCP) forms a complex with the sensor kinase CheA and the coupling protein CheW. This combination triggers autophosphorylation, which can then phosphorylate the response regulators CheB and CheY. Phosphorylated CheY (CheY-P) binds to the flagellar motor switch. CheZ dephosphorylates CheY-P. CheR continually adds methyl groups to the MCP. CheB-P (but not CheB) removes them. The degree of methylation of the MCPs controls their ability to respond to attractants and repellents and leads to adaptation.

Other Taxis

In addition to chemotaxis, several other forms of taxis are known, for example, *phototaxis* (movement toward light) and *aerotaxis* (movement toward oxygen) (➡ Section 2.19). Many of the cytoplasmic Che proteins that function to control flagellar activity in chemotaxis also play a role in these other taxes. For example, in phototaxis, a light sensor protein replaces the MCPs of chemotaxis, and in aerotaxis, a redox protein monitors levels of oxygen. These sensors then interact with cytoplasmic Che proteins to direct runs or tumbles. Thus several different kinds of environmental signals converge on the same flagellar control system, and this allows the cell to economize on its regulatory systems.

MINIQUIZ

- What are the primary response regulator and the primary sensor kinase for regulating chemotaxis?
- Why is adaptation during chemotaxis important?
- How does the response of the chemotaxis system to an attractant differ from its response to a repellent?

7.9 Quorum Sensing

Many prokaryotes respond to the presence in their surroundings of other cells of their species, and in some, regulatory pathways are controlled by the density of cells of their own kind. This is a phenomenon called **quorum sensing** (the word “quorum” in this sense means “sufficient numbers”).

Mechanism of Quorum Sensing

Quorum sensing is a mechanism to assess population density. Many bacteria use this approach to ensure that sufficient cell numbers are present before initiating activities that require a certain cell density to work effectively. For example, a pathogenic (disease-causing) bacterium that secretes a toxin will have no effect as a single cell; production of toxin by one cell alone would merely waste resources. However, if a sufficiently large population of cells is present, the coordinated expression of the toxin may successfully cause disease and release resources from the host that can be used by the pathogen.

Quorum sensing is widespread among gram-negative bacteria but is also found in gram-positive bacteria. Each species that employs quorum sensing synthesizes a specific signal molecule called an **autoinducer**. This molecule usually diffuses freely across the cell envelope in either direction. Because of this, the autoinducer reaches high concentrations inside the cell only if there are many cells nearby, each making the same autoinducer. Inside the cell, the autoinducer binds to a specific transcriptional activator protein or a sensor kinase of a two-component system, ultimately triggering transcription of specific genes (Figure 7.20b).

While several different classes of autoinducers exist, the first to be identified were the *acyl homoserine lactones* (AHLs) (Figure 7.20a). Several different AHLs, with acyl groups of different lengths, are found in different species of gram-negative bacteria. In addition, many gram-negative bacteria make autoinducer 2 (AI-2; a cyclic furan derivative). This is apparently used as a common autoinducer

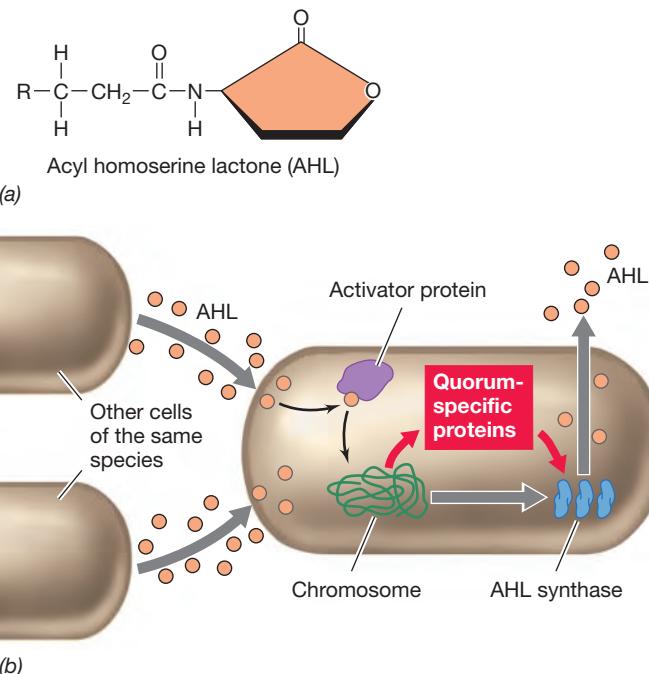

Figure 7.20 Quorum sensing. (a) General structure of an acyl homoserine lactone (AHL). Different AHLs are variants of this parent structure. R = alkyl group (C₁–C₁₇); the carbon next to the R group is often modified to a keto group (C=O). (b) A cell capable of quorum sensing expresses AHL synthase at basal levels. This enzyme makes the cell's specific AHL. When cells of the same species reach a certain density, the concentration of AHL rises sufficiently to bind to the activator protein, which activates transcription of quorum-specific genes.

between many species of bacteria. Gram-positive bacteria generally use certain short peptides as autoinducers.

The phenomenon of quorum sensing was discovered as the mechanism by which light emission in bioluminescent bacteria is regulated (➡ Section 15.4). Several bacterial species can emit light, including the marine bacterium *Aliivibrio fischeri*. Figure 7.21 shows bioluminescent colonies of *A. fischeri*. The light is generated by an enzyme called *luciferase*. The *lux* operons encode the proteins needed for bioluminescence. They are under control of the activator protein LuxR and are induced when the concentration of the specific *A. fischeri* AHL, N-3-oxohexanoyl homoserine lactone, becomes high enough. This AHL is synthesized by the enzyme encoded by the *luxI* gene.

Quorum sensing also occurs in microbial eukaryotes. For example, in the yeast *Saccharomyces cerevisiae*, specific aromatic alcohols are produced as autoinducers and control the transition between growth of *S. cerevisiae* as single cells and as elongated filaments. Similar transitions are seen in other fungi, some of which cause disease in humans. An example is *Candida*, whose quorum sensing is mediated by the long-chain alcohol farnesol. As the concentration of farnesol increases in this dimorphic fungus, the transition from budding yeast to elongated hyphae is prevented.

Virulence Factors

Various genes are controlled by quorum sensing, including some in pathogenic bacteria. For example, Shiga toxin-producing *Escherichia coli*, such as the notorious foodborne

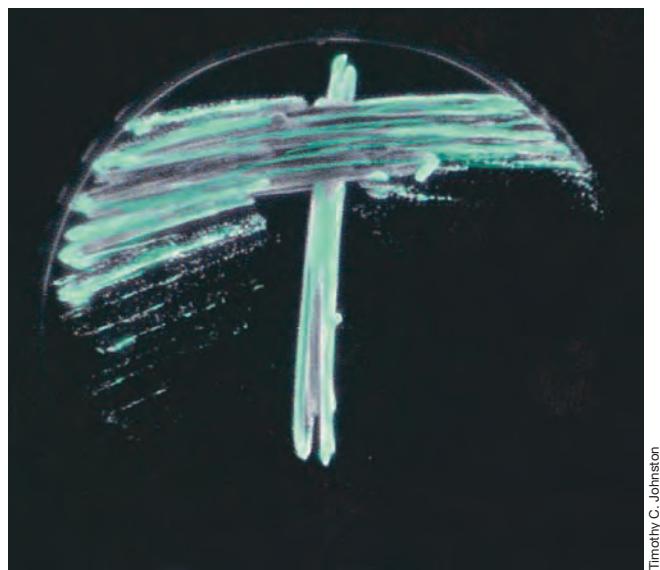

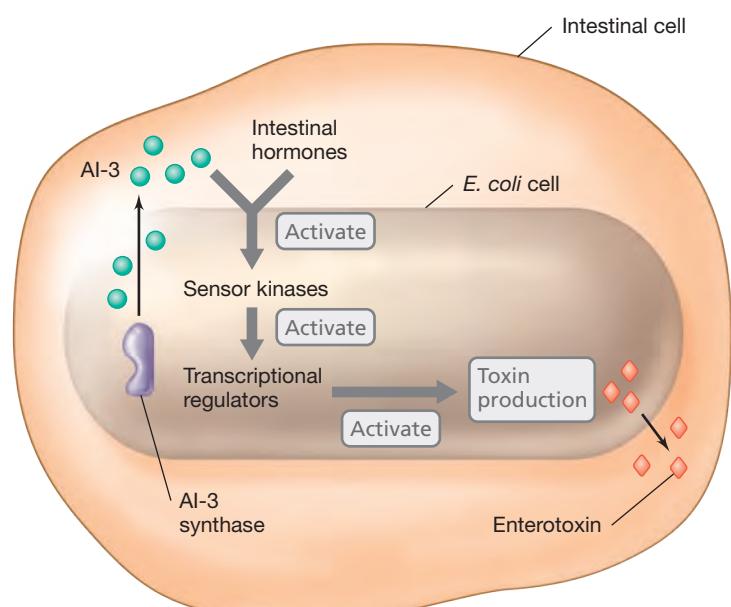

Figure 7.21 Bioluminescent bacteria producing the enzyme luciferase. Cells of the bacterium *Aliivibrio fischeri* were streaked on nutrient agar in a Petri dish and allowed to grow overnight. The photograph was taken in a darkened room using only the light generated by the bacteria.

pathogen *E. coli* O157: H7 (Section 31.11), produces an AHL called AI-3 that induces virulence genes. As the *E. coli* population increases in the intestine, bacterial cells produce AI-3 while host intestinal cells produce the stress hormones epinephrine

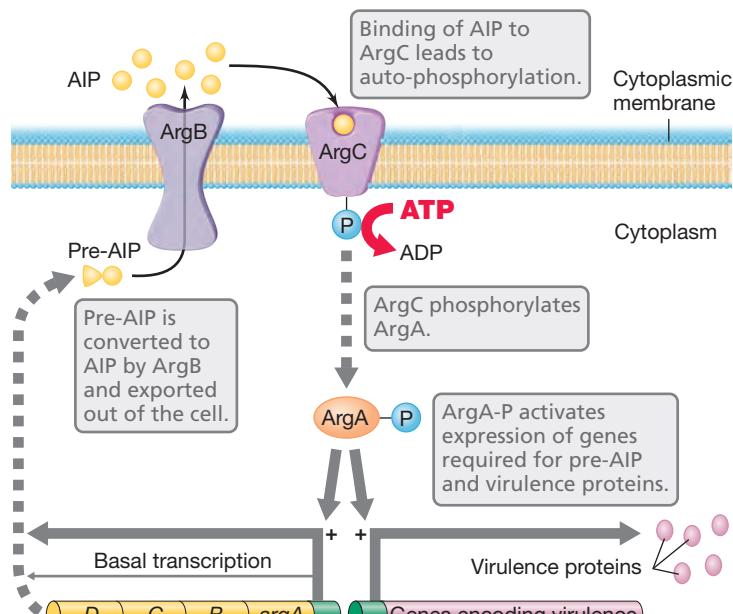

(a) Virulence factor production in Shiga toxin-producing *Escherichia coli*

Figure 7.22 Quorum sensing regulation of virulence factors. (a) As the bacterial population increases, AI-3 produced by *E. coli* and epinephrine and norepinephrine produced by the intestinal cell accumulate and bind to sensor kinases, initiating a cascade of events necessary for virulence factor

(for example, enterotoxin) production. (b) Basal level transcription of the *argABCD* operon in *Staphylococcus* leads to production of ArgD, the pre-autoinducing peptide (AIP). ArgB trims ArgD into the functional AIP and exports it out of the cell. As the cell population increases, the AIP concentration increases and binds to ArgC, leading to

and norepinephrine. All three of these signal molecules bind to two separate sensor kinases in the *E. coli* cytoplasmic membrane, resulting in the phosphorylation and activation of two transcriptional activator proteins (Figure 7.22a). These proteins activate transcription of genes encoding motility functions and secretion of the enterotoxin as well as genes encoding proteins that form lesions on the host intestinal mucosa. This is a rare example of a system that senses both bacterial and eukaryotic chemical signals to regulate gene expression.

The pathogenesis of *Staphylococcus aureus* (Section 29.9) requires, among many other things, the production and secretion of small extracellular peptides that damage host cells or that interfere with the host's immune system. The genes encoding these virulence factors are under the control of a quorum-sensing system that uses a small peptide called the *autoinducing peptide* (AIP), encoded by the *argD* gene, as the autoinducer. After synthesis of ArgD (pre-AIP), the membrane-bound ArgB protein trims the peptide into its active AIP form and secretes the small peptide outside of the cell (Figure 7.22b). As the cell density of *S. aureus* increases, so does the concentration of AIP. ArgC is a membrane-bound sensor kinase that binds to AIP, resulting in autophosphorylation. ArgC-P transfers its phosphate to the transcriptional activator ArgA. ArgA-P increases transcription of *argABCD* genes that encode the signal transduction system as well as an RNA molecule that controls production of a range of virulence proteins.

(b) Virulence factor production in *Staphylococcus*

autophosphorylation of ArgC. ArgC-P then activates the transcriptional activator ArgA by transfer of a phosphate group. ArgA-P increases transcription of the *argABCD* operon as well as activating the transcription of an RNA that leads to the production of virulence proteins.

Some eukaryotes produce molecules that specifically interfere with bacterial quorum sensing. Thus far, most of these have been furanone derivatives containing a halogen atom. These components mimic the AHLs or AI-2 and disrupt bacterial behavior that relies on quorum sensing. Quorum-sensing disruptors have been proposed as potential drugs to disperse bacterial biofilms and prevent the expression of virulence genes.

Biofilm Formation

Numerous signals, including cell-to-cell communication, lead to bacteria transitioning from growing freely suspended in liquid (planktonic growth) to growing in a semisolid matrix called a *biofilm* (☞ Section 19.4 and Explore the Microbial World, “Stick or Swim,” in Chapter 5). *Pseudomonas aeruginosa* forms a biofilm by producing specific polysaccharides that subsequently increase its pathogenicity and prevent the penetration of antibiotics. Quorum sensing triggers expression of a subset of the genes necessary for biofilm formation (Figure 7.23). Cells of *P. aeruginosa* possess two separate quorum-sensing systems, Las and Rhl, that respond to specific AHLs and activate the transcription of genes encoding exopolysaccharide synthesis as cell number increases.

Intracellular signaling also plays a role in *P. aeruginosa* biofilm formation. One of the secondary messages important in biofilm architecture is the regulatory nucleotide *cyclic di-guanosine monophosphate* (c-di-GMP). While regulatory nucleotides play an important role in all domains of life (Section 7.5), cyclic di-GMP

is only produced by prokaryotes. In fact, prokaryotic genomes encode various proteins that both synthesize and catabolize cyclic di-GMP. The synthesis or degradation of cyclic di-GMP depends on both environmental and cellular cues, and its synthesis leads to numerous physiological changes and the expression of virulence genes. Effector proteins that bind cyclic di-GMP participate in diverse activities such as exopolysaccharide production, motility, transcriptional regulation, and protein localization (both secretion and cell surface). Cyclic di-GMP also binds small regulatory RNA molecules called riboswitches (Section 7.15).

In many bacteria the formation of biofilms is triggered by the accumulation of cyclic di-GMP in the cell. Biofilm formation in *P. aeruginosa*, a notorious biofilm producer, is assisted by the synthesis of an exopolysaccharide called Pel. Pel is produced by the cyclic di-GMP receptor protein PelD and functions as both a primary scaffold for the microbial community and a mechanism for resisting antibiotics. Similarly, expression of flagellum biosynthesis genes in *P. aeruginosa* is under positive control of the cyclic di-GMP-binding protein FleQ. Flagella help mediate the attachment of *P. aeruginosa* cells during the initial stages of biofilm formation.

MINIQUIZ

- What properties are required for a molecule to function as an autoinducer?
- How do the autoinducers used in quorum sensing by gram-negative bacteria differ from those used by gram-positive bacteria?
- Besides autoinducer synthesis, what intracellular molecule promotes biofilm formation in many bacteria?

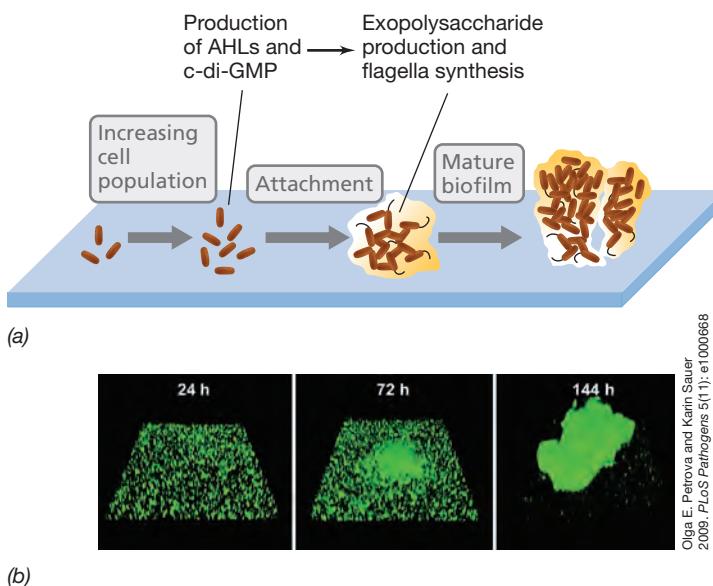

Figure 7.23 Biofilm formation in *Pseudomonas*. (a) Sequence of events leading to biofilm formation in *P. aeruginosa*. As the cell population increases, so does production of the signal molecules AHL (acyl homoserine lactones) and c-di-GMP. These signal molecules participate in activating the synthesis of exopolysaccharides and flagella necessary for full biofilm formation. (b) Confocal scanning laser microscopy showing the progression of *P. aeruginosa* biofilm formation over a 144-h period. Cells are stained with the LIVE/DEAD viability stain, which stains live cells green (☞ Figure 18.7). Each rectangular pattern of cells is about 0.2 mm wide. The mature biofilm is about 0.1 mm wide and 60 µm high. Data adapted from Petrova, O.E., and K. Sauer. 2009. A novel signaling network essential for regulating *Pseudomonas aeruginosa* biofilm development. *PLoS Pathogens* 5(11): e1000668.

7.10 Other Global Control Networks

Catabolite repression (Section 7.5) and quorum sensing (Section 7.9) are both examples of *global control*. There are several other global control systems in *Escherichia coli* (and probably in all prokaryotes), and a few of these are listed in Table 7.2. Global control systems regulate many genes comprising more than one regulon (Section 7.4). Global control networks may include activators, repressors, signal molecules, two-component regulatory systems, regulatory RNA (Section 7.14), and alternative sigma (σ) factors (☞ Section 4.7).

An example of a global response that is widespread in all three domains of life is the response to high temperature. In many bacteria this **heat shock response** is largely controlled by alternative σ factors.

Heat Shock Proteins

Most proteins are relatively stable, even to small increases in temperature. However, some proteins are less stable at elevated temperatures and tend to unfold (denature). Improperly folded proteins are recognized by protease enzymes and are degraded. Consequently, cells that experience heat stress induce the synthesis of a set of proteins—the **heat shock proteins**—that help counteract the damage. Heat shock proteins assist the cell in recovering from stress. They are induced not only by heat but

Table 7.2 Examples of global control systems known in *Escherichia coli*^a

System	Signal	Primary activity of regulatory protein	Number of genes regulated
Aerobic respiration	Presence of O ₂	Repressor (ArcA)	>50
Anaerobic respiration	Lack of O ₂	Activator (FNR)	>70
Catabolite repression	Cyclic AMP level	Activator (CRP)	>300
Heat shock	Temperature	Alternative sigma factors (RpoH and RpoE)	36
Nitrogen utilization	NH ₃ limitation	Activator (NRI)/alternative sigma factor (RpoN)	>12
Oxidative stress	Oxidizing agents	Activator (OxyR)	>30
SOS response	Damaged DNA	Repressor (LexA)	>20

^aFor many of the global control systems, regulation is complex. A single regulatory protein can play more than one role. For instance, the regulatory protein for aerobic respiration is a repressor for many promoters but an activator for others, whereas the regulatory protein for anaerobic respiration is an activator protein for many promoters but a repressor for others. Regulation can also be indirect or require more than one regulatory protein. Many genes are regulated by more than one global system.

also by several other stress factors that the cell may encounter. These include exposure to high levels of certain chemicals, such as ethanol, and exposure to high doses of ultraviolet (UV) radiation.

In *E. coli* and in most prokaryotes examined, there are three major classes of heat shock protein: Hsp70, Hsp60, and Hsp10. We have encountered these proteins before, although not by these names (Section 4.14 and Figure 4.41). The Hsp70 protein of *E. coli* is DnaK, which prevents aggregation of newly synthesized proteins and stabilizes unfolded proteins. Major representatives of the Hsp60 and Hsp10 families in *E. coli* are the proteins GroEL and GroES, respectively. These are *molecular chaperones* that catalyze the correct refolding of misfolded proteins. Another class of heat shock proteins includes various proteases that degrade denatured or irreversibly aggregated proteins.

Heat Shock Response

In many bacteria, such as *E. coli*, the heat shock response is controlled by the alternative σ factors RpoH (σ^{32}) and RpoE (Figure 7.24). RpoH controls expression of heat shock proteins in the cytoplasm, and RpoE regulates the expression of a different set of heat shock proteins that function in the periplasm and cell envelope. RpoH is normally degraded within a minute or two of its synthesis. However, when cells suffer a heat shock, degradation of RpoH is inhibited and its level therefore increases. Consequently, transcription of those operons whose promoters are recognized by RpoH increases too. The rate of degradation of RpoH depends on the level of free DnaK protein, which inactivates RpoH. In unstressed cells, the level of free DnaK is relatively high and the

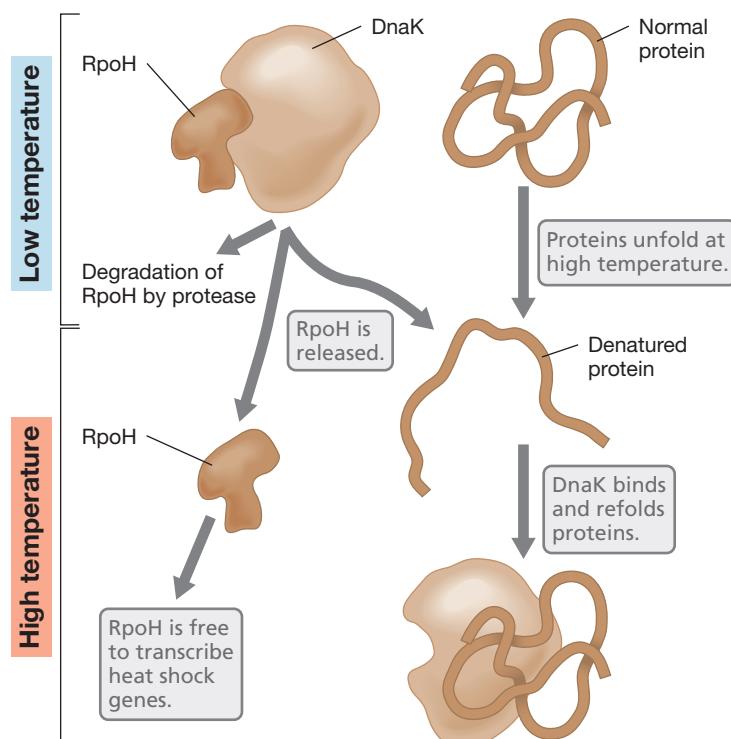

Figure 7.24 Control of heat shock in *Escherichia coli*. The RpoH alternative sigma factor is broken down rapidly by proteases at normal temperatures. This is stimulated by binding of the DnaK chaperonin to RpoH. At high temperatures, some proteins are denatured, and DnaK recognizes, binds, and refolds these unfolded polypeptide chains. This removes RpoH from DnaK, which slows the degradation rate. When the level of RpoH rises, the heat shock genes are transcribed.

level of intact RpoH is correspondingly low. However, if heat begins to unfold proteins, DnaK binds preferentially to unfolded proteins and so is no longer free to promote degradation of RpoH. Thus, the more denatured proteins there are, the lower the level of free DnaK and the higher the level of RpoH; the result is heat shock gene expression. When the stress situation has passed, for example, upon a temperature downshift, RpoH is once again inactivated by DnaK, and the synthesis of heat shock proteins is greatly reduced.

Because heat shock proteins perform vital functions in the cell, there is always a low level of these proteins present, even under optimal conditions. However, the rapid synthesis of heat shock proteins in stressed cells emphasizes their importance for surviving exposure to excessive heat, chemicals, or physical agents. Such stresses can generate large amounts of inactive proteins that need to be refolded (and in the process, reactivated) or degraded to release free amino acids for the synthesis of new proteins.

There is also a heat shock response in *Archaea*, even in species that grow best at very high temperatures. An analog of the bacterial Hsp70 is found in many *Archaea* and is structurally quite similar to that found in gram-positive species of *Bacteria*. Hsp70 is also present in eukaryotes. In addition, other types of heat shock proteins are present in *Archaea* that are unrelated to stress proteins of *Bacteria*.

Cold can also be a stressor. One problem faced by all cells during cold shock is that RNA, including mRNA, tends to form stable secondary structures, especially stem-loop structures, that may interfere with translation. To counter this, cold shock proteins are present that include several RNA-binding proteins. Some of these prevent RNA secondary structure formation and others (RNA helicases) unwind base-paired regions in RNA.

MINIQUIZ

- What triggers the heat shock response?
- Why do cells have more than one type of σ factor?
- Why might the proteins induced during heat shock not be needed during cold shock?

IV • Regulation of Development in Model Bacteria

Differentiation and development are largely characteristics of multicellular organisms. Because most prokaryotes grow as single cells, few show differentiation. Nonetheless, occasional examples among single-celled prokaryotes illustrate the basic principle of differentiation, namely that one cell gives rise to two genetically identical descendants that perform different roles and must therefore express different sets of genes. Here we discuss three well-studied examples: the formation of endospores in the gram-positive bacterium *Bacillus*; the formation of two cell types, motile and stationary, in the gram-negative bacterium *Caulobacter*; and the formation of heterocysts in the nitrogen-fixing cyanobacterium *Anabaena*.

Although forming just two different cell types may seem superficially simple, the regulatory systems that control these processes are highly complex. There are three major phases for the regulation of differentiation: (1) triggering the response, (2) development of the differentiated cell, and (3) reciprocal communication between the two differentiating and undifferentiated cells.

7.11 Sporulation in *Bacillus*

Many microorganisms, both prokaryotic and eukaryotic, respond to adverse conditions by converting growing cells, called *vegetative cells*, into spores (☞ Section 2.16). Once favorable conditions return, the spore germinates and the microorganism returns to its normal lifestyle. Among the *Bacteria*, the genus *Bacillus* is well known for the formation of *endospores*, that is, spores formed inside a mother cell. Prior to endospore formation, the cell divides asymmetrically. The smaller cell develops into the endospore, which is surrounded by the larger mother cell. Once development is complete, the mother cell bursts, releasing the endospore.

Endospore Formation

Endospore formation in *Bacillus subtilis* is triggered by unfavorable conditions, such as starvation, desiccation, or growth-inhibitory temperatures. Various conditions in the environment are monitored by a group of five sensor kinases. These function via a phosphotransfer relay system whose mechanism resembles that of a two-component regulatory system (Section 7.7) but is considerably more complex (Figure 7.25). The net result of multiple adverse conditions is the successive phosphorylation of several proteins called *sporulation factors*, culminating with sporulation factor Spo0A. When Spo0A is highly phosphorylated, sporulation proceeds. Spo0A controls the expression of several genes. The product of one of these, SpoIIE, is responsible for removing the phosphate from SpoIIAA. This allows SpoIIAA in turn

to remove an anti-sigma factor, SpoIIB, and liberate the sigma factor, σ F, as discussed below.

Once triggered, endospore development is controlled by four different σ factors, two of which, σ F and σ G, activate genes needed inside the developing endospore itself, and two of which, σ E and σ K, activate genes needed in the mother cell surrounding the endospore (Figure 7.25b). The sporulation signal, transmitted via Spo0A, activates σ F in the smaller cell that is destined to become the endospore (σ F is already present but is inactive, as it is bound by an anti-sigma factor, Figure 7.25a). Once free, σ F binds to RNA polymerase and promotes transcription (inside the prespore) of genes whose products are needed for the next stage of sporulation. These include the gene encoding the sigma factor σ G and the genes for proteins that cross into the mother cell and activate σ E. Active σ E is required for transcription of yet more genes inside the mother cell, including the gene for σ K. The sigma factors σ G (in the endospore) and σ K (in the mother cell) are required for transcription of genes needed even later in the sporulation process (Figure 7.25). Eventually, the many spore coats and other unique structures typical of the endospore (☞ Section 2.16 and Table 2.3) are formed, and the mature spore is released.

Nutrients for Endospore Formation

Nutrient limitation is a common trigger of sporulation in *Bacillus* (☞ Section 2.16). In such a case, how do cells obtain sufficient nutrients to complete the formation of endospores? One fascinating aspect of the regulation of endospore formation is another regulatory event in which sporulating cells cannibalize their own species. Those cells in which Spo0A has already become activated secrete a protein that lyses nearby cells whose Spo0A protein has not yet become activated. This toxic protein is accompanied by a second protein that delays sporulation of neighboring cells. Cells committed to sporulation also make an antitoxin protein to protect themselves against the effects of their own toxin. When lysed, their sacrificed sister cells are used as a source of nutrients for developing endospores. Shortages of certain nutrients, in particular phosphate, increase transcription of the toxin-encoding gene.

MINIQUIZ

- How are different sets of genes expressed in the developing endospore and the mother cell?
- What is an anti-sigma factor and how can its effect be overcome?

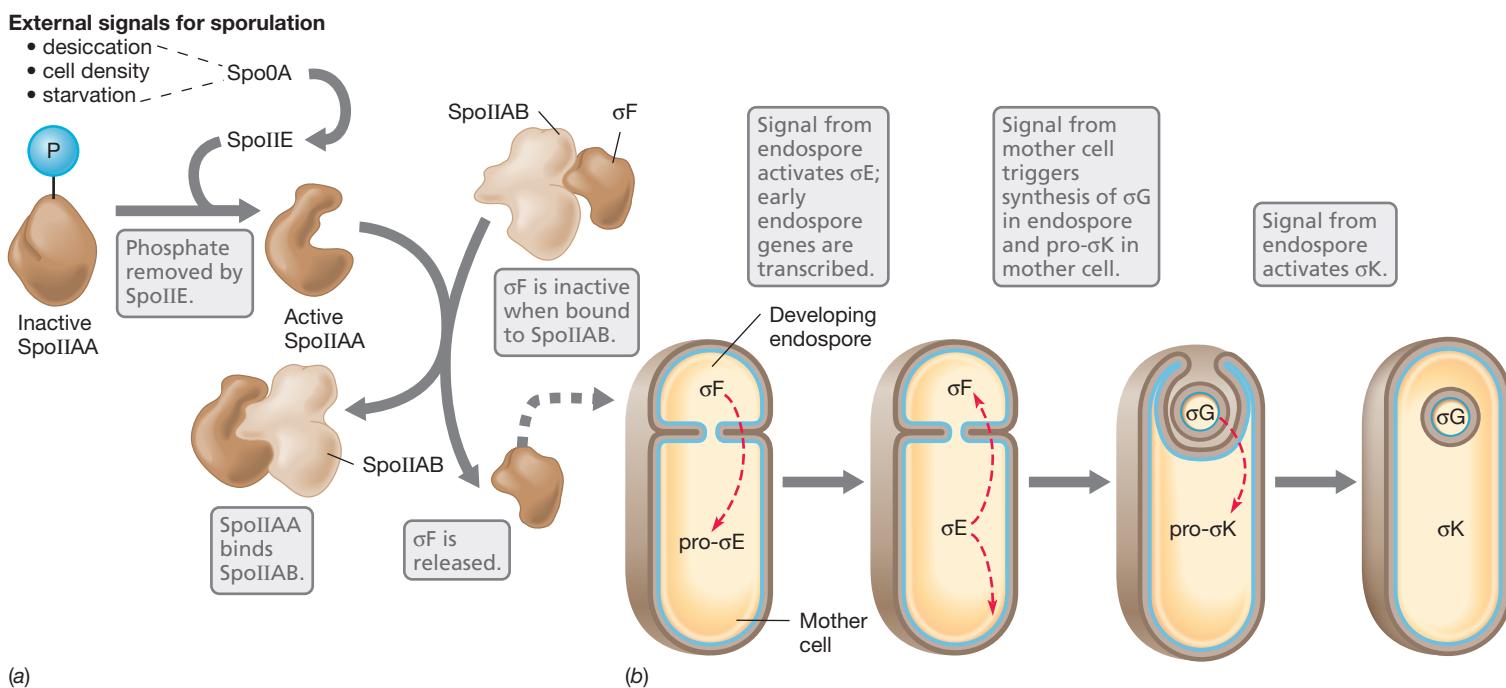

Figure 7.25 Control of endospore formation in *Bacillus*. After an external signal is received, a cascade of sigma (σ) factors controls differentiation. (a) Active SpoIIAA binds the anti- σ factor SpoIIB, thus liberating the first σ factor, σ F. (b) σ F initiates a cascade of sigma factors, some of which already exist and need to be activated, others of which are not yet present and whose genes must be expressed. These σ factors then promote transcription of genes needed for endospore development.

7.12 Caulobacter Differentiation

The gram-negative bacterium *Caulobacter* provides another example in which a cell divides into two genetically identical daughter cells that are structurally distinct and perform different roles and express different sets of genes. *Caulobacter* is a species of *Proteobacteria* that is common in aquatic environments, typically in waters that are nutrient-poor (oligotrophic, [Section 19.8](#)). In the *Caulobacter* life cycle, free-swimming (swarmer) cells alternate with cells that lack flagella and are attached to surfaces by a stalk with a holdfast at its end. The role of the swarmer cells is dispersal, as swarmers cannot divide or replicate their DNA. Conversely, the role of the stalked cell is reproduction ([Figure 7.26](#)).

Regulatory Features

The *Caulobacter* cell cycle is controlled by three major regulatory proteins whose concentrations oscillate in succession. Two of these are the transcriptional regulators, GcrA and CtrA. The third is DnaA, a protein that functions both in its normal role in initiating DNA replication and also as a transcriptional regulator. Each of these regulators is active at a specific stage in the cell cycle, and each controls many other genes that are needed at that particular stage in the cycle.

CtrA is activated by phosphorylation in response to external signals. Once phosphorylated, CtrA-P activates genes needed for the synthesis of the flagella and other functions in swarmer cells. Conversely, CtrA-P represses the synthesis of GcrA and also inhibits the initiation of DNA replication by binding to and blocking the origin of replication ([Figure 7.26](#)). As the cell cycle proceeds, CtrA is degraded by a specific protease; as a consequence, levels of DnaA

rise. The absence of CtrA-P allows access to the chromosomal origin of replication, and, as in all *Bacteria*, DnaA binds to the origin and triggers the initiation of DNA replication ([Section 4.5](#)). In addition, *Caulobacter* DnaA activates several other genes needed for chromosomal replication. The level of DnaA then falls due to protease degradation, and the level of GcrA rises. The GcrA regulator promotes the elongation phase of chromosome replication, cell division, and the growth of the stalk on the immobile daughter cell. Eventually, GcrA levels fall and high levels of CtrA reappear (in the daughter cell destined to swim away) ([Figure 7.26](#)).

Caulobacter as a Model for the Eukaryotic Cell Cycle

Both external stimuli and internal factors such as nutrient and metabolic levels result in the precise coordination of morphological and metabolic events within the *Caulobacter* cell cycle. Since its genome has been sequenced and good genetic systems for gene transfer and analysis are available, differentiation in *Caulobacter* has been used as a model system for studying cell developmental processes in other organisms as well. This focus is due to the strict cell cycle followed by *Caulobacter*, which resembles that of eukaryotic cells in many respects. In fact, terminology used to describe the eukaryotic cell cycle has been adapted to the *Caulobacter* system.

In eukaryotic cells, phase G1 of cell division is where growth and normal metabolic events occur while in phase G2 the cell prepares for subsequent mitotic events, which occur in the M phase. Between G1 and G2 is the S phase, where DNA replication occurs. In the *Caulobacter* life cycle there is no mitosis, of course, but analogs of the G1, G2, and S phases are apparent ([Figure 7.26](#)), and these make this bacterium an excellent model for studying cell division events in higher organisms.

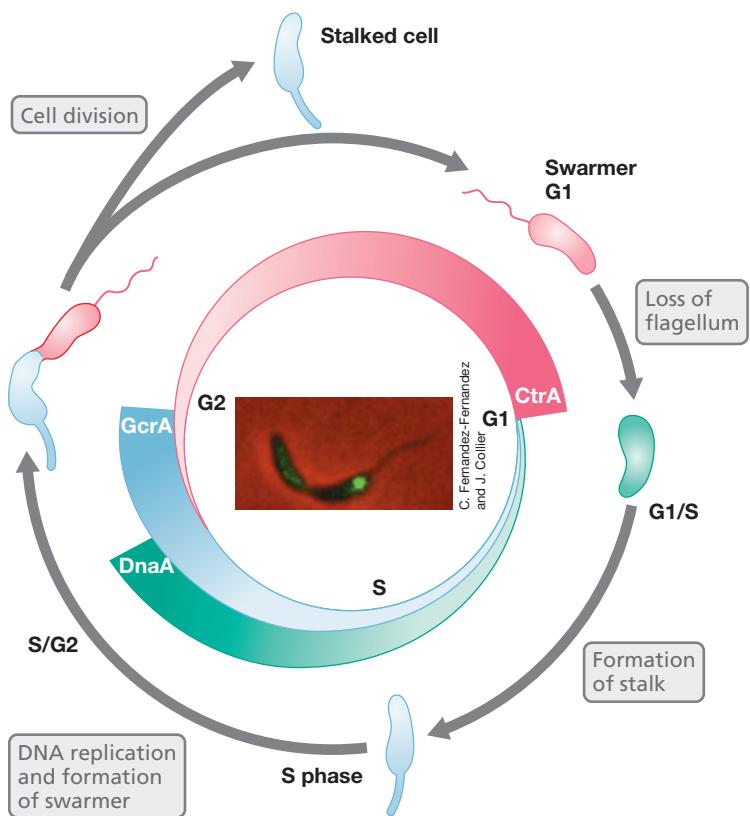

Figure 7.26 Cell cycle regulation in *Caulobacter*. Three global regulators, CtrA, DnaA, and GcrA, oscillate in levels through the cycle as shown. G1 and G2 are the two growth phases and S is the DNA synthesis phase. In G1 swarmer cells, CtrA represses initiation of DNA replication and expression of GcrA. At the G1/S transition, CtrA is degraded and DnaA levels rise. DnaA binds to the origin of replication and initiates replication (see inset photo). GcrA also rises and activates genes for cell division and DNA synthesis. At the S/G2 transition, CtrA levels begin to rise again and shut down GcrA expression. GcrA levels slowly decline in the stalked cell but are rapidly degraded in the swarmer. CtrA is degraded in the stalked cell. Inset: Using a fusion to the green fluorescent protein as a reporter (Section 7.1), a subunit of DNA polymerase is localized in the end of the stalked *Caulobacter* cell where DNA replication occurs. Each cell of the dividing *Caulobacter* pair is about 2 μm long.

MINIQUIZ

- Why are the levels of DnaA protein controlled during the *Caulobacter* cell cycle?
- When do the regulators CtrA and GcrA carry out their main roles during the *Caulobacter* life cycle?

7.13 Nitrogen Fixation, Nitrogenase, and Heterocyst Formation

Nitrogen fixation is the process of reducing N_2 to NH_3 for incorporation into biological molecules. Nitrogen fixation is catalyzed by the enzyme *nitrogenase*, which is composed of two proteins, *dinitrogenase* and *dinitrogenase reductase* (Section 3.17). Because the process of N_2 fixation is highly energy demanding, the synthesis and activity of nitrogenase and the many other enzymes required for N_2 fixation are highly regulated. Nitrogenase is also inactivated by oxygen; therefore, it would be wasteful to synthesize the enzyme under aerobic conditions.

Some filamentous cyanobacteria, such as the genera *Anabaena* and *Nostoc*, are able to fix nitrogen even though they produce oxygen during photosynthesis. To avoid this incompatibility, these cyanobacteria undergo a developmental process that forms dedicated nitrogen-fixing cells called *heterocysts* at regular intervals along a filament (see Figure 7.28a). Heterocysts are anoxic and lack photosystem II, the series of reactions that lead to O_2 production. Heterocysts arise from the differentiation of vegetative cells that perform normal photosynthesis (Section 14.2). The development of heterocysts is a coordinated process that requires both monitoring external conditions as well as cell-to-cell signaling. We begin our discussion with the regulation of nitrogenase and end with heterocyst development.

Regulation of Nitrogenase Synthesis

While the chemoorganotrophic bacterium *Klebsiella pneumoniae* does not form heterocysts, the regulation of its nitrogenase has been well studied and will be our focus here. The genes for nitrogen fixation form a regulon (Section 7.4) called the *nif regulon*, which spans 24 kilobase pairs of DNA and contains 20 genes arranged in operons such that genes whose products have similar functions are cotranscribed (Figure 7.27). In addition to nitrogenase structural genes, the genes for FeMo-co synthesis (FeMo-co is a cofactor needed for nitrogenase functions, Section 3.17), genes controlling the electron transport proteins, and a number of regulatory genes are also present in the *nif* regulon. Within the regulon, dinitrogenase is encoded by the *nifD* and *nifK* genes, while dinitrogenase reductase is encoded by the *nifH* gene. FeMo-co is encoded by several genes, including *nifN*, *V*, *Z*, *W*, *E*, *B*, and *Q*.

Nitrogenase is subject to strict regulatory controls. Nitrogen fixation is repressed by O_2 and by fixed forms of nitrogen, including NH_3 , NO_3^- , and certain amino acids. A major part of this regulation occurs in the expression of *nif* structural genes, whose transcription is activated by the *positive* regulator NifA (Figure 7.27). By contrast, NifL is a *negative* regulator of *nif* gene expression and contains a molecule of FAD (recall that FAD is a redox coenzyme for flavoproteins, Section 3.10) that functions as an O_2 sensor. In the presence of sufficient O_2 , NifL FAD is oxidized and the protein can then repress transcription of other *nif* genes; this prevents synthesis of the oxygen-labile nitrogenase.

Ammonia prevents nitrogen fixation through a second protein, called NtrC, whose genes are not part of the *nif* operon. NtrC activity is regulated by the nitrogen status of the cell. When NH_3 is limiting, NtrC is active and promotes transcription of *nifA*. This encodes NifA, the nitrogen fixation activator protein, and *nif* gene transcription begins. The NH_3 produced by nitrogenase (Figure 3.33) does not itself prevent enzyme synthesis because it is incorporated into amino acids and used in biosynthesis soon after it is made. But when NH_3 is in excess (as in natural environments or culture media high in NH_3), nitrogenase synthesis is repressed. In this way, ATP is not wasted in making ammonia when it is already available in ample amounts.

Heterocyst Formation

Heterocyst formation in filamentous cyanobacteria requires numerous morphological and metabolic changes that are regulated

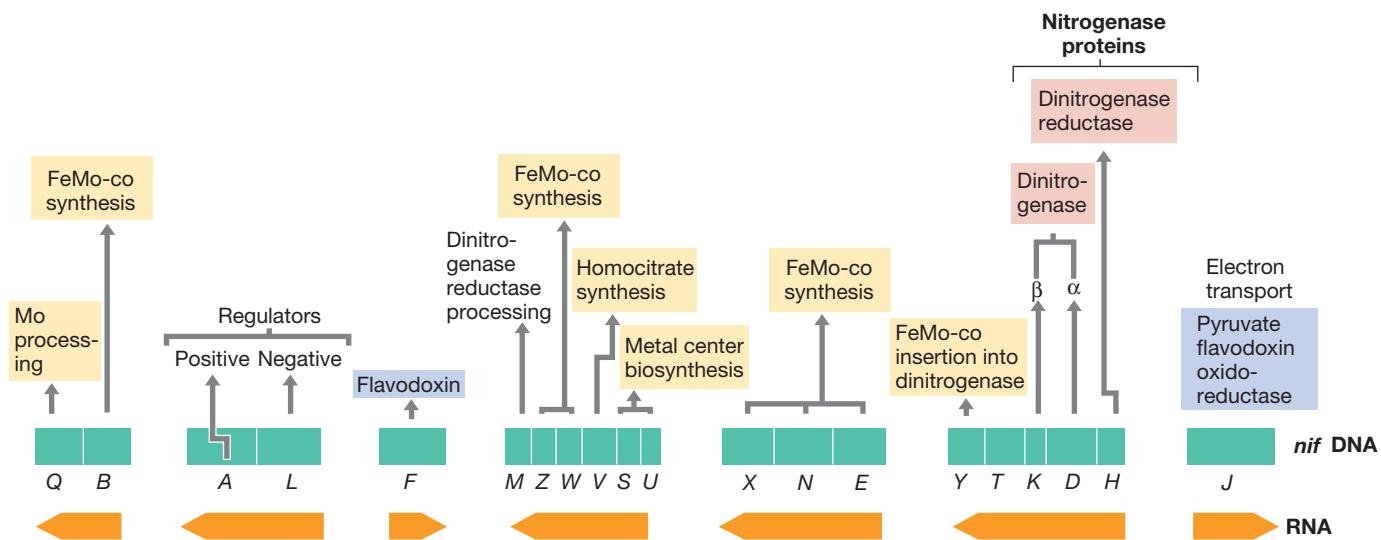

Figure 7.27 The *nif* regulon in *Klebsiella pneumoniae*, the best-studied nitrogen-fixing bacterium. The function of the *nifT* gene product is unknown. The mRNA transcripts are shown below the genes; arrows indicate the direction of transcription. Proteins that catalyze FeMo-co synthesis are shown in yellow.

by a network of systems that sense both external conditions and intracellular signaling molecules. These processes include formation of a thickened envelope to prevent O₂ diffusion into the cell, inactivation of photosystem II, expression of nitrogenase, and “patterning” of heterocyst differentiation along the filament (Figure 7.28a). Because nutrients can be exchanged between heterocysts and adjacent vegetative cells, other regulatory steps must be initiated to prevent nearby vegetative cells from undergoing the developmental process.

The cascade of events leading to heterocyst formation is initiated by nitrogen limitation, which is sensed as an elevation in levels of α-ketoglutarate, the acceptor molecule for formation of glutamate, in the cell. When the cell is nitrogen starved, α-ketoglutarate accumulates and activates the transcriptional

global regulator NtcA. NtcA then activates transcription of the *hetR* gene, which encodes HetR, the major transcriptional regulator controlling heterocyst formation. HetR activates a cascade of genes necessary for differentiation of the heterocyst, expression of cytochrome *c* oxidases to remove O₂, as well as expression of the *nif* operon (Figure 7.27) for synthesis of nitrogenase (Figure 7.28c).

Heterocyst development in *Anabaena* is triggered by nitrogen starvation, and only specific cells within the filament form heterocysts. Interestingly, this occurs in a fairly consistent pattern (Figure 7.28a) and is under strict control. Intercellular connections between cells in an *Anabaena* filament allow vegetative cells to provide fixed carbon to the heterocyst (as an electron donor for N₂ fixation) in exchange for fixed nitrogen. However, the cell connections also allow for intercellular communication by regulatory

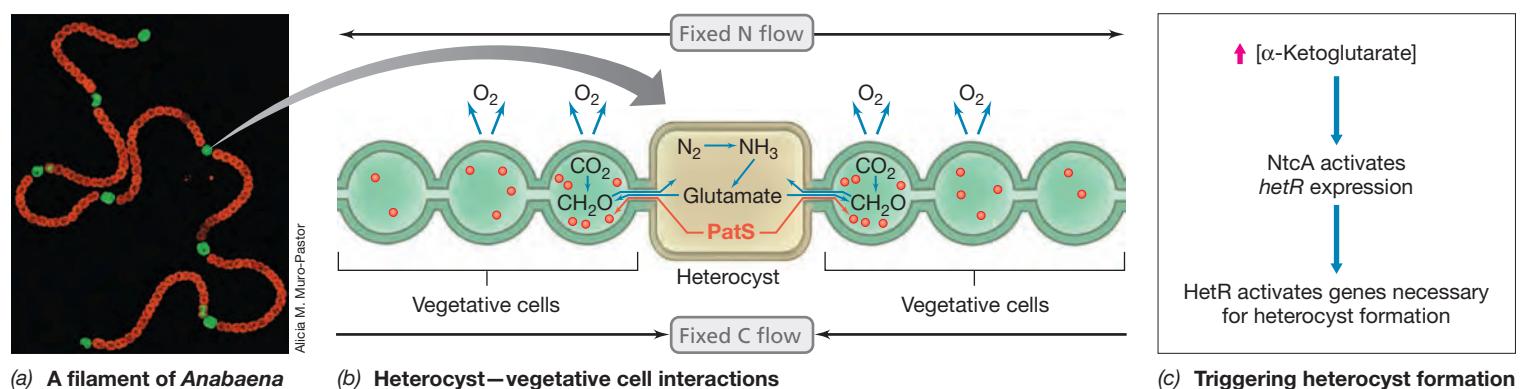

Figure 7.28 Regulation of heterocyst formation. (a) Fluorescence microscopy showing *Anabaena* filaments expressing the green fluorescent protein linked to heterocyst-specific genes; vegetative cells are red from chlorophyll *a* fluorescence. (b) Molecule dispersion in heterocysts. Fixed carbon from photosynthesis in the vegetative cells is transferred to the heterocyst, while fixed nitrogen produced in the heterocyst is shared with the vegetative cells. The protein PatS, which is synthesized by heterocysts, is also dispersed to neighboring vegetative cells where it inhibits expression of genes necessary for heterocyst formation. (c) Cascade of events in the activation of genes necessary for heterocyst formation. The cascade is initiated by an increase in α-ketoglutarate concentration.

molecules. In this regard, differentiating cells produce a small peptide called PatS that diffuses away from the developing heterocyst to form a gradient along the vegetative cells in the filament (Figure 7.28b). PatS is believed to inhibit differentiation in vegetative cells by preventing HetR from activating genes necessary for heterocyst formation. A second regulator called PatA, a response regulator analogous to the chemotaxis response regulator CheY

(Figure 7.19), also participates in heterocyst pattern development. PatA promotes the activity of HetR, decreases the activity of PatS, and may also participate in cell division.

While other regulatory links in heterocyst formation are still under study, the differentiation of vegetative cells to heterocysts in heterocystous cyanobacteria is a unique example of multicellular patterning in prokaryotes.

V • RNA-Based Regulation

Thus far we have focused on regulatory mechanisms in which proteins sense signals or bind to DNA. In some cases a single protein does both; in other cases, separate proteins carry out these two activities. Nonetheless, all of these mechanisms rely on regulatory *proteins*. However, in some cases *RNA* can regulate gene expression, both at the level of transcription and at the level of translation.

RNA molecules that are not translated to give proteins are collectively known as **noncoding RNA (ncRNA)**. This category includes the rRNA and tRNA molecules that participate in protein synthesis and the RNA present in the signal recognition particle that catalyzes some types of protein secretion (Section 4.14). Noncoding RNA also includes small RNA molecules necessary for RNA processing, especially the splicing of mRNA in eukaryotes. *Small RNAs* (sRNAs) that range from approximately 40–400 nucleotides long and regulate gene expression are widely distributed in both prokaryotes and eukaryotes. In *Escherichia coli*, for example, a number of sRNA molecules regulate various aspects of cell physiology in response to environmental or cellular signals by binding to other RNAs or in some cases to other small molecules; the end result is control of gene expression.

7.14 Regulatory RNAs: Small RNAs and Antisense RNA

Small RNAs (sRNAs) exert their effects by base-pairing directly to other RNA molecules, usually mRNAs, which have regions of complementary sequence. This binding immediately modulates the rate of target mRNA translation because a ribosome cannot translate double-stranded RNA. Thus, sRNAs provide an additional mechanism to regulate a protein's synthesis once its corresponding mRNA has already been transcribed.

Mechanisms of sRNA Activity

Small RNAs alter the translation of their mRNA target by four distinct mechanisms (Figure 7.29). Some sRNAs will base-pair to their target mRNA, changing its secondary structure to either block a previously accessible ribosome-binding site (RBS) (Section 4.11) or to open up a previously blocked RBS, allowing access for the ribosome. These two events decrease or increase expression of the protein encoded by the target mRNA, respectively. The other two mechanisms of sRNA interaction affect mRNA

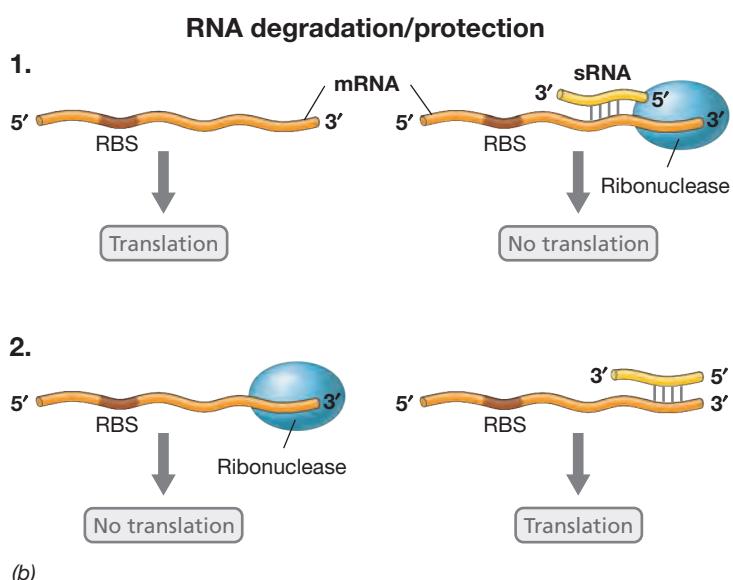

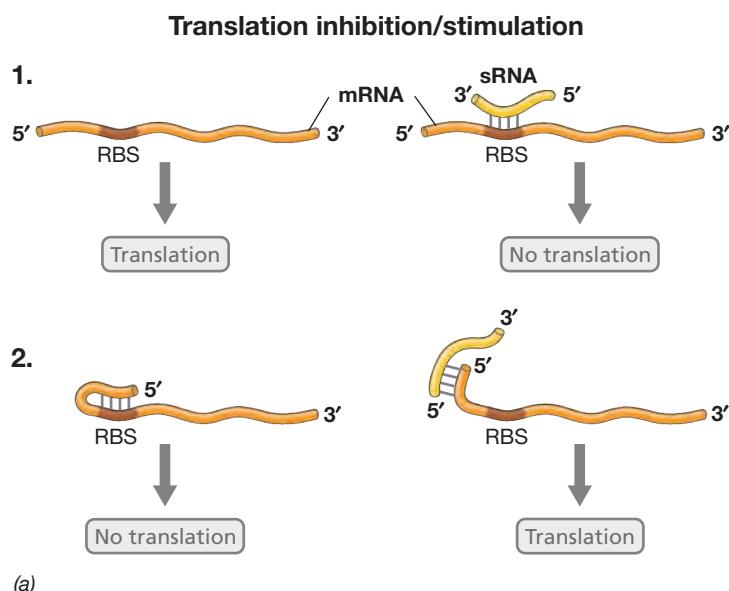

Figure 7.29 Small RNA mechanisms for modulating the translation of mRNA. (a) Binding of a ribosome to mRNA requires that the ribosome-binding site (RBS) of the mRNA be single-stranded. Binding of an sRNA to the RBS (shown in 1) can prevent translation, while the binding of an sRNA to an mRNA whose RBS has secondary structure (shown in 2) can stimulate translation. (b) Ribonuclease degrades RNA. Ribonuclease binding to partially double-stranded RNA results in RNA degradation (shown in 1), while sRNA binding at the ribonuclease binding site (shown in 2) can protect the mRNA from degradation.

stability; binding of the sRNA to its target can either increase or decrease degradation of the transcript by bacterial ribonucleases, thus modulating protein expression. Increased degradation of an mRNA prevents the synthesis of new protein molecules encoded by that mRNA. Alternatively, increasing the stability of mRNA will lead to higher corresponding protein levels in the cell (Figure 7.29).

Types of Small RNA

Small RNAs that are made by transcribing the nontemplate strand of the same gene that yielded the target mRNA are called *antisense* small RNAs and are thus complementary in base sequence. Transcription of antisense RNA is often enhanced under conditions in which its target genes need to be turned off. For example, the RyhB antisense RNA of *Escherichia coli* is transcribed when iron is limiting for growth. RyhB antisense RNA binds to several distinct target mRNAs that encode proteins needed for iron metabolism or that use iron as cofactors. Binding of RyhB sRNA blocks the RBS of the mRNA and thus inhibits translation (Figure 7.29). The base-paired RyhB/mRNA molecules are then degraded by ribonucleases, in particular, ribonuclease E. This forms part of the mechanism by which *E. coli* and related bacteria respond to a shortage of iron. Other responses to iron limitation in *E. coli* include transcriptional controls by repressor and activator proteins (Sections 7.3 and 7.4) that decrease and increase, respectively, the capacity of cells to take up iron or to tap into intracellular iron reserves.

Other sRNAs called *trans-sRNAs* are encoded in intergenic regions and can be spatially separated from their mRNA target. As such, these sRNAs usually have limited complementarity to their target molecule and may only base-pair with a 5- to 11-nucleotide stretch. The binding of trans-sRNAs to their targets often depends on a small protein called Hfq (Figure 7.30) that binds to both RNA molecules to facilitate their interaction. Hfq forms hexameric rings with RNA-binding sites on both surfaces. Hfq and functionally similar proteins are called *RNA chaperones*, as they help small RNA molecules, including many sRNAs, maintain their correct structure (Figure 7.30).

Small RNAs do not always work by affecting mRNA. For example, replication of the high copy number plasmid ColE1 in *Escherichia coli* is regulated by an sRNA that primes DNA synthesis on the plasmid and its antisense partner that blocks initiation of

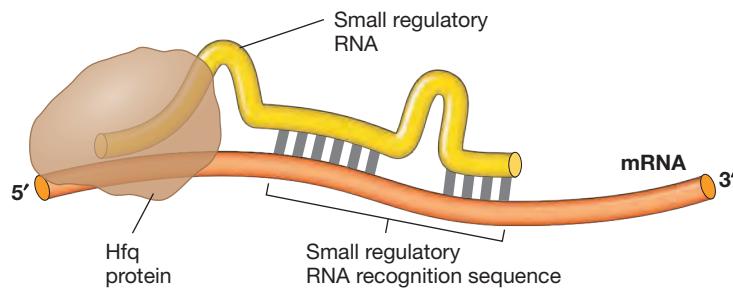

Figure 7.30 The RNA chaperone Hfq holds RNAs together. Binding of sRNA to mRNA often requires the Hfq protein. Small RNA molecules usually have several stem-loop structures. One consequence is that the complementary base sequence that recognizes the mRNA is noncontiguous.

DNA synthesis. The level of the antisense RNA determines how often replication is initiated. Some sRNAs also bind to proteins and modulate their activity.

MINIQUIZ

- How do sRNAs alter the translation of target mRNAs?
- Why do trans-sRNAs often require a chaperone protein?

7.15 Riboswitches

RNA can carry out many roles once thought to be limited to proteins. In particular, RNA can specifically recognize and bind other molecules, including low-molecular-weight metabolites. It is important to emphasize that such binding does not require complementary base pairing (as does binding of the sRNAs described in the previous section) but results from the folding of the RNA into a specific three-dimensional structure that recognizes the target molecule, much as a protein enzyme recognizes its substrate. RNA molecules that are catalytically active are called *ribozymes*. Other RNA molecules resemble repressors and activators in binding small metabolites and regulating gene expression; these are the **riboswitches**.

Riboswitch RNAs contain regions upstream of the coding sequences that can fold into specific three-dimensional structures that bind small molecules. These recognition domains are riboswitches and exist as two alternative structures, one with the small molecule bound and the other without (Figure 7.31). Alteration between the two forms of the riboswitch thus depends on the presence or absence of the small molecule, which in turn controls

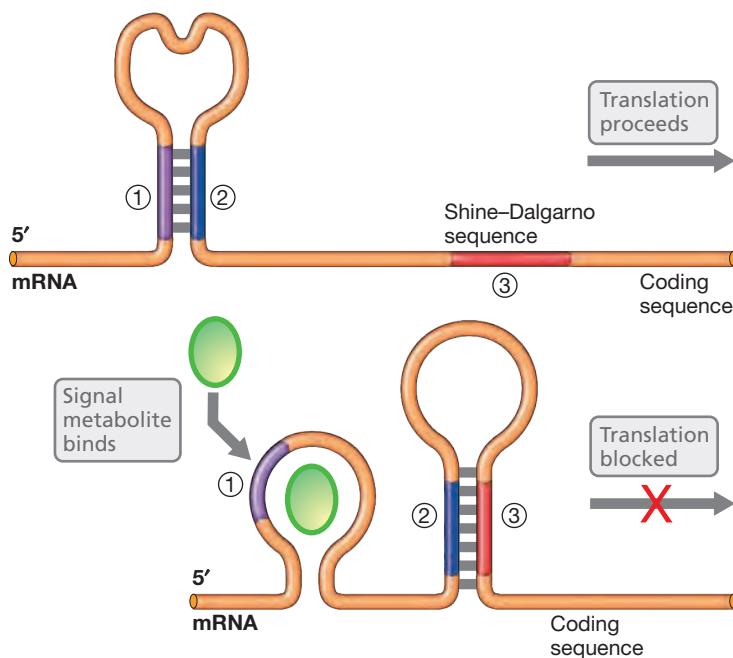

Figure 7.31 Regulation by a riboswitch. Binding of a specific metabolite alters the secondary structure of the riboswitch domain, which is located in the 5' untranslated region of the mRNA, preventing translation. Numbers indicate regions within the riboswitch that can base-pair together. The Shine–Dalgarno site is where the ribosome binds the RNA.

Table 7.3 Riboswitches in biosynthetic pathways of *Escherichia coli*

Type	Example
Vitamins	Cobalamin (B_{12}), tetrahydrofolate (folic acid), thiamine
Amino acids	Glutamine, glycine, lysine, methionine
Nitrogen bases of nucleic acids	Adenine, guanine (purine bases)
Others	Flavin mononucleotide (FMN), S-adenosylmethionine (SAM), glucosamine 6-phosphate (peptidoglycan precursor), cyclic di-GMP (biofilm signaling molecule)

expression of the mRNA. Riboswitches have been found that control the synthesis of enzymes in biosynthetic pathways for various vitamins, a few amino acids, some nitrogen bases, and for a precursor in peptidoglycan synthesis (Table 7.3).

Mechanism of Riboswitches

Earlier in this chapter we discussed the regulation of gene expression by negative control of transcription (Section 7.3). In this process, a specific metabolite interacts with a specific repressor protein to prevent transcription of genes encoding enzymes for the biosynthetic pathway of the metabolite. In contrast to this, in a riboswitch, there is no regulatory protein. Instead, the metabolite binds directly to the riboswitch at the 5' end of the mRNA. Riboswitches usually exert their control after the mRNA has already been synthesized. Therefore, most riboswitches control *translation* of the mRNA, rather than its *transcription* (Figure 7.31).

The metabolite that is bound by the riboswitch is typically the product of a biosynthetic pathway whose constituent enzymes are encoded by the mRNAs that carry the corresponding riboswitches. For example, the thiamine riboswitch that binds thiamine pyrophosphate lies upstream of the coding sequences for enzymes that participate in the thiamine biosynthetic pathway. When the pool of thiamine pyrophosphate is sufficient in the cell, this metabolite binds to its specific riboswitch mRNA. The new secondary structure of the riboswitch blocks the ribosome-binding site on the mRNA and prevents the mRNA from binding to the ribosome; this prevents translation (Figure 7.31). If the concentration of thiamine pyrophosphate drops sufficiently low, this molecule can dissociate from its riboswitch mRNA. This unfolds the mRNA and exposes the ribosome-binding site, allowing the mRNA to bind to the ribosome and be translated.

Despite being part of the mRNA, some riboswitches nevertheless do control transcription. The mechanism is similar to that seen in attenuation (Section 7.16) where a conformational change in the riboswitch causes premature termination of the synthesis of the mRNA that carries it.

Riboswitches and Evolution

How widespread are riboswitches and how did they evolve? Thus far riboswitches have been found only in some bacteria and a few plants and fungi. Some scientists believe that riboswitches are remnants of the RNA world, a period eons ago before cells, DNA, and protein, when it is hypothesized that catalytic RNAs

were the only self-replicating life forms. In such an environment, riboswitches may have been a primitive mechanism of metabolic control—a simple means by which RNA life forms could have controlled the synthesis of other RNAs. As proteins evolved, riboswitches might have been the first control mechanisms for their synthesis as well. If this is true, the riboswitches that remain today may be the last vestiges of this simple form of control because, as we have seen in this chapter, metabolic regulation is almost exclusively carried out by way of regulatory *proteins*.

MINIQUIZ

- What happens when a riboswitch binds the small metabolite that regulates it?
- What are the major differences between a repressor protein and a riboswitch in the control of gene expression?

7.16 Attenuation

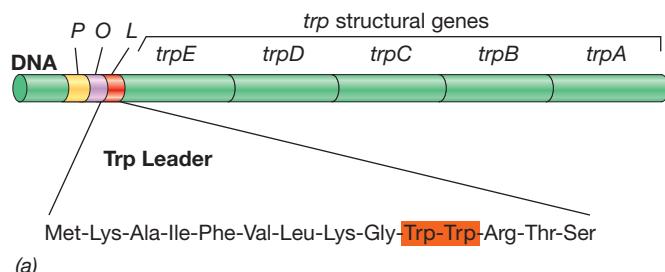

Attenuation is a form of transcriptional control in *Bacteria* (and likely in *Archaea* as well) that functions by premature termination of mRNA synthesis. That is, in attenuation, control is exerted *after* the initiation of transcription but *before* its completion. Consequently, the number of completed transcripts from an operon is reduced, even though the number of initiated transcripts is not.

The basic principle of attenuation is that the first part of the mRNA to be made, called the *leader*, can fold into two alternative secondary structures. In this respect, the mechanism of attenuation resembles that of riboswitches (Figure 7.31). In attenuation, one mRNA secondary structure allows continued synthesis of the mRNA, whereas the other secondary structure causes premature termination. Folding of the mRNA depends either on events at the ribosome or on the activity of regulatory proteins, depending on the organism. The best examples of attenuation are the regulation of genes controlling the biosynthesis of certain amino acids in gram-negative *Bacteria*. The first to be described was in the tryptophan operon in *Escherichia coli*, and we focus on it here. Because the processes of transcription and translation are spatially separated in eukaryotes, attenuation control is absent from *Eukarya*.

Attenuation in the Tryptophan Operon

The tryptophan operon contains structural genes for five proteins of the tryptophan biosynthetic pathway plus the usual promoter and regulatory sequences at the beginning of the operon (Figure 7.32). Like many operons, the tryptophan operon has more than one type of regulation. Transcription of the entire tryptophan operon is under negative control (Section 7.3). However, in addition to the promoter and operator regions needed for negative control, there is a sequence in the operon called the *leader sequence* that encodes a short polypeptide, the *leader peptide*. The leader sequence contains tandem tryptophan codons near its terminus and functions as an attenuator (Figure 7.32).

The basis of control of the tryptophan attenuator is as follows. If tryptophan is plentiful in the cell, there will be plenty of charged tryptophan tRNAs and the leader peptide will be synthesized. Synthesis of the leader peptide results in termination of

Threonine	Met-Lys-Arg-Ile-Ser-Thr-Thr-Ile-Thr-Thr-Thr-Ile-Thr-Ile-Thr-Gly-Asn-Gly-Ala-Gly
Histidine	Met-Thr-Arg-Val-Gln-Phe-Lys-His-His-His-His-His-Pro-Asp
Phenylalanine	Met-Lys-His-Ile-Pro-Phe-Phe-Phe-Ala-Phe-Phe-Phe-Thr-Phe-Pro

(b)

Figure 7.32 Attenuation and leader peptides in *Escherichia coli*. Structure of the tryptophan (*trp*) operon and of the tryptophan leader peptide and other leader peptides in *E. coli*. (a) Arrangement of the *trp* operon. Note that the leader (*L*) encodes a short peptide containing two tryptophan residues near its terminus (there is a stop codon following the Ser codon). The promoter is labeled *P*, and the operator is labeled *O*. The genes labeled *trpE* through *trpA* encode the enzymes needed for tryptophan synthesis. (b) Amino acid sequences of leader peptides of some other amino acid biosynthesis operons. Because isoleucine is made from threonine, it is an important constituent of the threonine leader peptide.

transcription of the remainder of the *trp* operon, which includes the structural genes for the biosynthetic enzymes. On the other hand, if tryptophan is scarce, the tryptophan-rich leader peptide will not be synthesized. If synthesis of the leader peptide is halted by a lack of tryptophan, the rest of the operon is transcribed.

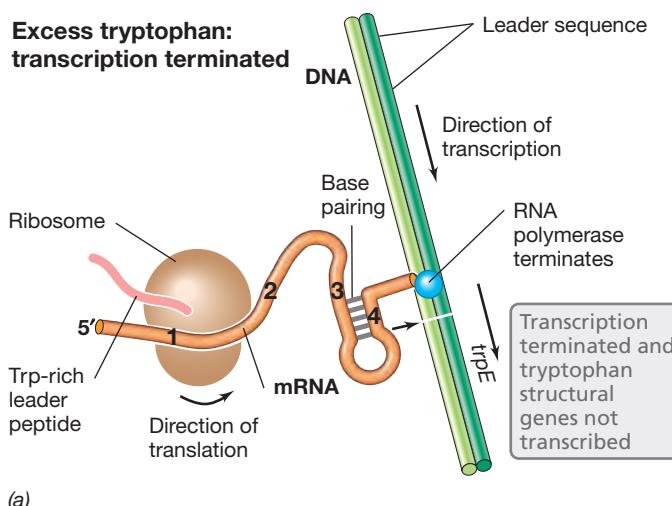

Mechanism of Attenuation

How does translation of the leader peptide regulate transcription of the tryptophan genes downstream? Consider that in prokaryotic cells transcription and translation are simultaneous processes; as mRNA is released from the DNA, the ribosome binds to it and translation begins (Section 4.13). That is, while transcription of downstream DNA sequences is still proceeding, translation of already transcribed sequences is under way (Figure 7.33).

Transcription is attenuated because a portion of the newly formed mRNA folds into a unique stem-loop that inhibits RNA polymerase activity. The stem-loop structure forms in the mRNA because two stretches of nucleotides near each other are complementary and can thus base-pair. If tryptophan is plentiful, the ribosome translates the leader sequence until it comes to the leader stop codon. The remainder of the leader sequence then forms a stem-loop, a transcription pause site, which is followed by a uracil-rich sequence that actually causes termination (Figure 7.33a).

If tryptophan is limiting, transcription of genes encoding tryptophan biosynthetic enzymes is obviously desirable. During transcription of the leader, the ribosome pauses at a tryptophan codon because of a shortage of charged tryptophan tRNAs. The presence of the stalled ribosome at this position allows a stem-loop to

Excess tryptophan: transcription terminated

Limiting tryptophan: transcription proceeds

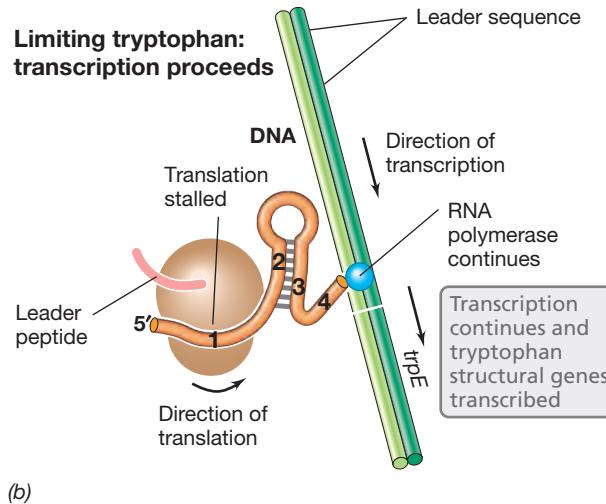

Figure 7.33 Mechanism of attenuation. Control of transcription of tryptophan (*trp*) operon structural genes by attenuation in *Escherichia coli*. The leader peptide is encoded by regions 1 and 2 of the mRNA. Two regions of the growing mRNA chain are able to form double-stranded loops, shown as 3:4 and 2:3. (a) When there is excess tryptophan, the ribosome translates the complete leader peptide, and so region 2 cannot pair with region 3. Regions 3 and 4 then pair to form a loop that terminates transcription. (b) If translation is stalled because of tryptophan starvation, a loop forms by pairing of region 2 with region 3, loop 3:4 does not form, and transcription proceeds past the leader sequence.

form (sites 2 and 3 in Figure 7.33b) that differs from the terminator stem-loop. This alternative stem-loop is not a transcription termination signal. Instead, it prevents the terminator stem-loop (sites 3 and 4 in Figure 7.33a) from forming. This allows RNA polymerase to move past the termination site and begin transcription of tryptophan structural genes. Thus, in attenuation control, the rate of transcription is influenced by the rate of translation.

MINIQUIZ

- Why does attenuation control not occur in eukaryotes?
- Explain how the formation of one stem-loop in the RNA can block the formation of another.

VI • Regulation of Enzymes and Other Proteins

We have just explored some of the key mechanisms for regulating the *amount* (or even the complete presence or absence) of an enzyme or other protein within a cell. Here we focus on the mechanisms the cell can employ to control the *activity* of enzymes already in the cell through processes such as feedback inhibition and post-translational regulation.

7.17 Feedback Inhibition

A major means of controlling enzymatic activity is by **feedback inhibition**. This mechanism temporarily shuts off the reactions in an entire biosynthetic pathway. The reactions are shut off because an excess of the end product of the pathway inhibits activity of an early (and typically the *first*) enzyme of the pathway. Inhibiting an early step effectively shuts down the entire pathway because no intermediates are generated for subsequent enzymes in the pathway (Figure 7.34a). Feedback inhibition is reversible, however, because once levels of the end product become limiting, the pathway again becomes functional.

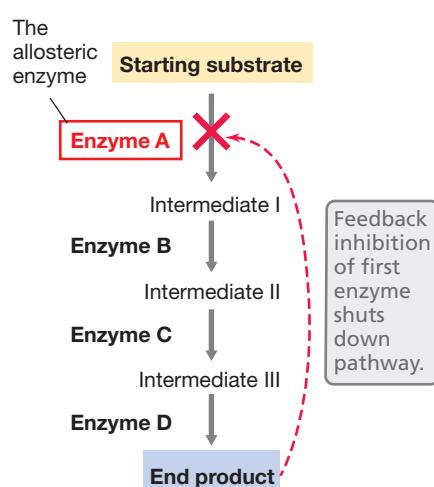

How can the end product of a pathway inhibit the activity of an enzyme whose substrate is quite unrelated to it? This occurs because the inhibited enzyme has two binding sites, the *active site* (where substrate binds, *↳* Section 3.5), and the *allosteric site*, where the end product of the pathway binds. When the end product is in

excess, it binds at the allosteric site, changing the conformation of the enzyme such that the substrate can no longer bind at the active site (Figure 7.34b). When the concentration of the end product in the cell begins to fall, however, the end product no longer binds to the allosteric site, so the enzyme returns to its catalytic form and once again becomes active.

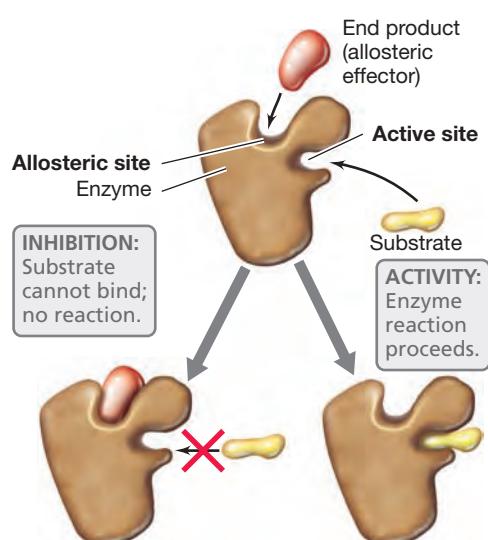

Isoenzymes

Some biosynthetic pathways controlled by feedback inhibition employ *isozymes* (“iso” means “same”). Isoenzymes are different proteins that catalyze the same reaction but are subject to different regulatory controls. Examples are enzymes required for the synthesis of the aromatic amino acids tyrosine, tryptophan, and phenylalanine in *Escherichia coli* (Figure 7.34c).

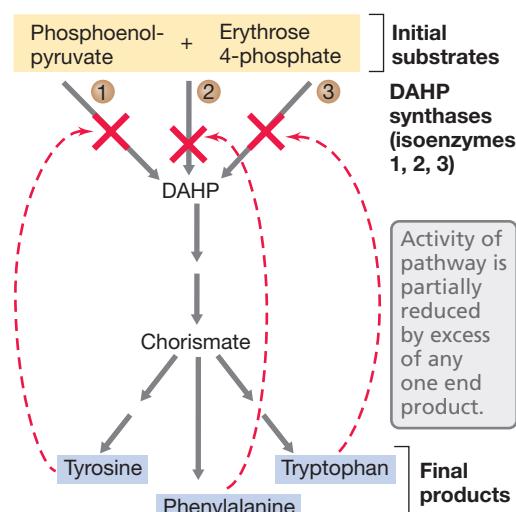

The enzyme 3-deoxy-D-arabino-heptulosonate 7-phosphate (DAHP) synthase plays a central role in aromatic amino acid biosynthesis. In *E. coli*, three DAHP synthase isozymes catalyze the first reaction in this pathway, each regulated independently by a different one of the end product amino acids. However, unlike the example of feedback inhibition where an end product completely inhibits enzyme activity, enzyme activity is diminished incrementally; enzyme activity falls to zero only when *all three* end products are present in excess (Figure 7.34c).

(a) Feedback inhibition

(b) Allosteric inhibition

(c) Isoenzyme inhibition

Figure 7.34 Inhibition of enzyme activity. (a) In feedback inhibition, the activity of the first enzyme of the pathway is inhibited by the end product, thus shutting off the production of the three intermediates and the end product. (b) The mechanism of allosteric inhibition by the end product of a pathway. When the end product binds at the

allosteric site, the conformation of the enzyme is so altered that the substrate can no longer bind to the active site. However, inhibition is reversible, and end product limitation will once again activate the enzyme. (c) Inhibition by isozymes. In *Escherichia coli*, the pathway leading to the synthesis of the aromatic amino acids contains three isozymes of

DAHP synthase. Each of these enzymes is feedback-inhibited by one of the aromatic amino acids. However, note how an excess of all three amino acids is required to completely shut off the synthesis of DAHP. In addition to feedback inhibition at the DAHP site, each amino acid feedback inhibits its further metabolism at the chorismate step.

MINIQUIZ

- What is feedback inhibition?
- What is the difference between an allosteric site and an active site?

7.18 Post-Translational Regulation

Some enzymes are regulated by covalent modification, typically the attachment or removal of some small molecule to the protein that subsequently affects enzyme activity. We have already discussed *phosphorylation*, a very common mechanism for regulating a protein post-translationally, when we considered two-component regulatory systems (Section 7.7). Biosynthetic enzymes can also be regulated by the attachment of other small molecules, such as the nucleotides adenosine monophosphate (AMP) and adenosine diphosphate (ADP), or by methylation. We consider here a single example of the well-studied case of glutamine synthetase, a key enzyme in ammonia (NH_3) assimilation (🔗 Section 3.15), whose activity is modulated by AMP in a process called *adenylylation*.

Regulation of Glutamine Synthetase Activity

Each molecule of glutamine synthetase (GS) is composed of 12 identical subunits, and each subunit can be adenylylated. When GS is fully adenylylated (that is, each molecule of the enzyme contains 12 AMP groups), it is catalytically inactive. When it is partially adenylylated, it is partially active. As the glutamine pool in the cell increases, GS becomes more adenylylated, and its activity diminishes. As glutamine levels diminish, GS becomes less adenylylated and its activity increases (Figure 7.35). Other enzymes in the cell add and remove the AMP groups from GS, and these enzymes are themselves controlled, ultimately by levels of NH_3 in the cell.

Why should there be all of this elaborate regulation surrounding the enzyme GS? The activity of GS requires ATP, and nitrogen assimilation is a major biosynthetic process in the cell. However, when NH_3 is present at high levels in the cell, it can be assimilated into amino acids by enzymes that do not consume ATP; under these conditions, GS remains inactive. When NH_3 levels are low, however, GS becomes catalytically active. By having GS active only when NH_3 is limiting, the cell conserves ATP that would be used unnecessarily if GS were active when NH_3 was present in excess.

The modulation of GS activity in this very precise way stands in contrast to enzymes subject to feedback inhibition (Figure 7.34) whose activity is either “on” or “off” depending on the concentration of the effector molecule. This finer type of control for GS allows GS to remain partially active until NH_3 is at such high levels that NH_3 -assimilating systems that have a lower affinity for NH_3 and do not require ATP are fully active.

Other Examples of Post-Translational Regulation

Throughout this chapter we have encountered other avenues in which the cell regulates the activity of proteins. One such mechanism is protein–protein interactions. In Section 7.10 we described how the σ factor RpoH is inactivated by DnaK under normal temperature conditions in the heat shock response (Figure 7.24). In addition, regulation by protein–protein interaction occurs during sporulation in *Bacillus* when the anti-sigma factor SpoIIAB binds

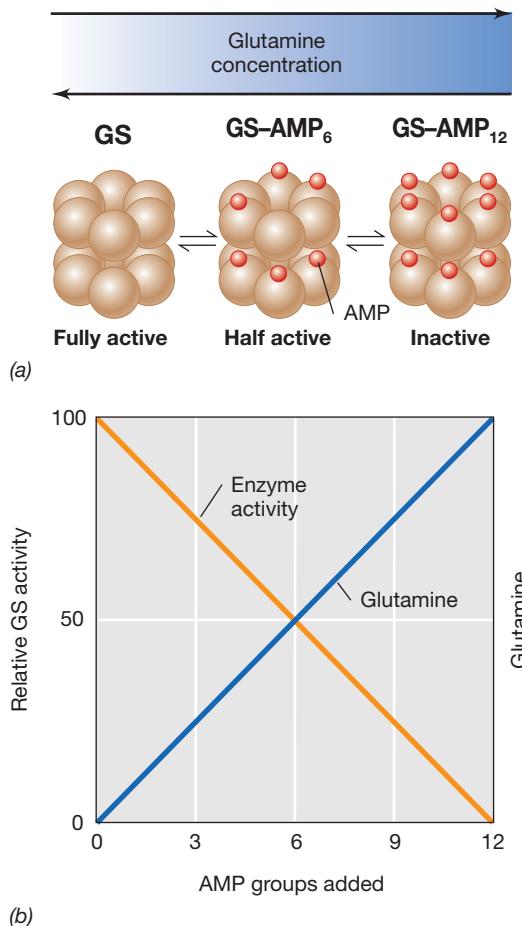

Figure 7.35 Regulation of glutamine synthetase by covalent modification.

(a) When cells are grown with excess ammonia (NH_3), glutamine synthetase (GS) is covalently modified by adenylylation; as many as 12 AMP groups can be added. When cells are NH_3 -limited, the groups are removed and form ADP. (b) Adenylylated GS subunits are catalytically inactive, so the overall GS activity decreases progressively as more subunits are adenylylated.

to σF , thereby preventing its association with RNA polymerase (Section 7.11 and Figure 7.25). Heterocyst formation is also controlled in part by post-translational regulation. In vegetative cells, the PatS peptide prevents HetR from activating transcription of heterocyst-formation genes (Section 7.13 and Figure 7.28).

Protease enzymes can also be employed to quickly remove damaged proteins from the cellular pool while molecular chaperones do just the opposite by refolding denatured proteins. However, regardless of the mechanism, in the final analysis it should be clear that regulating the synthesis and activities of a cell's proteins is (1) very important to its biology, (2) possible in many different ways, and (3) a major genetic investment. But the costs are worth it. At every turn in a highly competitive world, the very survival of a microorganism may well depend on its ability to conserve resources and energy output.

MINIQUIZ

- What is feedback inhibition?
- What does adenylylation do to the enzyme activity of glutamine synthetase?

BIG IDEAS

7.1 • Most genes encode proteins and most proteins are enzymes. Expression of an enzyme-encoding gene is regulated by controlling the activity of the enzyme or controlling the amount of enzyme produced.

7.2 • Certain proteins bind to DNA when specific domains of the proteins bind to specific regions of the DNA molecule. In most cases the interactions are sequence-specific. Proteins that bind to DNA are often regulatory proteins that affect gene expression.

7.3 • The amount of a specific enzyme in the cell can be controlled by regulatory proteins that bind to DNA and increase (induce) or decrease (repress) the amount of messenger RNA that encodes the enzyme. In negative control of transcription, the regulatory protein is called a repressor and it functions by inhibiting mRNA synthesis.

7.4 • Positive regulators of transcription are called activator proteins. They bind to activator-binding sites on the DNA and stimulate transcription. Inducers modify the activity of activating proteins. In positive control of enzyme induction, the inducer promotes the binding of the activator protein and thus stimulates transcription.

7.5 • Global control systems regulate the expression of many genes simultaneously. Catabolite repression is a global control system that helps cells make the most efficient use of available carbon sources. The *lac* operon is under the control of catabolite repression as well as its own specific negative regulatory system.

7.6 • *Archaea* resemble *Bacteria* in using DNA-binding activator and repressor proteins to regulate gene expression at the level of transcription.

7.7 • Signal transduction systems transmit environmental signals to the cell. In prokaryotes, signal transduction is typically carried out by a two-component regulatory system that includes a membrane-integrated sensor kinase and a cytoplasmic response regulator. The activity of the response regulator depends on its state of phosphorylation.

7.8 • Chemotactic behavior responds in a complex manner to attractants and repellents. The regulation of chemotaxis affects the activity of proteins rather than their synthesis. Adaptation by methylation allows the system to reset itself to the continued presence of a signal.

7.9 • Quorum sensing allows cells to monitor their environment for cells of their own kind. Quorum sensing depends on the sharing of specific small molecules known as autoinducers. Once a sufficient concentration of the autoinducer is present, specific gene expression is triggered.

7.10 • Cells can control sets of genes by employing alternative sigma factors. These recognize only certain promoters and thus allow transcription of a select category of genes that is appropriate under certain environmental conditions. Cells respond to both heat and cold by expressing sets of genes whose products help the cell overcome stress.

7.11 • Sporulation in *Bacillus* during adverse conditions is triggered via a complex phosphotransfer relay system that monitors multiple aspects of the environment. The sporulation factor Spo0A then sets in motion a cascade of regulatory responses under the control of several alternative sigma factors.

7.12 • Differentiation in *Caulobacter* consists of the alternation between motile cells and those that are attached to surfaces. Three major regulatory proteins—CtrA, GcrA, and DnaA—act in succession to control the three phases of the cell cycle. Each in turn controls many other genes needed at specific times in the cell cycle.

7.13 • Heterocyst formation requires expression of the major regulatory protein HetR in the protoheterocysts. However, the protein must be inactivated in vegetative cells by diffusion of the PatS peptide along the filament.

7.14 • Cells can control genes in several ways by employing regulatory RNA molecules. One way is to take advantage of base pairing and use sRNA to promote or prevent translation of mRNAs.

7.15 • Riboswitches are RNA domains at the 5' ends of mRNA that recognize small molecules and respond by changing their three-dimensional structure to affect translation or transcriptional termination of the mRNA. Riboswitches are mostly used to control biosynthetic pathways for amino acids, purines, and a few other metabolites.

7.16 • Attenuation is a mechanism whereby transcription is controlled after initiation of mRNA synthesis. Attenuation mechanisms depend upon alternative stem-loop structures in the mRNA.

7.17 • In feedback inhibition, an excess of the final product of a biosynthetic pathway inhibits an allosteric enzyme at the beginning of the pathway. Enzyme activity can also be modulated by isoenzymes.

7.18 • Protein activity can be regulated after translation. Reversible covalent modification or interactions with other proteins can modulate protein activity.

REVIEW OF KEY TERMS

Activator protein a regulatory protein that binds to specific sites on DNA and stimulates transcription; involved in positive control

Allosteric protein a protein containing an active site for binding substrate and an allosteric site for binding an effector molecule such as the end product of a biochemical pathway.

Attenuation a mechanism for controlling gene expression that terminates transcription after initiation but before a full-length messenger RNA is produced

Autoinducer a small signal molecule that takes part in quorum sensing

Catabolite repression the suppression of alternative catabolic pathways by a preferred source of carbon and energy

Cyclic AMP a regulatory nucleotide that participates in catabolite repression

Domains regions of a protein with specific structure and function

Feedback inhibition a process in which an excess of the end product of a multistep pathway inhibits activity of the first enzyme in the pathway

Gene expression transcription of a gene followed by translation of the resulting mRNA into protein

Green fluorescent protein (GFP) a protein that fluoresces green and is widely used in genetic analysis

Heat shock proteins proteins induced by high temperature (or certain other stresses) that protect against high temperature, especially by refolding partially denatured proteins or by degrading them

Heat shock response response to high temperature that includes the synthesis of heat shock proteins together with other changes in gene expression

Induction production of an enzyme in response to a signal (often the presence of the substrate for the enzyme)

Negative control a mechanism for regulating gene expression in which a repressor protein prevents transcription of genes

Noncoding RNA (ncRNA) RNA that is not translated into protein; examples include ribosomal RNA, transfer RNA, and small regulatory RNAs

Operon one or more genes transcribed into a single RNA and under the control of a single regulatory site

Positive control a mechanism for regulating gene expression in which an activator protein functions to promote transcription of genes

Quorum sensing a regulatory system that monitors the population level and controls gene expression based on cell density

Regulatory nucleotide a nucleotide that functions as a signal rather than being incorporated into RNA or DNA

Regulon a series of operons controlled as a unit

Repression prevention of the synthesis of an enzyme in response to a signal

Repressor protein a regulatory protein that binds to specific sites on DNA and blocks transcription; involved in negative control

Response regulator protein one of the members of a two-component regulatory system; a protein that is phosphorylated by a sensor kinase and then acts as a regulator, often by binding to DNA

Riboswitch an RNA domain, usually in a messenger RNA molecule, that can bind a specific small molecule and alter its secondary structure; this, in turn, controls translation of the mRNA

Sensor kinase protein one of the members of a two-component regulatory system; a protein that phosphorylates itself in response to an external signal and then transfers the phosphoryl group to a response regulator protein

Signal transduction see two-component regulatory system

Two-component regulatory system a regulatory system consisting of two proteins: a sensor kinase and a response regulator

REVIEW QUESTIONS

- What are the two points at which the amount of protein synthesis can be regulated? (Section 7.1)
- Describe why a protein that binds to a specific sequence of double-stranded DNA is unlikely to bind to the same sequence if the DNA is single-stranded. (Section 7.2)
- Most biosynthetic operons need only be under negative control for effective regulation, whereas most catabolic operons need to be under both negative and positive control. Why? (Sections 7.3 and 7.4)
- What is the difference between an operon and a regulon? (Section 7.4)
- Describe the mechanism by which cAMP receptor protein (CRP), the regulatory protein for catabolite repression, functions. Use the lactose operon as an example. (Section 7.5)
- What are the two mechanisms used by archaeal repressor proteins to repress transcription? (Section 7.6)
- What are the two components that give their name to a signal transduction system in prokaryotes? What is the function of each of the components? (Section 7.7)
- Adaptation allows the mechanism controlling flagellar rotation to be reset. How is this achieved? (Section 7.8)
- How can quorum sensing be considered a regulatory mechanism for conserving cell resources? (Section 7.9)
- Describe the proteins produced when cells of *Escherichia coli* experience a heat shock. Of what value are they to the cell? (Section 7.10)
- Explain how alternative sigma factors control sporulation in *Bacillus*. (Section 7.11)
- What role does the DnaA protein play in differentiation in *Caulobacter*? (Section 7.12)

13. What molecule produced by heterocysts prevents differentiation in vegetative cells and how does the inhibitor reach the vegetative cells? (Section 7.13)
14. How does regulation by sRNA differ from that of riboswitches? (Sections 7.14 and 7.15)
15. Describe how transcriptional attenuation works. What is actually being “attenuated”? (Section 7.16)

16. Contrast regulation of DAHP synthase and glutamine synthetase. (Section 7.17)
17. What is the most common covalent modification to affect protein activity? (Section 7.18)

APPLICATION QUESTIONS

1. What would happen to regulation from a promoter under negative control if the region where the regulatory protein binds was deleted? What if the promoter was under positive control?
2. Promoters from *Escherichia coli* under positive control are not close matches to the promoter consensus sequence for *E. coli* (🔗 Section 4.7). Why?
3. The attenuation control of the tryptophan biosynthetic pathway genes in *Escherichia coli* involves coupled transcription and translation. Can you describe why this mechanism of regulation would not be appropriate for regulating the genes involved in the utilization of lactose?
4. Most of the regulatory systems described in this chapter employ regulatory proteins. However, regulatory RNA is also important.

Describe how one could achieve negative control of the *lac* operon using either of two different types of regulatory RNA.

5. Many amino acid biosynthetic operons under attenuation control are also under negative control. Considering that the environment of a bacterium can be highly dynamic, what advantage could be conferred by having attenuation as a second layer of control?
6. How would you design a regulatory system to make *Escherichia coli* use succinic acid in preference to glucose? How could you modify it so that *E. coli* prefers to use succinic acid in the light but glucose in the dark?

8 • Viruses and Virology

microbiologynow

Where Did Viruses Come From?

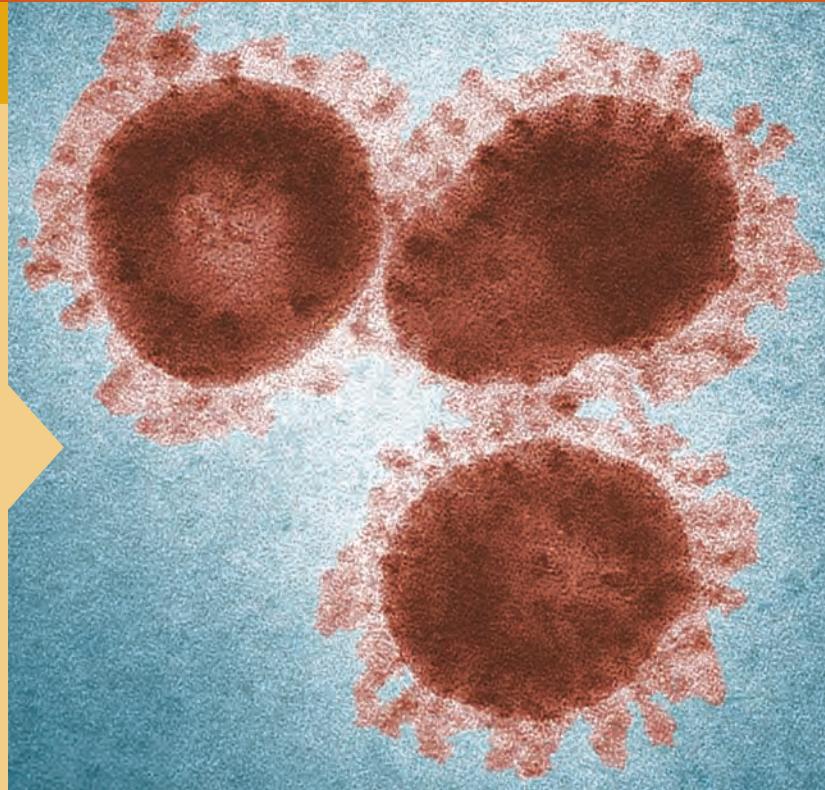

Despite the fact that we know much about the molecular properties of viruses, how they co-opt cellular activities to their own advantage, and the diseases that many of them cause, we know little about viral origins. But this secret of the viral world may be beginning to show some cracks.¹

It now seems likely that viruses arose before the appearance of the last universal common ancestor of cellular life (LUCA). This hypothesis has gained support from at least two sources. First, structural studies have shown that certain proteins in the viral shells (capsids) that surround viral genomes show significant structural homology across a wide variety of both RNA (photo, coronavirus) and DNA viruses. This suggests that despite their genomic diversity, viruses have distinct “lineages” that predate the origin of LUCA.

Second, it is clear that mutation rate and genome size are inversely related and that small RNA viruses have the highest of all known mutation rates. Moreover, single-stranded DNA viruses have lower mutation rates than single-stranded RNA viruses, and double-stranded DNA viruses have lower rates than single-stranded DNA viruses. The lowest rates of all are seen in cells, whose mutation rates are several orders of magnitude lower than those of viruses.

Perhaps Earth’s first self-replicating entities resembled single-stranded RNA viruses that mutated early and often, gradually resulting in increased fitness. From these, mutants were selected that had evolved more stable (DNA-based) genomes, and from these, the first cells. Although still a hypothesis, such a process of increasing genomic stability might have been a major catalyst for the evolution of cells. If that is true, the study of viral capsid proteins and genomic mutation rates may have inadvertently provided important clues for scientists striving to understand how life began.

- I **The Nature of Viruses 246**
- II **Bacteriophage Life Cycles 251**
- III **Viral Diversity and Ecology 257**

A **virus** is a genetic element that can replicate only inside a living cell, called the **host cell**. Viruses possess their own genomes and in that sense are independent of the host cell's genome. However, viruses rely on the host cell for energy, metabolic intermediates, and protein synthesis. Viruses are therefore *obligate intracellular parasites*.

Viruses infect both prokaryotes and eukaryotes and are responsible for many infectious diseases of humans and other organisms. The study of viruses is called *virology*, and this chapter covers the basic principles of the science. In Chapter 9 we consider the genomic and diversity aspects of viruses in more detail.

I • The Nature of Viruses

8.1 What Is a Virus?

Although viruses are not cells they nonetheless possess a nucleic acid genome that encodes those functions needed to replicate and an extracellular form, called the **virion**, that allows the virus to travel from one host cell to another. Viruses cannot replicate unless the virion itself (or its genome, in the case of bacterial viruses) has gained entry into a suitable host cell, a process called *infection*.

Viral Structure and Activities

The virion of a virus consists of a protein shell, the **capsid**, which contains the virus genome. Most bacterial viruses are *naked*, with no further layers, whereas many animal viruses contain an outer layer consisting of protein plus lipid called the **envelope** (Figure 8.1). In enveloped viruses, the inner structure of nucleic acid plus capsid protein is called the **nucleocapsid**. The virion protects the viral genome when the virus is outside the host cell, and proteins on the virion surface are important in attaching it to its host cell. The virion may also contain one or more virus-specific enzymes that play a role during infection and replication, as discussed later.

Once inside the host cell, a viral genome can orchestrate one of two quite different events. The virus may replicate and destroy the host in a **virulent (lytic)** infection. In a lytic infection, the virus redirects host metabolism to support virus replication and the assembly of new virions. Eventually, new virions are released, and the process can repeat itself on new host cells. Alternatively, some viruses can undergo a **lysogenic** infection; in this case, the host cell is not destroyed but is genetically altered because the viral genome becomes part of the host genome.

Viral Genomes

All cells contain double-stranded DNA genomes. By contrast, viral genomes consist of either DNA or RNA and are further subdivided based on whether the genome is *single-stranded* or *double-stranded*. A very few highly unusual viruses use both DNA and RNA as genetic material, but at different stages of their life cycle (Figure 8.2).

Viral genomes can be either linear or circular, and single-stranded viral genomes may be of either the *plus sense* or *minus sense* in terms of their base sequence. Viral genomes of the plus configuration have the *exact same* base sequence as that of the viral mRNA that will be translated to form viral proteins. By contrast, viral genomes of the minus configuration are *complementary* in base sequence to viral mRNA. This interesting feature of viral genomes requires special genetic information flow processes, and we reserve our discussion of the details of these processes to Chapter 9.

Viral genomes are typically smaller than those of cells. The smallest bacterial genome known is about 145 kilobase pairs, encoding about 170 genes. Most viral genomes encode from a few up to about 350 genes. The smallest viral genomes are those of some small RNA viruses that infect animals. The genomes of these tiny viruses contain fewer than 2000 nucleotides and only two genes. A few very large viral genomes are known, such as the 1.25-Mbp DNA genome of a marine virus called *Megavirus*, which infects protozoans. RNA viruses typically have the smallest genomes and only DNA viruses have genomes encoding more than 40 genes.

Viruses can be classified on the basis of the hosts they infect as well as by their genome structure. Thus, we have bacterial viruses, archaeal viruses, animal viruses, plant viruses, protozoan viruses, and so on. Bacterial viruses are called **bacteriophages** (or simply *phage* for short) and have been intensively studied as model systems for the molecular biology and genetics of virus replication. In this chapter we will use bacteriophages many times to illustrate simple viral principles. Indeed, many of the basic tenets of virology were first discovered with bacteriophages and subsequently applied to viruses of higher organisms. Because of their frequent medical importance, animal viruses have been extensively studied, whereas plant viruses, although of enormous importance to modern agriculture, have been less well studied.

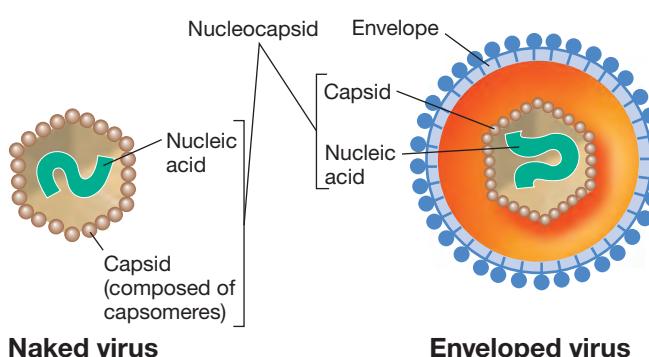

Figure 8.1 Comparison of naked and enveloped virus particles. The envelope originates from host cytoplasmic membrane.

MINIQUIZ

- How does a virus differ from a cell?
- Why does a virus need a host cell?
- Compared with cells, what is unusual about viral genomes?

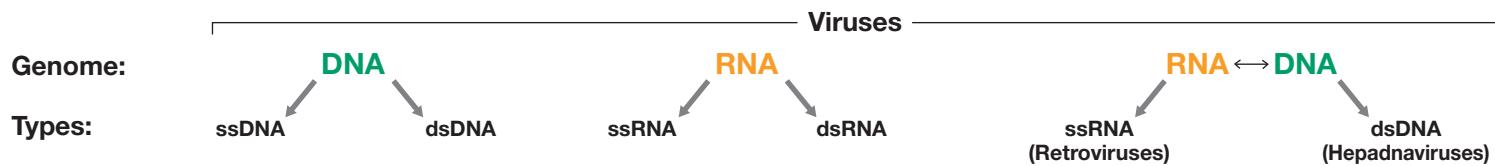

Figure 8.2 **Viral genomes.** The genomes of viruses can be either DNA or RNA, and some use both at different stages in their replication cycle. However, only one type of genomic nucleic acid is found in the virion of any particular type of virus. Viral genomes can be single-stranded (ss) or double-stranded (ds) and circular or linear.

8.2 Structure of the Virion

Virions come in many shapes and sizes. Most viruses are smaller than prokaryotic cells, ranging in size from 0.02 to 0.3 μm (20–300 nanometers, nm). Smallpox virus, one of the larger viruses, is about 200 nm in diameter, which is about the size of the smallest known bacterial cells. Poliovirus, one of the smallest viruses, is only 28 nm in diameter, which is about the size of a ribosome, the cell's protein-synthesizing machine.

Virion Structure

The structures of virions are quite diverse, varying widely in size, shape, and chemical composition (see Figures 8.19 and 8.21). The nucleic acid of a virion is always surrounded by its capsid (Figure 8.1). The capsid is composed of a number of individual protein molecules called **capsomeres** that are arranged in a precise and highly repetitive pattern around the nucleic acid.

The small size of most viral genomes restricts the number of distinct viral proteins that can be encoded. As a consequence, a few viruses have only a single kind of protein in their capsid. An example is the well-studied tobacco mosaic virus (TMV), which causes disease in tobacco, tomato, and related plants. TMV is a single-stranded RNA virus in which the 2130 copies of the simple capsomere protein are arranged in a helix with dimensions of 18 \times 300 nm (Figure 8.3).

The information required for the proper folding and assembly of viral proteins into capsomeres and subsequently into capsids is often embedded within the amino acid sequence of the viral proteins themselves. When this is the case, virion assembly is a spontaneous process and is called *self-assembly*. However, some virus proteins and structures require assistance from host cell folding proteins for proper folding and assembly. For example, the capsid protein of bacteriophage lambda (Section 8.8) requires assistance from the *Escherichia coli* chaperonin GroE (Section 4.14) in order to fold into its active conformation.

Virus Symmetry

Viruses are highly symmetric. When a symmetric structure is rotated around an axis, the same form is seen again after a certain number of degrees of rotation. Two kinds of symmetry are recognized in viruses, which correspond to the two primary viral shapes, rod and spherical. Rod-shaped viruses have *helical* symmetry while spherical viruses have *icosahedral* symmetry. A typical virus with helical symmetry is TMV (Figure 8.3). The lengths of helical viruses are determined by the length of the nucleic acid, and the width of the helical virion is determined by the size and packaging of the capsomeres.

Viruses with icosahedral symmetry contain 20 triangular faces and 12 vertices and are roughly spherical in shape (Figure 8.4a). Axes of symmetry divide the icosahedron into 5, 3, or 2 segments of identical size and shape (Figure 8.4b). Icosahedral symmetry is the most efficient arrangement of subunits in a closed shell because it requires the smallest number of capsomeres to build the shell. The simplest arrangement of capsomeres is 3 per triangular face, for a total of 60 capsomeres per virion. However, most viruses have more nucleic acid than can be packed into a shell made from 60 capsomeres and so viruses with 180, 240, or 360 capsomeres are more common. The capsid of the human papillomavirus virus (Figure 8.4c), for example, consists of 360 capsomeres, with the capsomeres arranged into 72 clusters of 5 each (Figure 8.4d).

The structure of some viruses is extremely complex, with the virion consisting of several parts each displaying its own shape and symmetry. The most complex of all viruses are the head-plus-tail

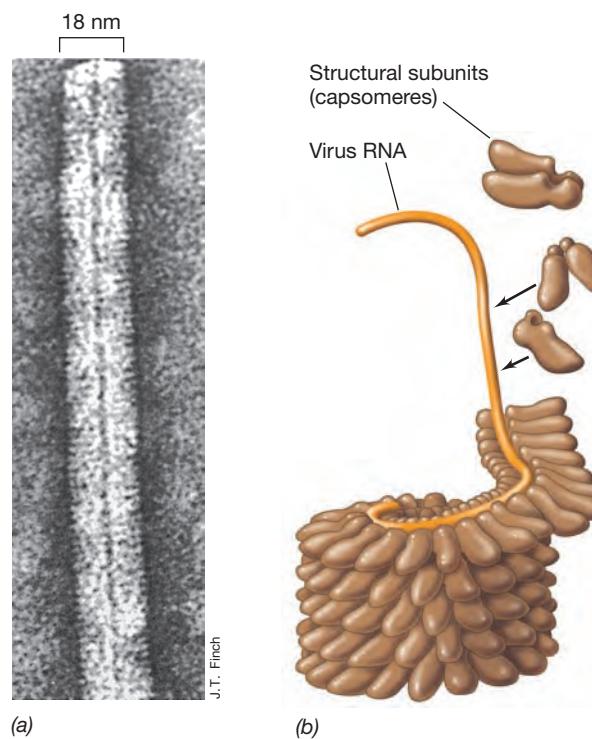

Figure 8.3 **The arrangement of RNA and protein coat in a simple virus, tobacco mosaic virus.** (a) A high-resolution electron micrograph of a portion of the tobacco mosaic virus particle. (b) Cutaway showing structure of the virion. The RNA forms a helix surrounded by the protein subunits (capsomeres). The center of the virus particle is hollow.

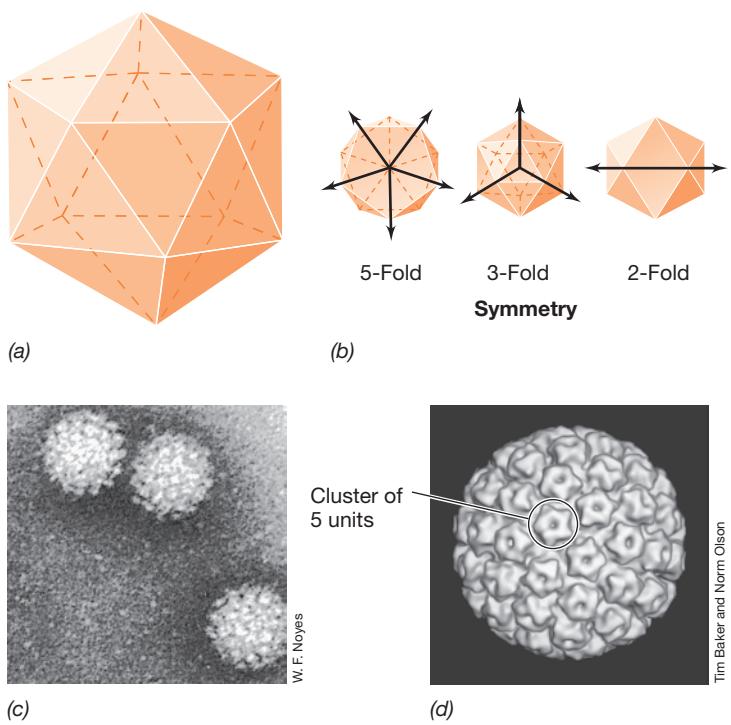

Figure 8.4 Icosahedral symmetry. (a) Model of an icosahedron. (b) Three views of an icosahedron showing 5-, 3-, or 2-fold symmetry. (c) Electron micrograph of human papillomavirus, a virus with icosahedral symmetry. The virion is about 55 nm in diameter. (d) Three-dimensional reconstruction of human papillomavirus; virion contains 360 units arranged in 72 clusters of 5 each.

bacteriophages that infect *Escherichia coli*, such as phage T4. A T4 virion consists of an icosahedral head plus a helical tail (see Figures 8.19 and 8.20). Some large viruses that infect eukaryotes are also structurally complex, although in ways quite distinct from the head-plus-tail bacteriophages. Mimivirus and pox virus (see Figure 8.5b) are good examples and are discussed in more detail in Chapter 9.

Enveloped Viruses

Enveloped viruses have a membrane surrounding the nucleocapsid (Figure 8.5) and can have either RNA or DNA genomes. Most

enveloped viruses (for example, influenza virus) (Figure 8.5a) infect animal cells in which the cytoplasmic membrane is directly exposed to the environment. By contrast, plant and bacterial cells are surrounded by a cell wall outside the cytoplasmic membrane, and thus few examples of enveloped viruses are known in these organisms. Typically, the entire virion enters an animal cell during infection, with the envelope, if present, assisting in the infection process by fusing with the host membrane. Enveloped viruses also exit more easily from animal cells. As they pass out of the host cell, they are draped in membrane material. The viral envelope consists primarily of host cytoplasmic membrane, but some viral surface proteins become embedded in the envelope as the virus passes out of the cell.

The viral envelope is important in infection as it is the component of the virion that makes contact with the host cell. The specificity of enveloped virus infection and some aspects of their penetration are thus controlled in part by the chemistry of their envelopes. The virus-specific envelope proteins are critical for both attachment of the virion to the host cell during infection and for release of the virion from the host cell after replication.

Enzymes Inside Virions

Viruses do not carry out metabolic processes and are thus metabolically inert. Nonetheless, some viruses carry enzymes in their virions that play important roles in infection. For example, some bacteriophages contain an enzyme that resembles lysozyme (Section 2.10), which is used to make a small hole in the bacterium's peptidoglycan to allow nucleic acid from the virion to get into the host cytoplasm. A similar protein is produced in the later stages of infection to lyse the host cell and release new virions. Some animal viruses also contain enzymes that aid in their release from the host. For example, influenza virus (Figure 8.5a) has envelope proteins called *neuraminidases* that destroy glycoproteins and glycolipids of animal cell connective tissue, thus liberating the virions (Section 9.9).

RNA viruses carry their own nucleic acid polymerases (called *RNA replicases*) that function to replicate the viral RNA genome and produce viral-specific mRNA. Such enzymes are necessary because cells cannot make RNA from an RNA template.

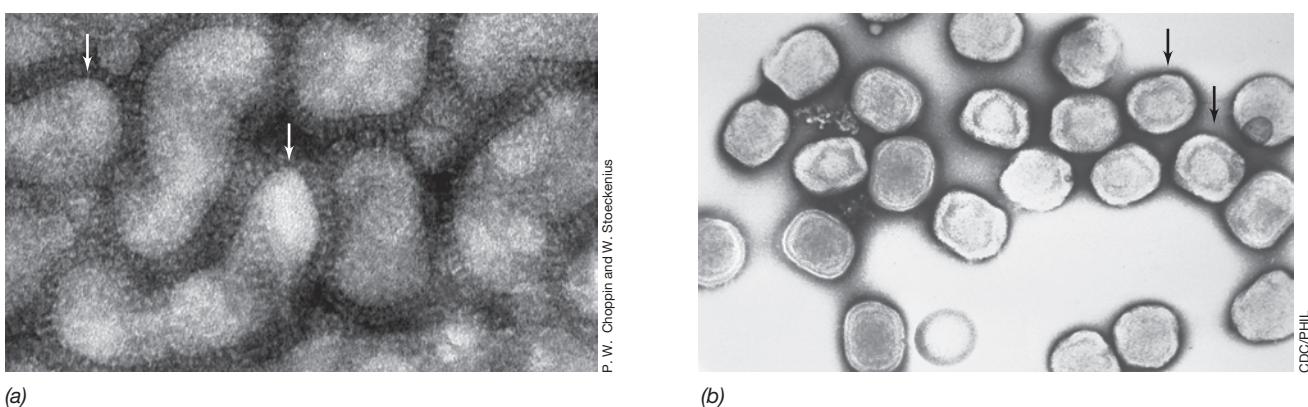

Figure 8.5 Enveloped viruses. (a) Electron micrograph of influenza virus. The virions are about 80 nm in diameter, and can have many shapes. (b) Electron micrograph of vaccinia virus, an enveloped icosahedral pox virus about 350 nm wide. The arrows in both micrographs point to the envelopes surrounding the nucleocapsids.

Retroviruses are unusual RNA animal viruses that replicate via DNA intermediates. Because making DNA from an RNA template is another process cells cannot do, retroviral virions contain an RNA-dependent DNA polymerase called *reverse transcriptase* (Section 8.10). So, although most viruses do not need to carry special enzymes in their virions, those that do absolutely require them for successful infection and replication.

MINIQUIZ

- Distinguish between a capsid and a capsomere. What is a common symmetry for spherical viruses?
- What is the difference between a naked virus and an enveloped virus?
- What kinds of enzymes can be found within the virions of RNA viruses? Why are they there?

8.3 Overview of the Virus Life Cycle

For a virus to replicate, it must induce a living host cell to synthesize all the essential components needed to make new virions. Because of these biosynthetic and energy requirements, dead host cells will not replicate viruses. During an active infection, viral components are assembled into new virions that are released from the cell. We use replication of a bacterial virus here as a simple example of a viral life cycle.

A cell that supports the complete replication cycle of a virus is said to be *permissive* for that virus. In a permissive host, the viral replication cycle can be divided into five steps (Figure 8.6).

1. *Attachment* (adsorption) of the virion to the host cell
2. *Penetration* (entry, injection) of the virion nucleic acid into the host cell
3. *Synthesis* of virus nucleic acid and protein by host cell machinery as redirected by the virus
4. *Assembly* of capsids and *packaging* of viral genomes into new virions
5. *Release* of new virions from the cell

The growth response during virus replication is illustrated in Figure 8.7. The response takes the form of a *one-step growth curve*, so named since a time course of virion numbers in the culture medium shows essentially no increase during the replication

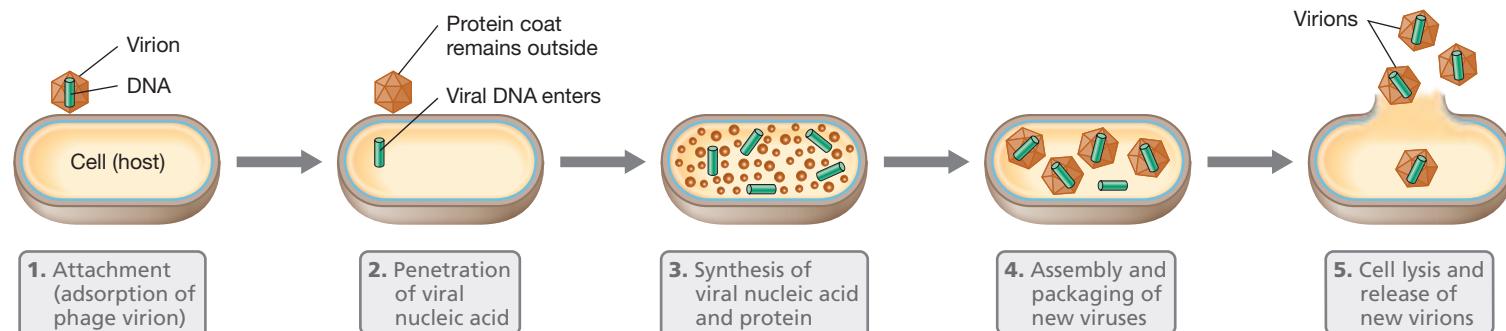

Figure 8.6 The replication cycle of a bacterial virus. The virions and cells are not drawn to scale. The burst size can be a hundred or more virions per host cell.

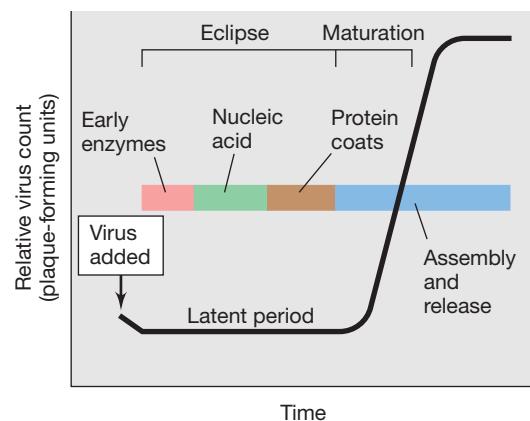

Figure 8.7 One-step growth curve of virus replication. Following adsorption, infectious virions cannot be detected in the growth medium, a phenomenon called *eclipse*. During the latent period, which includes the eclipse and early maturation phases, viral nucleic acid replicates and protein synthesis occurs. During the maturation period, virus nucleic acid and protein are assembled into mature virions and then released.

cycle until cells burst and release their newly synthesized virions. In the first few minutes after infection the virus enters the *eclipse* phase. Once attached to a permissive host cell, a virion is no longer available to infect another cell. This is followed by the entry of viral nucleic acid into the host cell (Figure 8.6). If the infected cell breaks open at this point, the virion no longer exists as an infectious entity since the viral genome is no longer inside its capsid.

The *maturation* phase (Figure 8.7) begins as newly synthesized viral nucleic acid molecules become packaged inside their capsids. During the maturation phase, the number of infectious virions inside the host cell rises dramatically. However, the new virions still cannot be detected in the culture medium unless the cells are artificially lysed to release them. Because newly assembled virions are not yet present outside the cell, the eclipse and maturation periods together comprise the *latent period* of viral infection (Figure 8.7).

At the end of maturation, mature virions are released, either as a result of cell lysis or by budding or excretion, depending on the virus. The number of virions released per cell, called the *burst size*, varies with the particular virus and the particular host cell,

and can range from a few to a few thousand. The duration of the virus replication cycle also varies, from 20–60 min (in many bacterial viruses) to 8–40 h (in most animal viruses).

In Sections 8.5–8.7 we use a specific example to revisit these stages of the virus replication cycle and examine each in more detail.

MINIQUIZ

- What is packaged into capsids during maturation?
- Explain the term burst size.
- Why is the latent period so named?

8.4 Culturing, Detecting, and Counting Viruses

Host cells need to be grown in order for viruses to replicate in them. Pure cultures of bacterial hosts are grown either in liquid or as “lawns” on the surface of agar plates and then inoculated with a virus suspension. Animal viruses are cultivated in *tissue cultures*, which are cells obtained from an animal organ and grown in sterile glass or plastic vessels containing an appropriate culture medium (see Figure 8.9). Tissue culture media are often highly complex, containing a wide assortment of nutrients including blood serum and antimicrobial agents to prevent bacterial contamination.

Detecting and Counting Viruses: The Plaque Assay

A viral suspension can be quantified to determine the number of infectious virions present per volume of fluid, a quantity called the **titer**. This is typically done using a *plaque assay*. When a virus infects host cells growing on a flat surface, a zone of cell lysis called a **plaque** forms and appears as a clear area in the

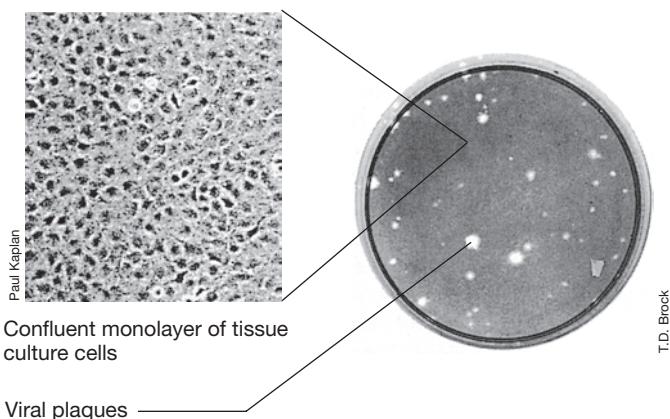

Figure 8.9 Animal cell cultures and viral plaques. The animal cells support replication of the virus, and lysed cells result in plaques.

lawn of host cells. With bacteriophages, plaques may be obtained when virions are mixed into a small volume of molten agar containing host bacteria that is spread on the surface of an agar medium (Figure 8.8a). During incubation, the bacteria grow and form a turbid layer (lawn) that is visible to the naked eye. However, wherever a successful viral infection has occurred, cells are lysed, forming a plaque (Figure 8.8b). By counting the number of plaques, one can calculate the titer of the virus sample (often expressed as “plaque-forming units” per milliliter). For replicating animal viruses, a tissue culture is grown and a diluted virus suspension overlaid upon it. As for bacterial viruses, plaques are revealed as cleared zones in the tissue culture cell layer, and from the number of plaques produced, an estimate of the virus titer can be made (Figure 8.9).

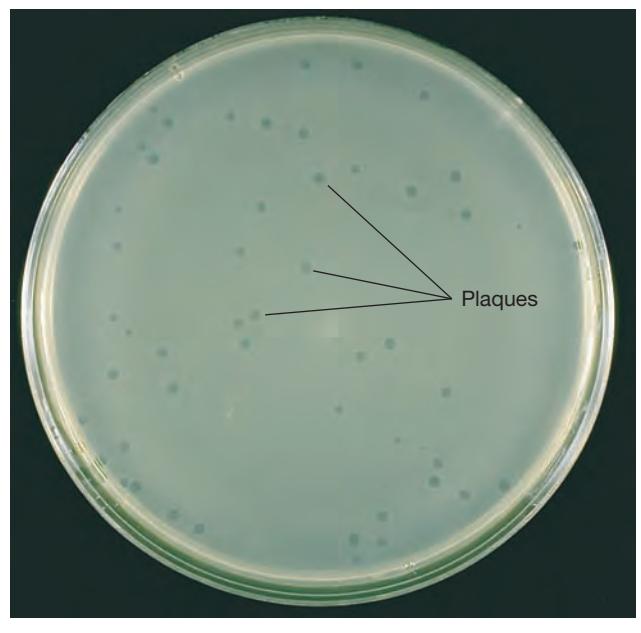

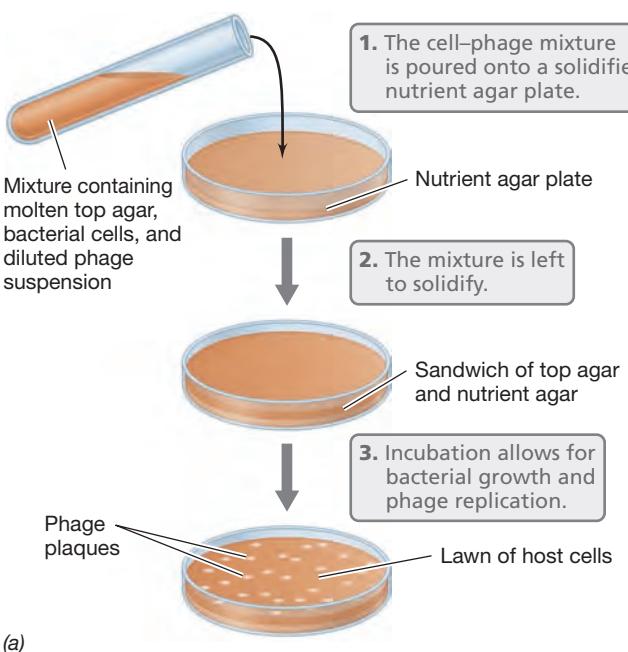

Figure 8.8 Quantification of bacterial virus by plaque assay. (a) “Top agar” containing a dilution of virions mixed with permissive host bacteria is poured over a plate of “bottom agar.” Infected cells are lysed, forming plaques in the lawn. (b) Plaques (about 1–2 mm in diameter) formed by bacteriophage T4.

The concept of *plating efficiency* is important in quantitative virology, whether of bacterial or animal viruses. In any given viral preparation, the number of plaque-forming units is always lower than actual counts of viral particles made microscopically (using an electron microscope). This is because the efficiency with which virions infect host cells is rarely 100% and may often be considerably less. Virions that fail to infect may have assembled incompletely during the maturation process or may contain defective genomes. Alternatively, a low plating efficiency may mean that viral growth conditions were not optimal or that some virions were damaged by handling or storage conditions. Although with bacterial viruses

the efficiency of plating is often higher than 50%, with many animal viruses it may be much lower, 0.1% or 1%. Knowledge of plating efficiency is useful in cultivating viruses because it allows one to estimate what a titer needs to be to yield a certain number of plaques.

MINIQUIZ

- What is meant by a viral titer?
- What is a plaque-forming unit?
- What is meant by the term plating efficiency?

II • Bacteriophage Life Cycles

Much of our understanding of lytic virus replication comes from the study of bacteriophages infecting *Escherichia coli*. Many RNA as well as DNA bacteriophages replicate in *E. coli* (Table 8.1). Here we choose one, bacteriophage T4, as our model for reviewing the individual stages of the virus life cycle (Figure 8.6) in more detail.

8.5 Attachment and Entry of Bacteriophage T4

The early steps in the life cycle of any bacteriophage are attachment to the surface of its host cell followed by penetration of the host cell outer layer(s) and entry of the viral genome into the cell.

Attachment

A major factor in host specificity of a virus is *attachment*. The virion itself has one or more proteins on its external surface that interact with specific host cell surface components called *receptors*. In the absence of its specific receptor, the virus cannot attach to the cell and hence cannot infect. Moreover, if the receptor is altered, for example by mutation, the host may become resistant to virus infection. The host range of a given virus is thus to a major extent determined by the presence of a suitable receptor that the virus can recognize and attach to.

Viral receptors are surface components of the host, such as proteins, carbohydrates, glycoproteins, lipids, or lipoproteins, or

cell structures made from these macromolecules (Figure 8.10). The receptors carry out normal functions for the cell; for example, the receptor for phage T1 is an iron-uptake protein (Figure 8.10) and that for bacteriophage lambda functions in maltose uptake. Carbohydrates in the lipopolysaccharide (LPS) outer membrane of gram-negative bacteria are the receptors recognized by bacteriophage T4, a phage that binds to the LPS of *Escherichia coli* (Figure 8.10). Appendages that project from the cell surface, such as flagella and pili, are also common receptors for bacterial viruses. Small icosahedral viruses often bind to the side of these structures, whereas filamentous bacteriophages typically bind at the tip, such as on the pilus (Figure 8.10). Regardless of the receptor used, however, once attachment has occurred, the stage is set for viral infection.

Penetration

Attachment of a virus to its host cell causes changes to both the virus and the host cell surface that result in penetration. Bacteriophages abandon the capsid outside the cell and only the viral genome reaches the cytoplasm. However, entry of the viral genome into a host cell only results in virus replication if the viral genome can be read. Consequently, for the replication of some viruses, for example RNA viruses, specific viral proteins must also enter the host cell along with the viral genome (Section 8.2).

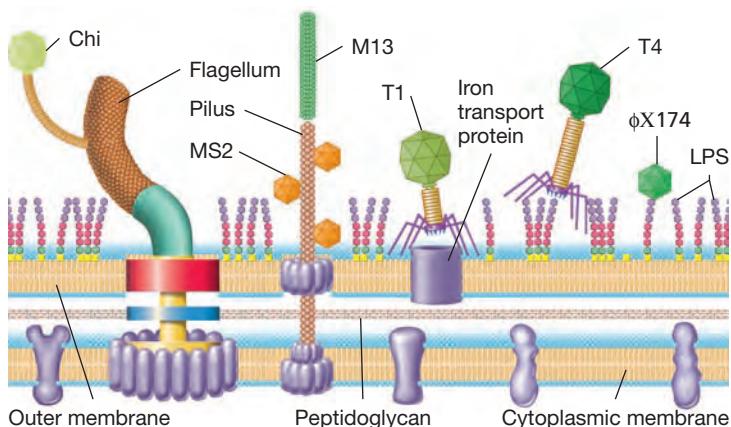

Figure 8.10 Bacteriophage receptors. Examples of the cell receptor sites used by different bacteriophages that infect *Escherichia coli*. All phages depicted except for MS2 are DNA phages.

Table 8.1 Some bacteriophages of *Escherichia coli*

Bacteriophage	Virion structure	Genome composition ^a	Genome structure	Size of genome ^b
MS2	Icosahedral	ssRNA	Linear	3,600
φX174	Icosahedral	ssDNA	Circular	5,400

Lambda	Head & tail	dsDNA	Linear	48,500
T7 and T3	Head & tail	dsDNA	Linear	40,000
T4	Head & tail	dsDNA	Linear	169,000
Mu	Head & tail	dsDNA	Linear	39,000

^aSS, single-stranded; ds, double-stranded.

^bIn bases (ss genomes) or base pairs (ds genomes). These viral genomes have been sequenced and thus their lengths are known precisely. However, the sequence and length often vary slightly among different isolates of the same virus. Hence, the genome sizes listed here have been rounded off in all cases.

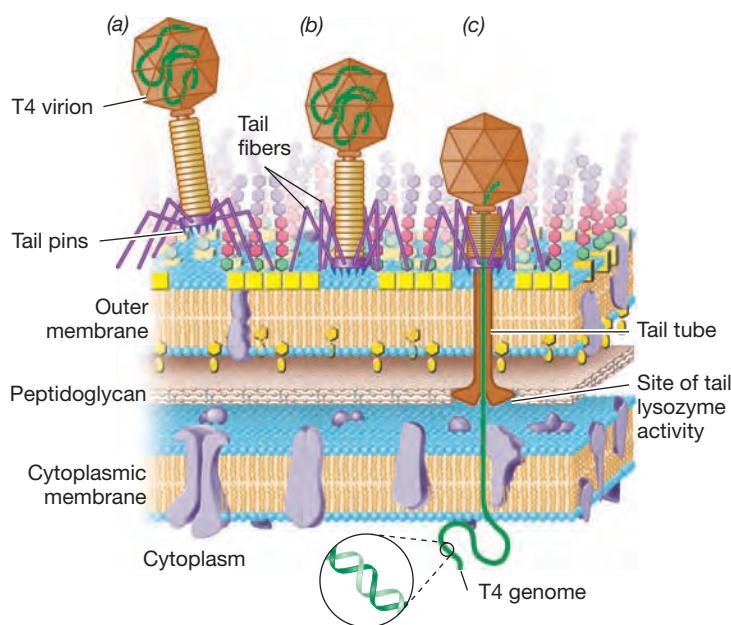

Figure 8.11 Attachment of bacteriophage T4 to an *Escherichia coli* cell.

(a) Initial attachment of a T4 virion to the cell outer membrane by tail fiber interactions with lipopolysaccharide (LPS). (b) Contact of the cell wall by the tail pins. (c) Contraction of the tail sheath and injection of the T4 genome. The tail tube penetrates the outer membrane, and T4 lysozyme digests a small opening through the peptidoglycan layer.

The most complex viral penetration mechanisms exist with the tailed bacteriophages. Bacteriophage T4 consists of an icosahedral head, within which the viral linear double-stranded DNA is folded, and a long, complex tail, which ends in a series of tail fibers and tail pins that contact the cell surface. Phage T4 virions first attach to *Escherichia coli* cells using their tail fibers (Figure 8.11). The ends of the tail fibers interact specifically with polysaccharides in the cell's LPS layer and then the tail fibers retract, allowing the tail itself to contact the cell wall via the tail pins. The activity of T4 lysozyme then forms a small pore in the peptidoglycan layer and the tail sheath contracts. When this occurs, T4 DNA enters the cytoplasm of the *E. coli* cell through a tail tube in a fashion resembling that of injection by a syringe. By contrast, the T4 capsid remains outside the cell (Figure 8.11). DNA inside bacteriophage heads is under high pressure, and because the interior of a bacterial cell is also under pressure from osmotic forces, the phage DNA injection process takes several minutes to complete.

We now consider some of the unique properties of the T4 genome that affect its replication and gene expression.

MINIQUIZ

- How does attachment contribute to virus–host specificity?
- Why does T4 need a lysozyme-like protein in order to infect its host?
- What part of phage T4 enters the host cytoplasm?

8.6 The T4 Genome

Once a permissive host cell has been infected by a virus, the earliest events surround the synthesis of new copies of the viral

genome. Because there are many types of viral genomes (Figure 8.2), there are many different schemes for virus genome replication (Section 9.1). In small DNA viruses, replication of the viral genome is done by the cell's DNA polymerase. However, in more complex DNA viruses such as bacteriophage T4, the virus encodes its own DNA polymerase. Other proteins that function in viral DNA replication such as primases and helicases (Sections 4.4–4.5) are also encoded by the T4 genome. In fact, T4 produces its own eight-protein DNA replisome complex (Section 4.6) to facilitate phage-specific genome synthesis.

Genome Replication and Circular Permutation

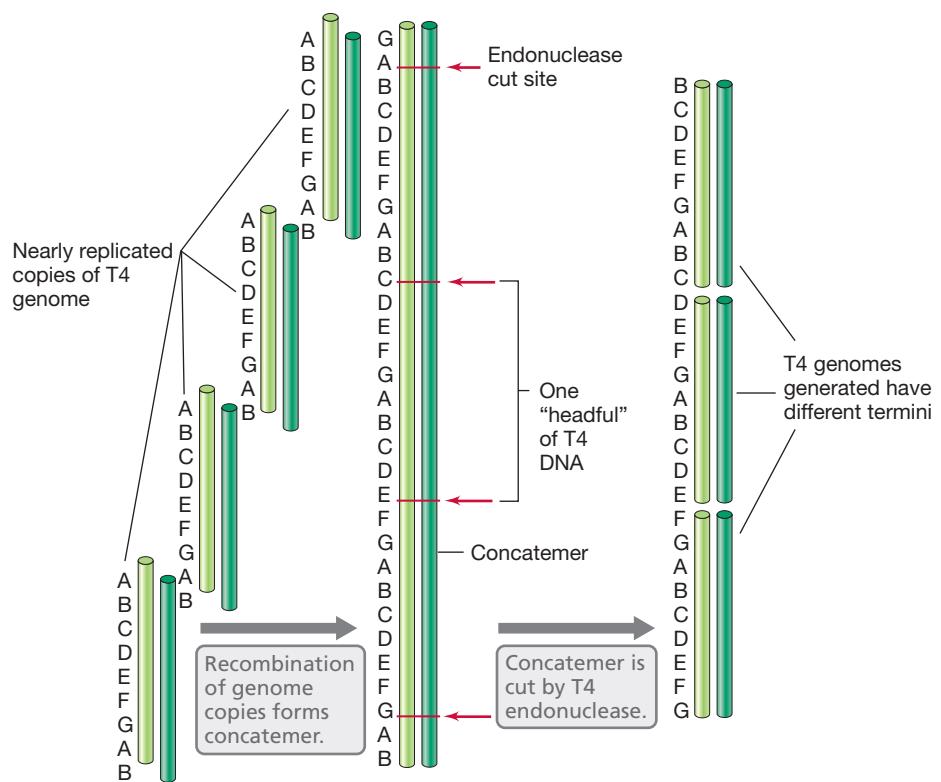

Chromosomes of higher organisms and genomes of bacteria contain the same genes in the same order in cells of different individuals of the same species. This is also true of many virus genomes, but not all. Sometimes a population of virions of a single virus contain genomes with the same set of genes but arranged in a different order. This is a phenomenon called *circular permutation* and is a hallmark of the T4 genome. The term circular permutation is derived from the fact that DNA molecules that are circularly permuted appear to have been linearized by opening identical circular genomes at different locations. Circularly permuted genomes are also *terminally redundant*, meaning that some DNA sequences are duplicated on both ends of the DNA molecule as a result of the mechanism that generated them.

The T4 genome is first replicated as a unit and then several genomic units are recombined end to end to form a long DNA molecule called a **concatemer** (Figure 8.12a). When the T4 DNA is packaged into capsids, the concatemer is not cut at a specific sequence but instead, linear segments of DNA just long enough to fill a phage head are generated. This is called *headful packaging*, and is common among bacteriophages. However, because the T4 head holds slightly more than a genome length, the headful mechanism generates terminal repeats of about 3–6 kbp at each end of the DNA molecule (Figure 8.12a).

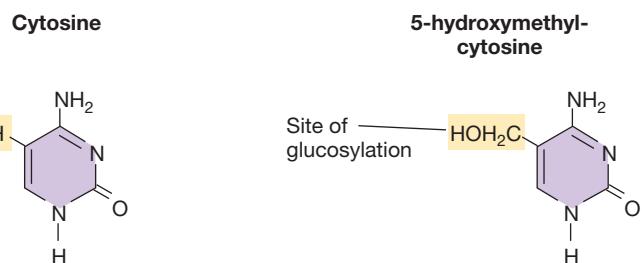

Restriction and Modification

Although they lack the immune systems of animals, bacteria possess several weapons against viral attack. An antiviral system called CRISPR (Section 10.12) is one of these, but in addition, bacteria can destroy double-stranded viral DNA by the activity of *restriction endonucleases*, bacterial enzymes that cleave foreign DNA at specific sites (Section 11.1). This process is called *restriction* and is a general host mechanism to prevent invasion by viral (or any other foreign) DNA. For such a system to be effective, however, the host must protect its own DNA from restriction enzyme attack. The host accomplishes this by *modification* of its DNA, typically by methylation of nucleotides at the sites where the restriction enzymes cut.

Restriction enzymes are specific for double-stranded DNA and thus single-stranded DNA viruses and all RNA viruses are unaffected by restriction enzymes. Although host restriction systems confer significant protection from viral attack, some double-stranded DNA viruses have overcome host restriction by modifying their own DNA so it is no longer subject to restriction enzyme attack. Many protective mechanisms are known, but in phage T4 this is accomplished by substituting the base *5-hydroxymethylcytosine* in place of cytosine in viral DNA. The hydroxy group of this

(a) Circularly permuted T4 DNA

(b) An unusual base in T4 DNA

Figure 8.12 Circular permutation and the unique DNA of bacteriophage T4. (a) Generation of virus-length T4 DNA molecules with permuted sequences by an endonuclease that cuts off constant lengths of DNA from a concatemer regardless of their sequence. (b) The unique base 5-hydroxymethylcytosine in the DNA of bacteriophage T4. Once this base is glucosylated, the T4 DNA is resistant to restriction enzyme attack.

modified base is glucosylated, meaning that a molecule of glucose is added (Figure 8.12b), and DNA with this modification is resistant to restriction enzyme attack. By virtue of this viral protection mechanism, copies of the T4 genome are preserved until they are packaged later in the phage replication cycle.

MINIQUIZ

- What is characteristic of a circularly permuted and terminally redundant genome?
- What is a concatemer?
- How does *Escherichia coli* try to protect itself from phage attack, and how does T4 protect itself from these weapons?

8.7 Replication of Bacteriophage T4

We now examine the steps in the replication cycle of bacteriophage T4, drawing on what we already know about attachment and penetration of T4 and properties of the T4 genome from the previous two sections.

Transcription and Translation

Shortly after infection, T4 DNA is transcribed and translated, and the process of new virion synthesis begins. In less than half an hour, the process culminates in the release of new virions from the lysed cell. The major events are summarized in **Figure 8.13**.

Within a minute after T4 DNA enters the host cytoplasm, the synthesis of host DNA and RNA ceases and transcription of specific phage genes begins. Translation of viral mRNA also begins quickly, and within 4 min of infection, phage DNA replication has already begun. The T4 genome encodes three major sets of proteins called **early proteins**, **middle proteins**, and **late proteins**, the terms referring to the general order of their appearance in the cell. Early proteins include enzymes for the synthesis and glucosylation of the unusual T4 base 5-hydroxymethylcytosine (Figure 8.12b), enzymes that function in the T4 replisome to produce copies of the phage-specific genome, and early proteins that modify host RNA polymerase. By contrast, middle and late proteins include additional RNA polymerase-modifying proteins, and virion structural and release proteins. These include, in particular, viral head and tail proteins and the enzymes required to liberate new virions from the cell (Figure 8.13).

The T4 genome does not encode its own RNA polymerase; instead, T4-specific proteins modify the specificity of the host RNA polymerase so that it recognizes only phage promoters (recall that promoters are the regions upstream

of a structural gene where RNA polymerase binds to initiate transcription, [Section 4.7](#)). These modification proteins are encoded by T4 early genes and are transcribed by the host RNA polymerase. Host transcription is shut down shortly after this by a phage-encoded anti-sigma factor that binds to the host RNA polymerase sigma factor and prevents it from recognizing promoters on host genes. This effectively switches the activity of host RNA polymerase from transcribing host genes to transcribing T4 genes. Later in the infection process other phage proteins modify the host RNA polymerase so it now recognizes T4 middle gene promoters. Finally, transcription of T4 late genes begins, and this requires a new T4-encoded sigma factor that directs host RNA polymerase to promoters for these genes only. At this point, viral assembly can begin.

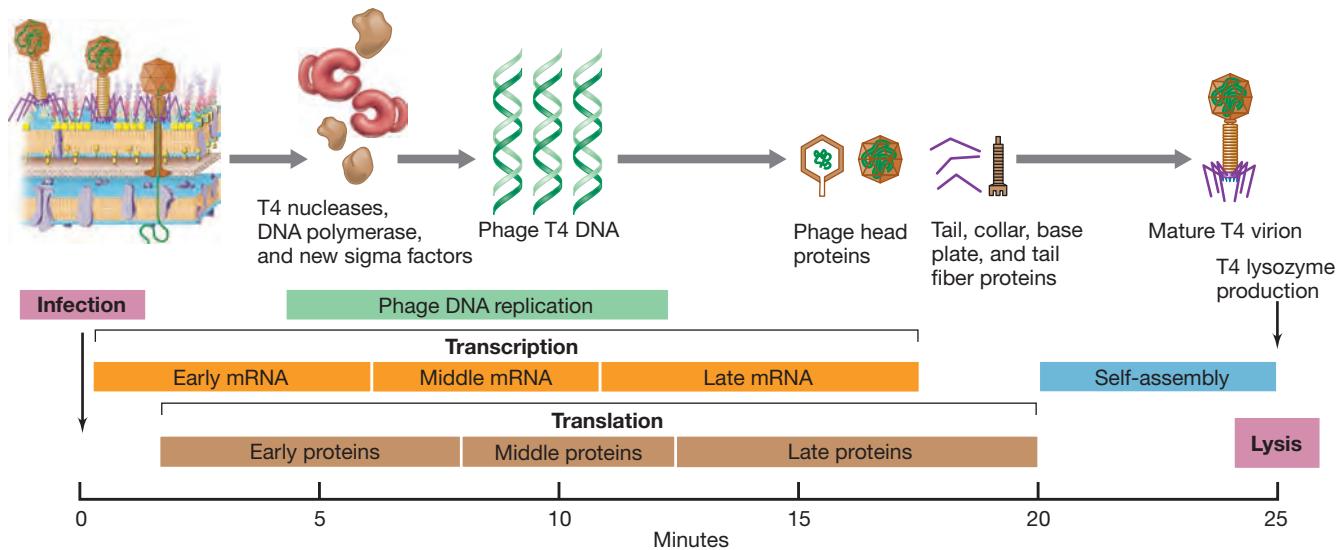

Figure 8.13 Time course of events in phage T4 infection. Following injection of DNA, early and middle mRNA is produced that encodes nucleases, T4 DNA polymerase, new phage-specific sigma factors, and other proteins needed for DNA replication. Late mRNA encodes virion structural proteins and T4 lysozyme, which is needed to lyse the cell and release new virions.

Packaging the T4 Genome and Virion Assembly and Release

The bacteriophage T4 DNA genome is forcibly pumped into a preassembled capsid using an energy-linked packaging motor. The motor components are encoded by viral genes, but host cell metabolism is needed to produce the proteins and supply the ATP required for the pumping process. The packaging process can be divided into three stages (Figure 8.14). First, precursors of the bacteriophage head called *proheads* are assembled but remain empty. Proheads contain temporary “scaffolding proteins” as well as head structural proteins. Second, a packaging motor is assembled at the opening to the prohead. The double-stranded linear T4 DNA genome (Figure 8.12) is then pumped into the prohead under pressure using ATP as the driving force. The prohead expands

when pressurized by the entering DNA and the scaffolding proteins are simultaneously discarded. Third, the packaging motor itself is discarded and the capsid head is sealed.

After the head has been filled, the T4 tail, tail fibers, and the other components of the virion are added, primarily by self-assembly (Figures 8.13 and 8.14). The phage genome encodes a pair of very late enzymes that combine to breach the two major barriers to virion release: the host cytoplasmic membrane and peptidoglycan layer. Once these structures are compromised, the cell breaks open by osmotic lysis and the newly synthesized virions are released. After each replication cycle, which takes only about 25 min (Figure 8.13), over 100 new virions are released from each host cell (the *burst size*, Section 8.3), and these are now free to infect neighboring host cells.

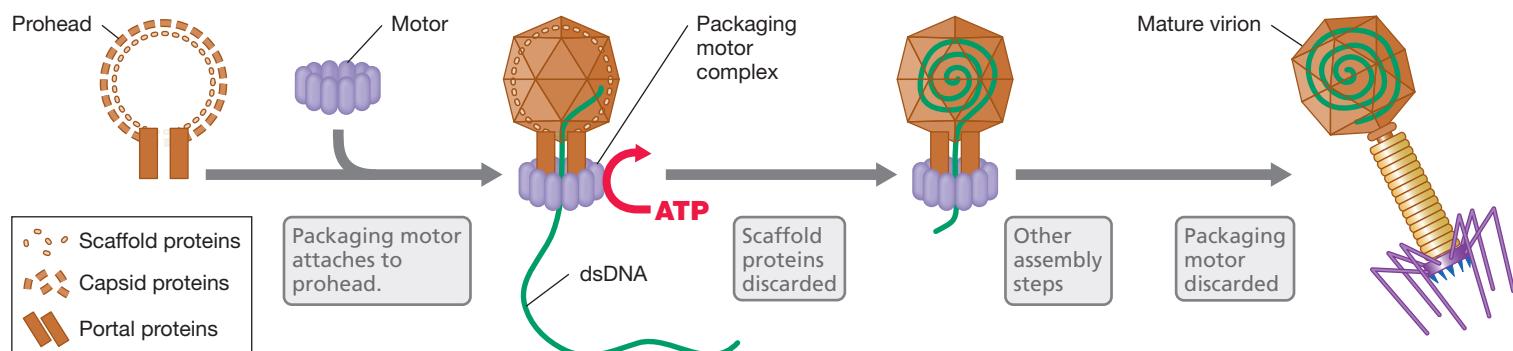

Figure 8.14 Packaging of DNA into a T4 phage head. Proheads are assembled from capsid and portal proteins, both of which remain in the mature virion. As the head fills with DNA, it expands and becomes more angular. Once the head is filled, the packaging motor detaches and the tail components are added.

MINIQUIZ

- Give one example each of T4 early, middle, and late proteins.
- How does T4 direct host RNA polymerase to phage-specific genes?
- What is required to package the T4 genome into its phage head?

8.8 Temperate Bacteriophages and Lysogeny

Bacteriophage T4 is a virulent virus and once infection begins, it always kills its host. However, some double-stranded DNA bacterial viruses, although able to catalyze a virulent cycle, can also infect their host and establish a long-term stable relationship. These viruses are called **temperate viruses**.

Temperate viruses can enter into a state called **lysogeny**. In this state, most virus genes are not transcribed and instead, the virus genome is replicated in synchrony with the host chromosome and passed to daughter cells at cell division. The lysogenic state may confer new genetic properties on the bacterial host cell—a condition called *lysogenic conversion*—and we will see several examples

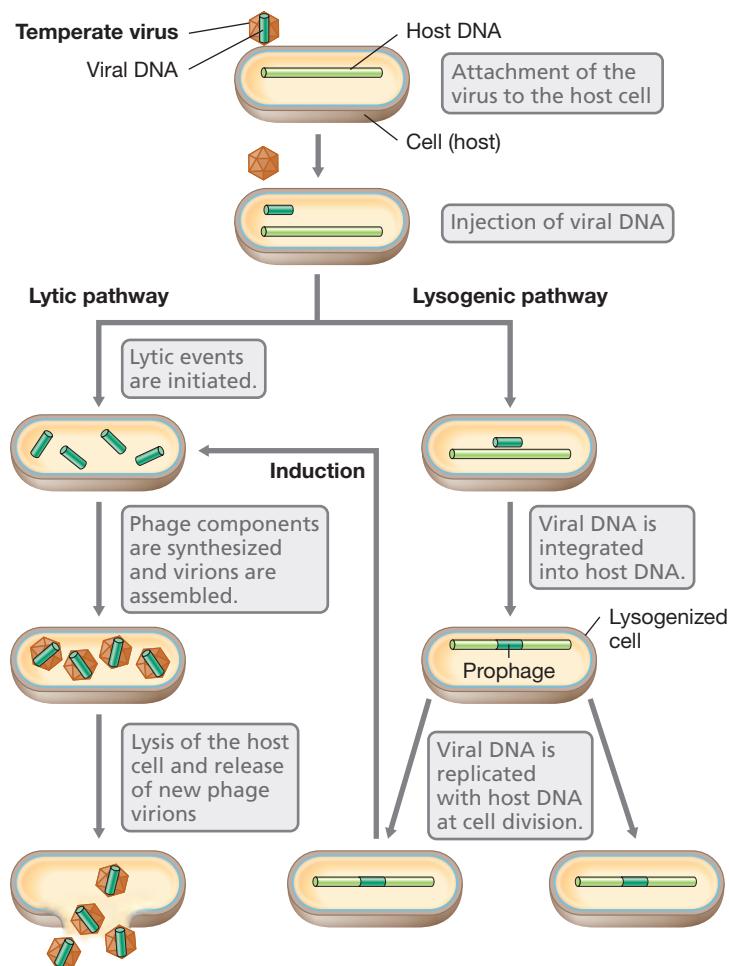

Figure 8.15 Consequences of infection by a temperate bacteriophage.

The alternatives upon infection are replication and release of mature virus (lysis) or lysogeny, often by integration of the virus DNA into the host DNA, as shown here. The lysogen can be induced to produce mature virus and lyse.

in later chapters of pathogenic bacteria whose virulence (ability to cause disease) is linked to a lysogenic bacteriophage. A cell that harbors a temperate virus is called a **lysogen**.

The Replication Cycle of a Temperate Phage

Two well-characterized temperate bacteriophages are lambda and P1. The life cycle of a temperate bacteriophage is shown in **Figure 8.15**. During lysogeny, the temperate virus genome is either integrated into the bacterial chromosome (lambda) or can exist in the cytoplasm as a plasmid (P1). In either case, the viral DNA, now called a **prophage**, replicates along with the host cell as long as the genes that activate the phage virulent pathway are repressed.

Maintenance of the lysogenic state is due to a phage-encoded **repressor protein**. Normally, low-level transcription of repressor genes and their subsequent translation maintains the repressor at a low level in the cell. However, if the phage repressor is inactivated or if its synthesis is in some way prevented, the prophage can be induced into the lytic stage. If induction occurs while the viral DNA is incorporated into the bacterial chromosome, the viral DNA is excised and phage genes are transcribed and translated; new virions are then produced, and the host cell is lysed (Figure 8.15). Various cell stress conditions, especially damage to host cell DNA, can induce a prophage to enter the lytic pathway. In contrast to this process, the viral “decision” to proceed to lysogeny or the lytic pathway upon initial viral infection is another matter altogether, and has been particularly well-studied in bacteriophage lambda. We explore this story now.

Bacteriophage Lambda

Bacteriophage lambda, which infects *Escherichia coli*, is a double-stranded DNA virus with a head and tail (Figure 8.16). At the 5' end of each DNA strand of the linear lambda genome is a single-stranded region 12 nucleotides long. These single-stranded “cohesive” ends are complementary in base sequence; when lambda DNA enters the host cell, they base-pair to form the **cos** site and cyclize (circularize) the genome (Figure 8.17a).

If lambda enters the lytic pathway, long, linear concatemers of genomic DNA are synthesized by a mechanism called **rolling circle replication**. In this process, one strand in the circular

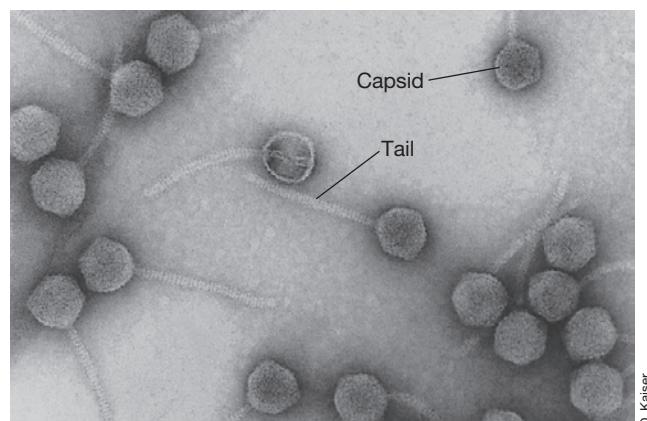

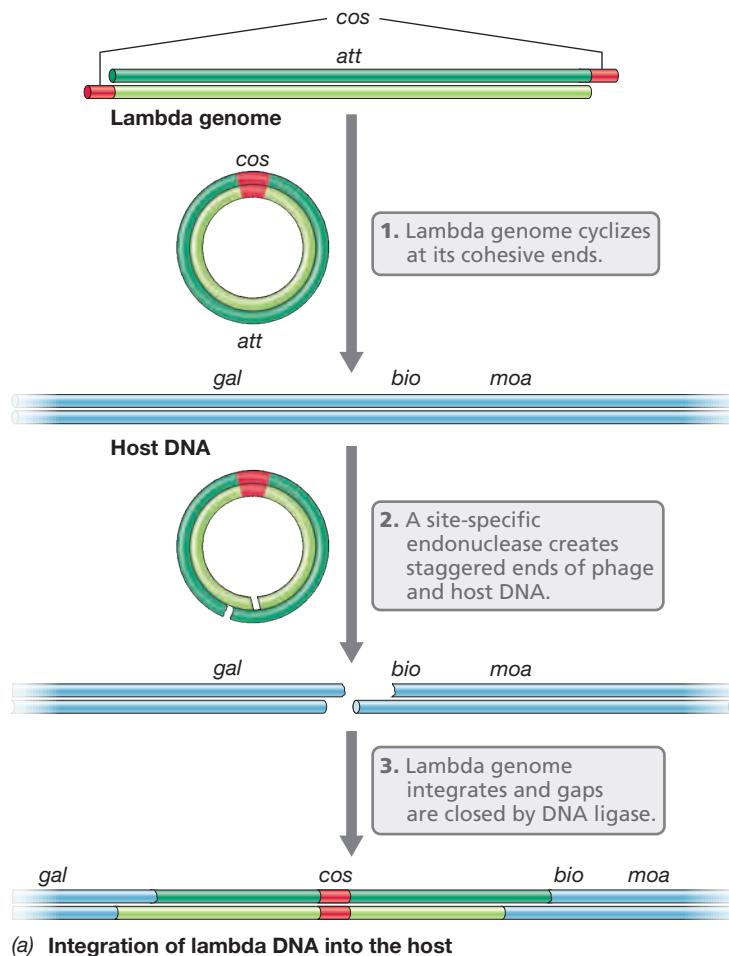

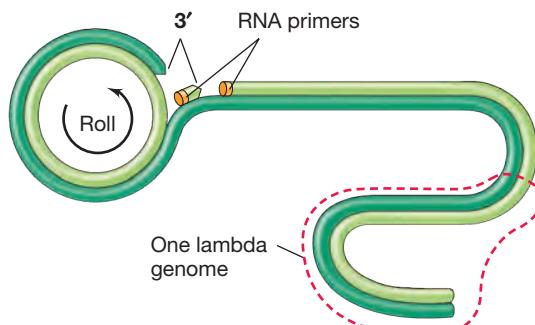

Figure 8.16 Bacteriophage lambda. Transmission electron micrograph of phage lambda virions. The head of each virion is about 65 nm in diameter and contains linear dsDNA.

(a) Integration of lambda DNA into the host

(b) Rolling circle replication of lambda genome

Figure 8.17 Integration of lambda DNA and rolling circle replication. (a) Lambda DNA integrates at specific attachment (*att*) sites on both the host and phage genomes. Host genes near *att* include *gal*, galactose utilization; *bio*, biotin synthesis; and *moa*, molybdenum cofactor synthesis. Lambda integrase is required, and specific pairing of the complementary ends results in integration of lambda DNA. (b) During rolling circle replication, as one strand (dark green) rolls out, it is both replicated at its opposite end and serves as a template for synthesis of the complementary strand.

lambda genome is nicked and is “rolled out” as a template for synthesis of the complementary strand (Figure 8.17b). The double-stranded concatemer is then cut into genome-sized lengths at the *cos* sites and the resulting genomes packaged into lambda phage heads. Once the tail has been added and mature

lambda virions have been assembled (Figure 8.16), cell lysis occurs and the virions are released. In its role as a lytic phage, lambda can also package a few chromosomal genes from its lysed host in newly synthesized virions and then transfer these to a second host cell, a process called *transduction*. Transduction is an important means of horizontal gene transfer in nature (Section 8.11) and is also an important tool in bacterial genetics (Section 10.7).

Instead of the lytic pathway, if lambda takes the lysogenic route, its genome integrates into the *E. coli* chromosome. This requires a protein called *lambda integrase*, a phage-encoded enzyme that recognizes the phage and bacterial genome attachment sites (*att* in Figure 8.17a) and facilitates integration of the lambda genome. From this relatively stable state, certain events such as host DNA damage can initiate the lytic cycle once again. After such a trigger, a lambda excision protein excises the lambda genome from the host chromosome, transcription of lambda DNA begins, and lytic events unfold.

We now consider how these opposing processes of lysis and lysogeny are controlled upon initial infection of an *E. coli* cell by a phage lambda virion.

Lysis or Lysogeny?

Whether lysis or lysogeny occurs in a lambda infection depends in large part on the levels of two key repressor proteins that can accumulate in the cell following infection: the *lambda repressor*, also called the *cI protein*, and a second repressor called *Cro*. In a nutshell, the first repressor to accumulate will control the outcome of the infection.

If genes encoding the *cI* protein are rapidly transcribed following infection and *cI* accumulates, it represses the transcription of all other lambda-encoded genes, including *cro*. When this happens, the lambda genome integrates into the host’s genome and becomes a prophage (Figure 8.18). *Cro*, on the other hand, represses expression

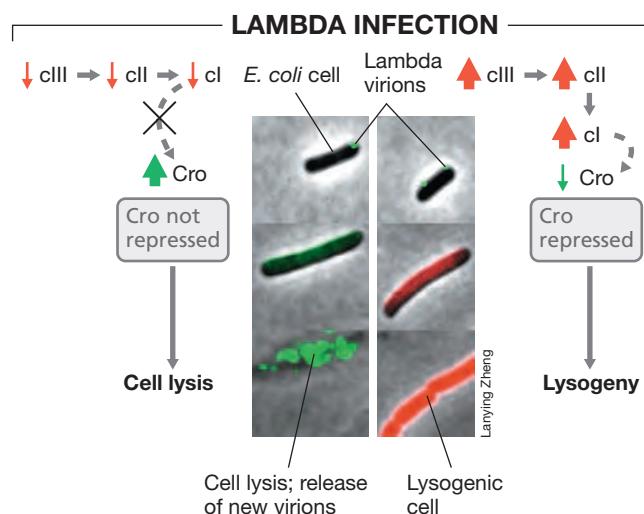

Figure 8.18 Regulation of lytic and lysogenic events in phage lambda. The photomicrographs show time courses of cells of *Escherichia coli* following a course of lytic (left panel, green) or lysogenic (right panel, red) events, as controlled by various repressors. The colors originate from genetically engineered lambda phage that trigger the production of specific fluorescent proteins when either lytic genes (green) or lysogenic genes (red) are expressed. Lytic cells are killed while *E. coli* lysogens continue to grow and divide.

of a protein called cII whose function is to activate the synthesis of cI. Hence, following infection, if cI is present at insufficient levels to repress expression of phage-specific genes, Cro can accumulate in the cell; if this happens, lambda travels the lytic pathway.

Control of these alternative lifestyles—lysis or lysogeny—of lambda has been likened to a “genetic switch,” where a defined series of events must occur for one pathway to be favored over the other. Although infection of an *E. coli* cell by a lambda virion typically results in the lytic cycle, as we have said, lytic events can be switched off if sufficient concentrations of cII are present to ensure adequate levels of cI (Figure 8.18). But how does this come about? Levels of protein cII are controlled by the relative activity of a protease in the cell that slowly degrades cII and on levels of yet another protein, cIII, whose function is to stabilize cII and

prevent it from protease attack. We thus have a cascade of regulatory events here: cIII controls cII, which in turn controls cI. But even this is not the end of the story. Several other proteins not described here also play a role in the lambda lytic/lysogenic “decision,” and hence the progress of a lambda infection is a highly complex series of events. Indeed, this tiny bacteriophage employs some of the most complex regulatory systems known in virology.

MINIQUIZ

- What is a lysogen and what is a prophage?
- How does DNA replication in lambda differ from that of its host?
- What commits lambda to the lytic versus the lysogenic pathway?

III • Viral Diversity and Ecology

8.9 An Overview of Bacterial Viruses

The most common bacteriophages are head-and-tail phages containing double-stranded DNA genomes (Sections 8.5–8.7). However, many other bacteriophages are known, including a wide variety that contain single-stranded genomes. Examples of the various classes of bacteriophages, based on the properties of their genomes (Figure 8.2), are shown schematically in Figure 8.19.

Bacteriophages with Single-Stranded Genomes

Bacteriophages ϕ X174, M13, and MS2 (Figure 8.19) are three well-characterized *Escherichia coli* phages that contain single-stranded genomes. Phage ϕ X174 contains a circular DNA genome inside an icosahedral virion only 25 nm in diameter. Such small

DNA viruses possess only a few genes and rely entirely upon the DNA replication machinery of the host cell. M13 is a filamentous bacteriophage that also contains a circular DNA genome. The single-stranded genomes of bacteriophages ϕ X174 and M13 are of the plus sense (Section 8.1), and before replication occurs, they are converted into a double-stranded **replicative form**. From these, single-stranded genome copies are derived and transcription of viral genes takes place.

Bacteriophage MS2 is a small icosahedral virus (Figure 8.19) whose single-stranded RNA genome encodes only four proteins. A key one of these is **RNA replicase**, the enzyme needed to replicate the viral RNA genome. Such an enzyme is needed because bacterial and animal cells do not possess enzymes that synthesize RNA from an RNA template. Because the RNA genome of phage MS2 is of the plus sense (Section 8.1), the genome is also mRNA and can therefore be translated directly upon entry into the cell by the host’s translational machinery.

An interesting feature of many small DNA and RNA bacteriophages is their **overlapping genes**. The genomes of these tiny viruses typically contain too few genes to encode all of the proteins they need. To solve this problem, some of their open reading frames overlap, allowing the virus to produce more than a single polypeptide from a given gene. We discuss examples of overlapping genes and some of the other interesting features of small DNA and RNA bacteriophages in more detail in Chapter 9.

Head-and-Tail Bacteriophages

Head-and-tail bacteriophages with double-stranded DNA genomes have been used as models for virus replication and have revealed many of the fundamental principles of molecular biology and genetics. The first series of tailed phages to be studied were designated T1, T2, and so on, up to T7, with the T referring to the tail. T4 has a much larger genome than that of other T phages and, along with phage lambda (Section 8.8), is probably the best studied of all bacteriophages. The steps in a T phage infection were detailed in Sections 8.5–8.7.

The structure of the T4 virion is perhaps the most complicated of all viruses. The virion consists of an elongated icosahedral head

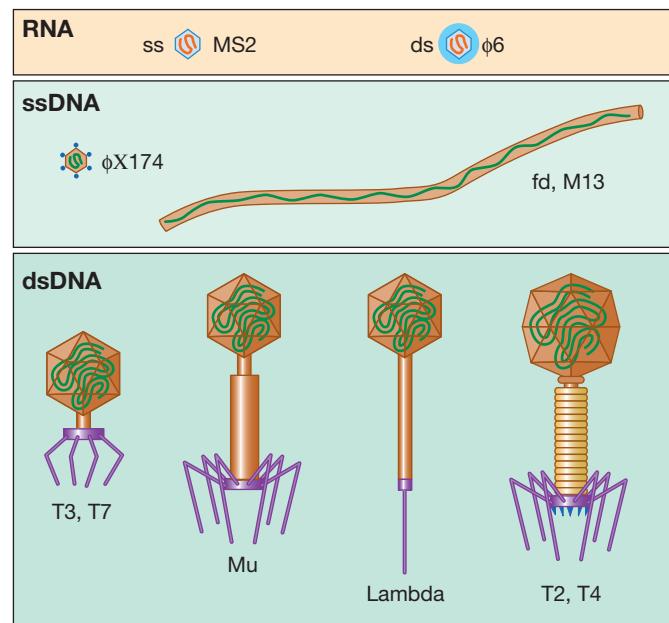

Figure 8.19 Schematic representations of the main types of bacterial viruses. Sizes are to approximate scale. The nucleocapsid of bacteriophage ϕ 6 is surrounded by a membrane (blue).

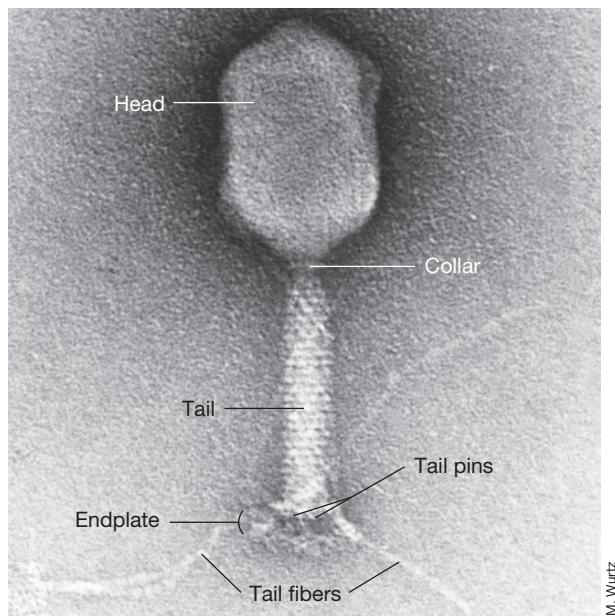

Figure 8.20 Structure of T4, a complex bacteriophage. Transmission electron micrograph of bacteriophage T4 of *Escherichia coli*. The tail components function in attachment of the virion to the host and injection of the nucleic acid (see Figure 8.11). The T4 head is about 85 nm in diameter.

whose overall dimensions are 85×110 nm (Figure 8.20). Attached to the head is a complex tail consisting of 20 different proteins that form a helical tube surrounded by a sheath. At one end the tail is joined to the head by a “neck” with a “collar” and at the other end is an end plate carrying long, jointed tail fibers (Figure 8.20). Following attachment of a T4 virion to a host cell (by way of its tail fibers, Figure 8.11), the tail contracts to make small incisions in both the host peptidoglycan and cytoplasmic membrane and inject the T4 genome into the cell. The genome of T4 is a linear DNA molecule of about 170 kilobase pairs that encodes nearly 300 proteins, including many needed for phage DNA replication (Section 8.7). Although no virus encodes its own translational apparatus, the T4 genome does encode eight of its own tRNAs. These likely assist in reading certain T4 codons, since T4 codon bias (Section 4.11) differs significantly from that of *E. coli*.

MINIQUIZ

- What type of nucleic acid is most common in bacteriophage genomes?
- What is the function of RNA replicase?
- What does the T in T4 stand for?

8.10 An Overview of Animal Viruses

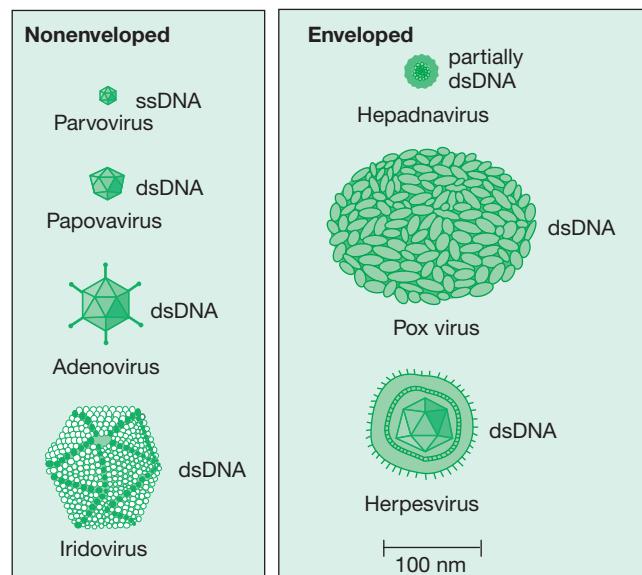

Viruses that infect plants and animals share many properties with bacterial viruses but differ in some key respects. The major tenets of virology—presence of a capsid to carry the viral DNA or RNA genome, infection and takeover of host metabolic processes, and assembly and release from the cell—are universal, regardless of the nature of the host. However, two key differences between

bacterial and animal viruses are that (1) the entire virion of animal viruses (rather than just the nucleic acid) enters the host cell, and (2) eukaryotic cells contain a nucleus, where many animal viruses replicate. We explore some aspects of animal viruses here.

Classification of Animal Viruses

Various types of animal viruses are illustrated in Figure 8.21. As for bacterial viruses, animal viruses are classified by the structure of their genomes (Figure 8.2). Animal viruses are known in all genomic categories, and most animal viruses that have been studied in detail are those that can replicate in cell cultures (Section 8.4 and Figure 8.9.)

The majority of important human viral diseases are caused by RNA viruses, and some examples are listed in Table 8.2. Most of these

(a) DNA viruses

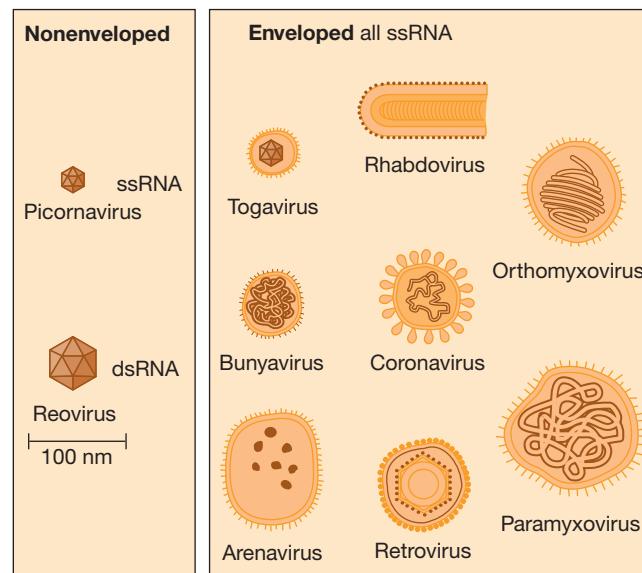

Figure 8.21 Diversity of animal viruses. The shapes and relative sizes of the major groups of vertebrate viruses. The hepadnavirus genome has one complete DNA strand and part of the complementary strand.

Table 8.2 Representative viral diseases of humans

Disease	Virus	Genome DNA or RNA ^a	Size ^b
Cold sores/genital herpes	Herpes simplex	dsDNA	152,000
Smallpox	Variola major	dsDNA	190,000
Polio	Poliovirus	ssRNA (+)	7,500
Rabies	Rabies virus	ssRNA (-)	12,000
Influenza	Influenza A virus	ssRNA (-)	13,600
Measles	Measles virus	ssRNA (-)	15,900
Ebola hemorrhagic fever	Ebola virus	ssRNA (-)	19,000
Severe acute respiratory syndrome (SARS)	SARS virus	ssRNA (+)	29,800
Infant diarrhea	Rotavirus	dsRNA	18,600
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	ssRNA/dsDNA (a retrovirus) (+)	9,700

^aSS, single-stranded; ds, double-stranded. +, plus-strand virus; −, negative-strand virus (Section 8.1).

^bIn bases (ss genomes) or base pairs (ds genomes). These viral genomes have been sequenced and thus their lengths are known precisely. However, the sequence and length often varies slightly among different isolates of the same virus. Hence, the genome sizes listed here have been rounded off in all cases.

RNA viruses have single-stranded genomes, the only exception being the reoviruses whose genomes consist of double-stranded RNA. As can be seen, the RNA viruses in general have relatively small genomes in contrast to the two listed DNA viruses, smallpox and herpesviruses (Table 8.2).

Unlike a bacteriophage infection, in which one of only two outcomes—lysis or lysogeny—is possible depending on the virus, other events are possible in an animal virus infection. We explore these possibilities now.

Consequences of Virus Infection in Animal Cells

Different animal viruses can catalyze at least four different outcomes (Figure 8.22). *Virulent infection* results in lysis of the host cell; this is the most common outcome. By contrast, in a *latent infection*, viral DNA does not replicate and the host cells are unharmed. With some enveloped animal viruses, release of virions, which occurs by a kind of budding process, may be slow, and the host cell may not be lysed. Such infections are called *persistent infections*. Finally, certain animal viruses can convert a normal cell into a tumor cell, a process called *transformation*.

Animal virus receptors are typically cell surface macromolecules used in cell–cell contact or that function in the immune system. For

example, the receptors for poliovirus and for HIV (the causative agent of AIDS) are normally used in intercellular communication between human cells. In multicellular organisms, cells in different tissues or organs often express different proteins on their cell surfaces. Consequently, viruses that infect animals often infect only certain tissues. For example, viruses that cause the common cold infect only cells of the upper respiratory tract.

Animal viruses must eventually lose their outer coat to expose the viral genome. Some enveloped animal viruses are uncoated at the host cytoplasmic membrane, releasing the nucleocapsid into the cytoplasm. However, the entire virion of naked animal viruses and many enveloped animal viruses enters the cell via endocytosis. In these cases, the virion is uncoated in the host cytoplasm and the genome passes through the nuclear membrane to the nucleus, where viral nucleic acid replication occurs. Many animal viruses are enveloped, and when these exit the cell, they may pick up part of the cell's cytoplasmic membrane and use it as part of the viral envelope.

Of all the viruses listed in Figure 8.2 and Table 8.2, one group stands out as having an absolutely unique mode of replication. These are the retroviruses. We explore them next as an example of a complex and highly unusual animal virus with significant medical implications.

Retroviruses and Reverse Transcriptase

Retroviruses contain an RNA genome. However, the genome is replicated inside the host cell via a DNA intermediate. The prefix *retro* means “backward,” and the term *retrovirus* refers to the

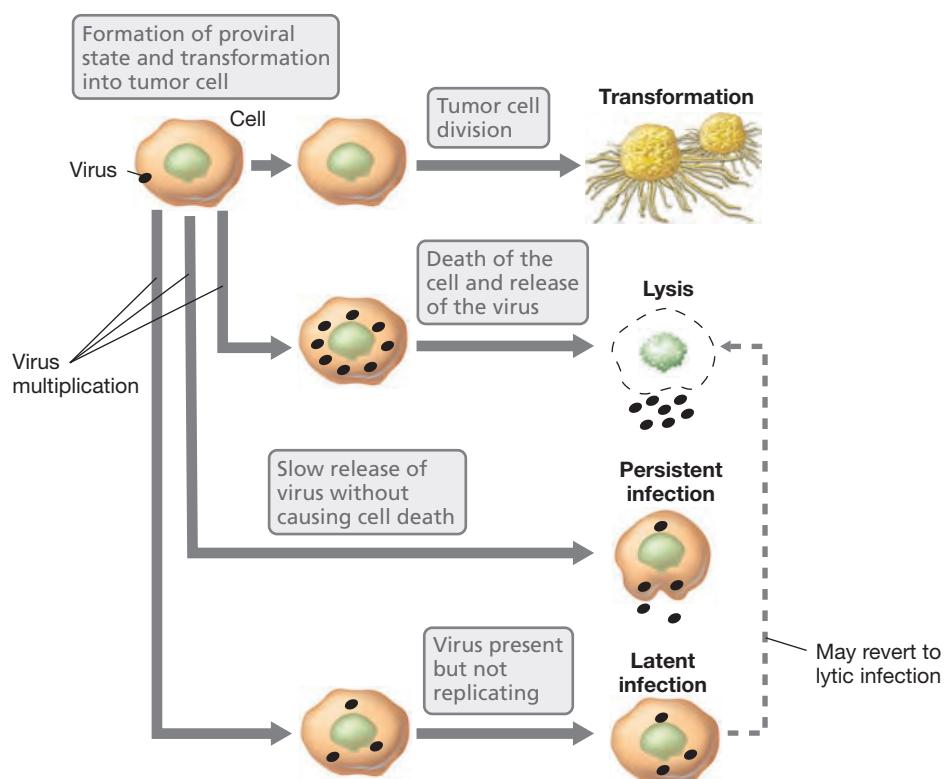

Figure 8.22 Possible effects that animal viruses may have on cells they infect. Most animal viruses are lytic, and only a very few are known to cause cells to transform and become cancerous.

fact that these viruses transfer information from RNA to DNA (in contrast to genetic information flow in cells, which is just the opposite). Retroviruses use the enzyme **reverse transcriptase** to carry out this unusual process. Retroviruses were the first viruses shown to cause cancer, and the human immunodeficiency virus (HIV) is a retrovirus that causes acquired immunodeficiency syndrome (AIDS).

Retroviruses are enveloped viruses that carry several enzymes in the virion (Figure 8.23a). These include *reverse transcriptase*, *integrase*, and a retroviral-specific *protease*. The genome of the retrovirus is unique and consists of two identical single-stranded RNAs of the plus sense (Section 8.1). The genome contains the genes *gag* (structural proteins), *pol* (reverse transcriptase and integrase), and *env* (envelope proteins) (Figure 8.23b). At each end of the retrovirus genome are repeated sequences that are essential for viral replication.

The replication of a retrovirus begins with the virion entering the host cell where the envelope is removed and reverse transcription begins in the nucleocapsid (Figure 8.24). A single strand of DNA is produced and then reverse transcriptase uses this as a template to make a complementary strand; double-stranded DNA is the final product. The latter is released from the nucleocapsid, enters the host nucleus along with the integrase protein, and the integrase facilitates the incorporation of the retroviral DNA into the host genome. The retroviral DNA is now a **provirus**. The latter remains in the host genome indefinitely and proviral DNA can

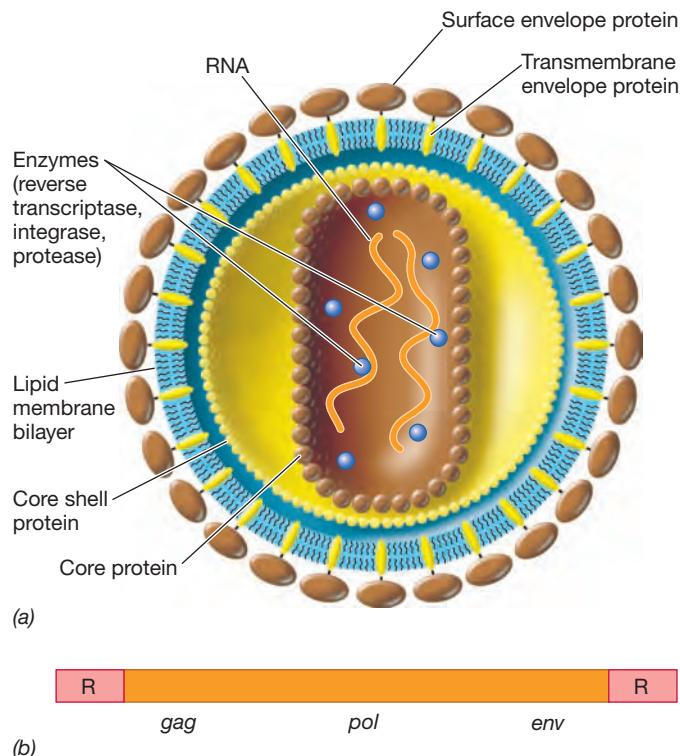

Figure 8.23 Retrovirus structure and function. (a) Structure of a retrovirus. (b) Genetic map of a typical retrovirus genome. Each end of the genomic RNA contains direct repeats (R).

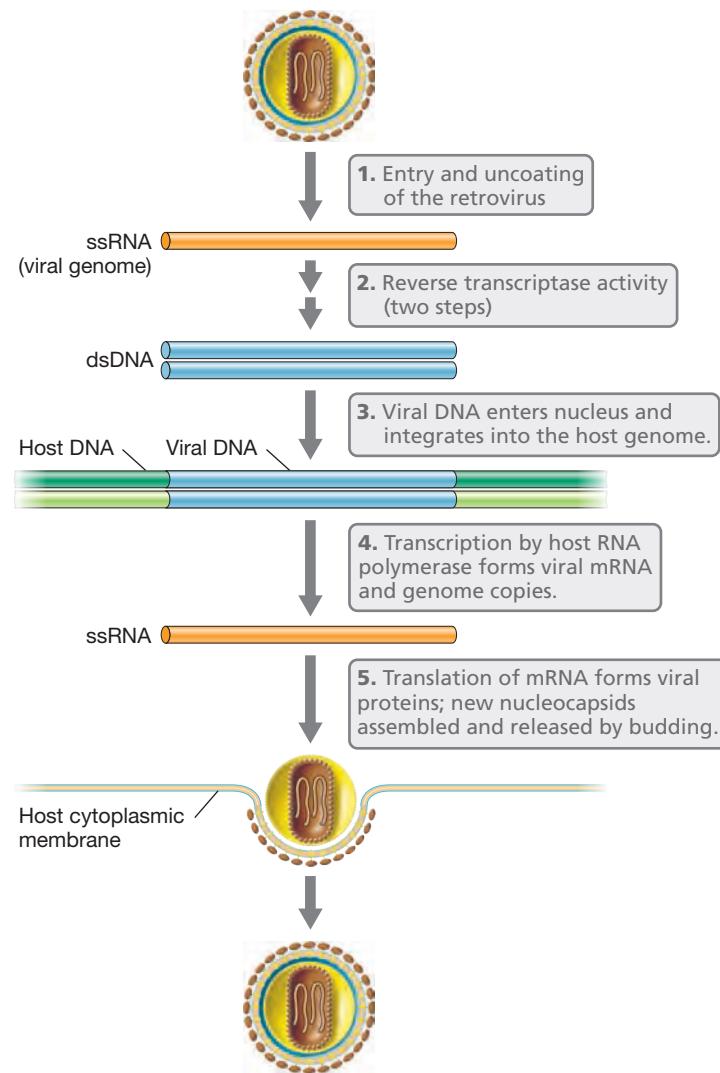

Figure 8.24 Replication of a retrovirus. The virion carries two identical copies of the RNA genome (orange). Reverse transcriptase, carried in the virion, makes single-stranded DNA from viral RNA and then double-stranded DNA that integrates into the host genome as a provirus. Transcription and translation of proviral genes leads to the production of new virions that are then released by budding.

be transcribed by the host RNA polymerase to form copies of the retroviral RNA genome and mRNA. Eventually, nucleocapsids are assembled that contain two copies of the retroviral RNA genome and are enveloped as they bud through the host cell cytoplasmic membrane (Figure 8.24). From here, the mature retrovirus virions are free to infect neighboring cells.

MINIQUIZ

- What is the difference between a persistent and a latent viral infection?
- Why are retroviruses so named? What is required to carry out this process?

8.11 The Virosphere and Viral Ecology

Viruses are present in every environment on Earth that contains cells and are present in enormous numbers. The number of prokaryotic cells on Earth is far greater than the total number of eukaryotic cells; estimates of total prokaryotic cell numbers are on the order of 10^{30} (☞ Table 1.2). However, the number of viruses is even greater than this, an estimated 10^{31} . The best estimates of both cell and virus numbers in nature have come from studies done on seawater.

Viruses of Prokaryotes

There are about 10^6 prokaryotes/ml of seawater and approximately ten times as many viruses. It has been estimated that at least 5% and as many as 50% of the prokaryotes in seawater are killed by bacteriophages each day, and most of the others are eaten by protozoa. Although viruses account for most of the total microorganisms present in seawater in terms of numbers, due to their small size they constitute only about 5% of the total biomass (Figure 8.25).

By far the most common type of bacteriophages, at least in the oceans, are head-and-tail phages containing double-stranded DNA. By contrast, RNA-containing bacteriophages are comparatively rare. As we have seen, lysogenic bacteriophages can integrate into the genomes of their bacterial hosts (Section 8.8), and when they do, they can confer new properties on the cell. Moreover, some lytic phages facilitate the transfer of bacterial genes from one cell to another by transduction, a major means of horizontal gene transfer between prokaryotes (☞ Section 10.7). As agents of transduction, bacteriophages are thought to have a major influence on bacterial evolution. For example, transferred genes may confer new metabolic or other beneficial properties on the recipient cells and allow them to colonize and be successful in new habitats.

Many of the prokaryotes in the marine environment are *Archaea*. In particular, a major group of marine *Archaea* of great ecological relevance are the *Thaumarchaeota*. These ammonia-oxidizing species are capable of consuming the vanishingly low levels of ammonia present in planktonic (open ocean) waters. Although lytic archaeal viruses have yet to be demonstrated for this group, at least one species of *Thaumarchaeota* has been shown to harbor a viral genome within its own genome (that is, it contains a provirus). It is thus likely that at least some, and perhaps even many, of the viruses in seawater infect marine *Archaea* instead of marine *Bacteria*. This is bolstered by the observation that virtually all known archaeal viruses are double-stranded DNA viruses, the most commonly observed group in the oceans.

Survival Strategies and Diversity of Viruses in Nature

When hosts are plentiful in nature, it is thought that bacteriophages adopt the lytic lifestyle and thus large numbers of host

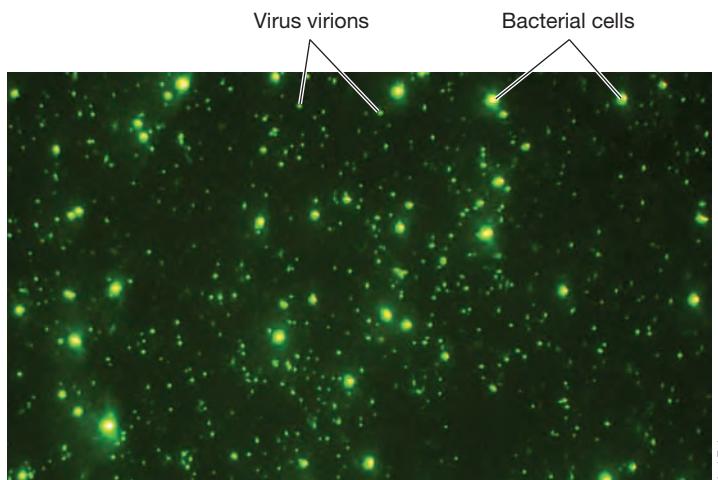

Figure 8.25 Viruses and bacteria in seawater. A fluorescence photomicrograph of seawater stained with the dye SYBR Green to reveal prokaryotic cells and viruses. Although viruses are too small to be seen with the light microscope, fluorescence from a stained virus is visible.

cells are killed. By contrast, when host numbers are low, it may be difficult for viruses to find a new host cell, and under such circumstances, lysogeny would be favored if the virus is lysogenic. Under these conditions, the virus would survive as a prophage until host numbers rebounded. Supporting this is the observation that in the depths of the ocean where bacterial numbers are lower than in surface waters, around half the bacteria examined have been found to contain one or more lysogenic viruses. As far as is known, single-stranded DNA viruses and all RNA viruses cannot enter a lysogenic state, and so how these viruses might survive periods of low host numbers is unknown.

Most of the genetic diversity on Earth resides in viruses, mostly bacteriophages. The *viral metagenome* is the sum total of all the virus genes in a particular environment. Several viral metagenomic studies have been undertaken, and they invariably show that immense viral diversity exists on Earth. For example, approximately 75% of the gene sequences found in viral metagenomic studies show no similarity to any other genes cataloged in viral or cellular gene databases. By comparison, surveys of bacterial metagenomes typically reveal approximately 10% unknown genes. Thus, most viruses still await discovery and most viral genes have unknown functions. This makes the study of viral diversity one of the most exciting areas of microbiology today.

MINIQUIZ

- What type of bacteriophages are most common in the oceans?
- How can bacteriophages affect bacterial evolution?
- What does the viral metagenome suggest?

BIG IDEAS

8.1 • A virus is an obligate intracellular parasite that requires a suitable host cell for replication. A virion is the extracellular form of a virus and contains either an RNA or a DNA genome inside a protein shell. Once inside the cell, either the virion or its nucleic acid redirects host metabolism to support virus replication. Viruses are classified by the characteristics of their genome and hosts. Bacteriophages infect bacterial cells.

8.2 • In the virion of a naked virus, only nucleic acid and protein are present; the entire unit is called the nucleocapsid. Enveloped viruses have one or more lipoprotein layers surrounding the nucleocapsid. The nucleocapsid is arranged in a symmetric fashion, with the icosahedron being a common morphology. Although virus particles are metabolically inert, one or more key enzymes are present within the virion in some viruses.

8.3 • The virus replication cycle can be divided into five major stages: attachment (adsorption), penetration (uptake of the entire virion or injection of the nucleic acid only), protein and nucleic acid synthesis, assembly and packaging, and virion release.

8.4 • Viruses can replicate only in their correct host cells. Bacterial viruses have proved useful as model systems because their host cells are easy to grow and manipulate in culture. Many animal viruses can be grown in cultured animal cells. Viruses can be quantified (titered) by a plaque assay. Plaques are clearings that develop on lawns of host cells, and in analogy to bacterial colonies, arise from the viral infection of a single cell.

8.5 • The attachment of a virion to a host cell is a highly specific process. Recognition proteins on the virus recognize specific receptors on the host cell. Sometimes the entire virion enters the host cell, whereas in other cases, as with most bacteriophages, only the viral genome enters.

8.6 • Bacteriophage T4 contains a double-stranded DNA genome that is both circularly permuted and terminally redundant. T4 encodes its own DNA polymerase and several other replication proteins. Cells employ restriction enzymes in attempts to destroy viral and other foreign DNA, but T4 has chemically modified its DNA to make it resistant to such attack. Cells also modify their own DNA to protect it from their own restriction enzymes.

8.7 • After a T4 virion penetrates a host cell, viral genes are expressed and regulated so as to redirect the host synthetic machinery to make viral nucleic acid and protein. Early viral genes encode viral genome replication events; middle and late viral genes encode structural proteins and capsid assembly. Once T4 components have been synthesized, new virions are made, primarily by self-assembly, and the virions released after lysis of the host cell.

8.8 • Some bacteriophages are temperate, meaning that they can initiate lytic events or integrate into the host genome as a prophage. This initiates a state called lysogeny in which the virus does not destroy the cell. A well-studied lysogenic virus of *Escherichia coli* is phage lambda; this phage uses a complex regulatory system to govern whether the lytic or lysogenic state is initiated following infection.

8.9 • The most common viruses on Earth are the complex bacteriophages with heads and tails, such as T4 and lambda. The double-stranded DNA genomes of these phages encode hundreds of proteins. These viruses have been used as model systems not only for virus replication but also for molecular biology and genetics.

8.10 • There are animal viruses with all known modes of viral genome replication. Many animal viruses are enveloped, picking up portions of host membrane as they leave the cell. Viral infection of animal host cells can result in cell lysis, but latent or persistent infections are also common, and a few animal viruses can cause cancer. Retroviruses like the AIDS virus are RNA viruses that employ the enzyme reverse transcriptase to replicate their RNA genome through a DNA intermediate. The DNA can integrate into the host chromosome where it can later be transcribed to yield viral mRNA and genomic RNA.

8.11 • The number of viruses on Earth is greater than the number of cells by 10-fold. Most of the genetic diversity on Earth resides in virus genomes, most of which are still to be investigated. Viruses affect their host cells by either culling the host population or by carrying out horizontal gene transfer from one bacterial cell to another. In the oceans, both *Bacteria* and *Archaea* are likely to be infected with viruses.

REVIEW OF KEY TERMS

Bacteriophage a virus that infects bacterial cells
Capsid the protein shell that surrounds the genome of a virus particle
Capsomere the subunit of a capsid
Concatemer two or more linear nucleic acid molecules joined covalently in tandem
Early protein a protein synthesized soon after virus infection and before replication of the virus genome
Enveloped in reference to a virus, having a lipoprotein membrane surrounding the virion
Host cell a cell inside which a virus replicates
Late protein a protein, typically a structural protein, synthesized late in virus infection
Lysogen a bacterium containing a prophage
Lysogeny a state in which the viral genome is replicated in step with the genome of the host
Lytic pathway the type of virus infection that leads to virus replication and destruction of the host cell

Middle protein a protein with either a structural or catalytic function synthesized after the early proteins in a virus infection
Nucleocapsid the complex of nucleic acid and proteins of a virus
Overlapping genes two or more genes in which part or all of one gene is embedded in the other
Plaque a zone of lysis or growth inhibition caused by virus infection of a lawn of sensitive host cells
Prophage the lysogenic form of a bacteriophage (See *proivirus*)
Provirus the genome of a temperate or latent animal virus when it is replicating in step with the host chromosome
Replicative form a double-stranded DNA molecule that is an intermediate in the replication of viruses with single-stranded DNA genomes
Retrovirus a virus whose RNA genome is replicated via a DNA intermediate

Reverse transcriptase the retroviral enzyme that can produce DNA from an RNA template
RNA replicase an enzyme that can produce RNA from an RNA template
Rolling circle replication a DNA replication mechanism in which one strand is nicked and unrolled for use as a template to synthesize a complementary strand
Temperate virus a virus whose genome can replicate along with that of its host without causing cell death, in a state called lysogeny (bacterial viruses) or latency (animal viruses)
Titer the number of infectious virions in a viral suspension
Virion the infectious virus particle; the viral genome surrounded by a protein coat and sometimes other layers
Virulent virus a virus that lyses or kills the host cell after infection
Virus a genetic element containing either RNA or DNA surrounded by a protein capsid and that replicates only inside host cells

REVIEW QUESTIONS

1. Define virus. What are the minimal features needed to fit your definition? (Section 8.1)
2. In what ways do viral genomes differ from those of cells? (Section 8.1)
3. What are the major components of a virus particle? (Section 8.2)
4. Why does a one-step growth curve differ in shape from that of a bacterial growth curve? (Section 8.3)
5. Describe the events that occur on an agar plate containing a bacterial lawn when a single bacteriophage particle causes the formation of a bacteriophage plaque. (Section 8.4)
6. How is a viral suspension quantified and what is meant by the word “titer”? (Section 8.4)
7. What is required for a bacteriophage T4 virion to attach to an *Escherichia coli* cell? (Section 8.5)
8. What is different about the penetration process of bacteriophages versus animal viruses? (Sections 8.5 and 8.10)
9. In terms of its structure, how does the genome of bacteriophage T4 resemble and how does it differ from that of *Escherichia coli*? (Section 8.6)
10. Bacteriophage T4 has “early genes” and “late genes.” What is meant by these classifications, and what types of proteins are encoded by each? (Section 8.7)
11. What is a temperate bacteriophage? Name a well-studied temperate phage that infects cells of *Escherichia coli*. (Section 8.8)
12. Describe different shapes of bacterial viruses. Which is the most common in nature? (Section 8.9)
13. Describe the types of genomes found in bacterial viruses. Give an example of one virus for each type of genome. (Section 8.9)
14. Describe the types of genomes found in animal viruses. (Section 8.10)
15. Why can it be said that the retrovirus genome is unique in all of biology? (Section 8.10)
16. How do viral numbers compare to those of bacteria in seawater? (Section 8.11)
17. Explain how viruses can affect *Bacteria* and *Archaea* in nature in both positive and negative ways. (Section 8.11)

APPLICATION QUESTIONS

- What causes the viral plaques that appear on a bacterial lawn to stop growing larger?
- The promoters on genes encoding early proteins in viruses like T4 have a different sequence than the promoters on genes encoding late proteins in the same virus. Explain how this benefits the virus.
- Under some conditions, it is possible to obtain nucleic acid–free protein coats (capsids) of certain viruses. Under the electron microscope, these capsids look very similar to complete virions. What does this tell you about the role of the virus nucleic acid in the virus assembly process? Would you expect such particles to be infectious?
- Contrast the enzyme(s) present in the virions of a retrovirus and a positive-strand RNA bacteriophage. Why do they differ if each has plus configuration single-stranded RNA as its genome?

9 • Viral Genomes and Diversity

microbiologynow

Ever-Expanding Viral Diversity

Viruses infect all organisms, including *Bacteria* and *Archaea*, and, collectively, viruses represent the greatest repository of genetic diversity on the planet. Many bacterial viruses (bacteriophages) and archaeal viruses have been isolated and characterized thus far. For *Bacteria*, these include both DNA and RNA phages, some with single-stranded and others with double-stranded genomes. For *Archaea*, however, no RNA viruses are known. Is this because such viruses do not exist?

All known archaeal viruses have DNA genomes, and with rare exception, double-stranded circular DNA genomes. In the past decade, researchers exploring viral diversity in hot springs in Yellowstone National Park (photo) have discovered a large number of these unusually shaped and structurally tough archaeal parasites (photo inset), but often wondered why evidence for RNA archaeal viruses never emerged in their studies. Well, now it has.

Using the powerful tools of metagenomics, researchers studying highly acidic *Archaea*-dominated Yellowstone hot springs have detected viral RNA genome segments highly diverged from those of RNA viruses of eukaryotes and even more distant from the genomes of RNA bacteriophages.¹ The viral RNA pieces were assembled into several different intact genomes that were all single-stranded and of the plus sense. Sequence analyses confirmed that each genome encoded an RNA replicase—a hallmark of RNA viruses—and that some of the archaeal viruses likely replicated by way of polyprotein formation, a replication mechanism employed by some eukaryotic plus-sense RNA viruses, such as poliovirus.

This metagenomics approach to viral diversity revealed that RNA archaeal viruses indeed exist. When further work complements this with the actual isolation of RNA virions that replicate in cultures of *Archaea*, virology will have a new window for exploring the amazing diversity of the viral world.

- II **Viruses with DNA Genomes 270**
- III **Viruses with RNA Genomes 277**
- IV **Subviral Agents 285**

Viruses have DNA or RNA genomes that can be either single-stranded or double-stranded. Compared with cells, viral genomes can create some unusual challenges for genetic information flow. In this chapter we will explore viral diversity from a genomic

perspective. Our coverage will group viruses by genome structure rather than by the type of host cell they infect, since viruses with the same genome structure face common problems in genetic information flow.

I • Viral Genomes and Evolution

9.1 Size and Structure of Viral Genomes

Viral genomes vary almost a thousandfold in size from smallest to largest. DNA viruses exist along this entire gradient from the tiny circovirus, whose 1.75-kilobase single-stranded genome pales in comparison to that of the 1.25-megabase-pair double-stranded DNA genome of *Megavirus* (Figure 9.1). RNA genomes, whether single- or double-stranded, are typically smaller than DNA viruses. Although some viral genomes are larger than those of some prokaryotes, genomes of prokaryotes are typically much larger than those of viruses, and genomes of eukaryotes much larger than those of prokaryotes (Figure 9.1).

Whether a viral genome is large or small, once a virus has infected its host, transcription of viral genes must occur and new copies of the viral genome must be made. Only later, once viral proteins begin to appear from the translation of viral transcripts, can viral assembly begin. For certain RNA viruses, the genome is also the mRNA. For most viruses, however, viral mRNA must first be made by transcription off of the DNA or RNA genome, and we consider the variations on how this occurs now.

Viral Genome Structure: The Baltimore Scheme

The virologist David Baltimore, who along with Howard Temin and Renato Dulbecco shared the Nobel Prize for Physiology or Medicine in 1975 for the discovery of retroviruses and reverse transcriptase, developed a classification scheme for viruses. The scheme is based on the relationship of the viral genome to its mRNA and recognizes seven classes of viruses (Figure 9.2). By convention in virology, viral mRNA is always considered to be of the *plus* configuration. Thus, to understand the molecular biology of a particular class of virus, one must know the nature of the viral genome and what steps are necessary to produce plus complementary mRNA (Figure 9.2).

Double-stranded DNA viruses are in Baltimore class I. The mechanism of mRNA production and genome replication of class I viruses is the same as that used by the host cell, and we saw this with bacteriophage T4, a typical class I virus (► Section 8.7). A virus containing a single-stranded genome may be either a **positive-strand** virus (also called a “plus-strand virus”) or a **negative-strand** virus (also called a “minus-strand virus”). Class II viruses contain single-stranded plus-strand DNA genomes. Transcription of such a genome would yield a message of the minus sense. Therefore, before mRNA can be produced from class II viruses, a complementary DNA strand must first be made to form a double-stranded DNA intermediate; this is called the **replicative form**. The latter is used for transcription and as the source of new genome copies, the plus strand becoming the genome while the minus strand is discarded (Figure 9.2). With only one known exception, all single-stranded DNA viruses are positive-strand viruses.

The production of mRNA and genome replication will obviously be different for RNA viruses than for DNA viruses. Cellular RNA polymerases do not catalyze the formation of RNA from an RNA template, but instead require a DNA template. Therefore, depending on the virus, RNA viruses must either carry in their virions or encode in their genomes an RNA-dependent RNA polymerase called *RNA replicase* (► Section 8.2). With positive-strand RNA viruses (class IV), the genome is also mRNA. But for negative-strand RNA viruses (class V), RNA replicase must synthesize a plus strand of RNA off of the negative strand template, and the plus strand is then used as mRNA. The latter is also used as a template to make more negative-strand genomes (Figure 9.2). RNA viruses of class III face a similar problem but start with double-stranded (+/−) RNA instead of only a positive or negative strand.

Retroviruses are animal viruses whose genomes consist of single-stranded RNA of the plus configuration but which replicate through a double-stranded DNA intermediate (class VI). The

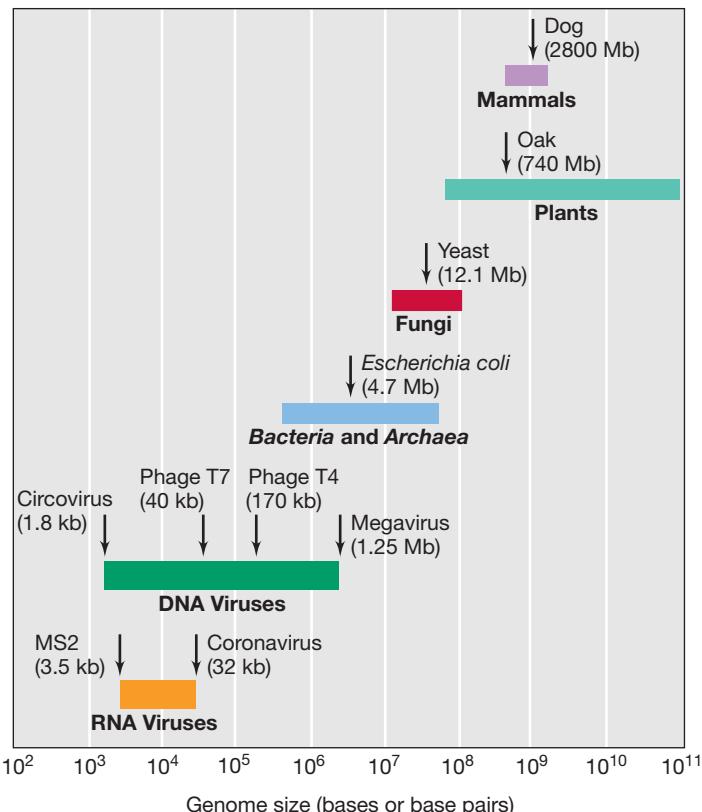

Figure 9.1 Comparative genomics. A size comparison of viral genomes and those of major groups of living organisms.

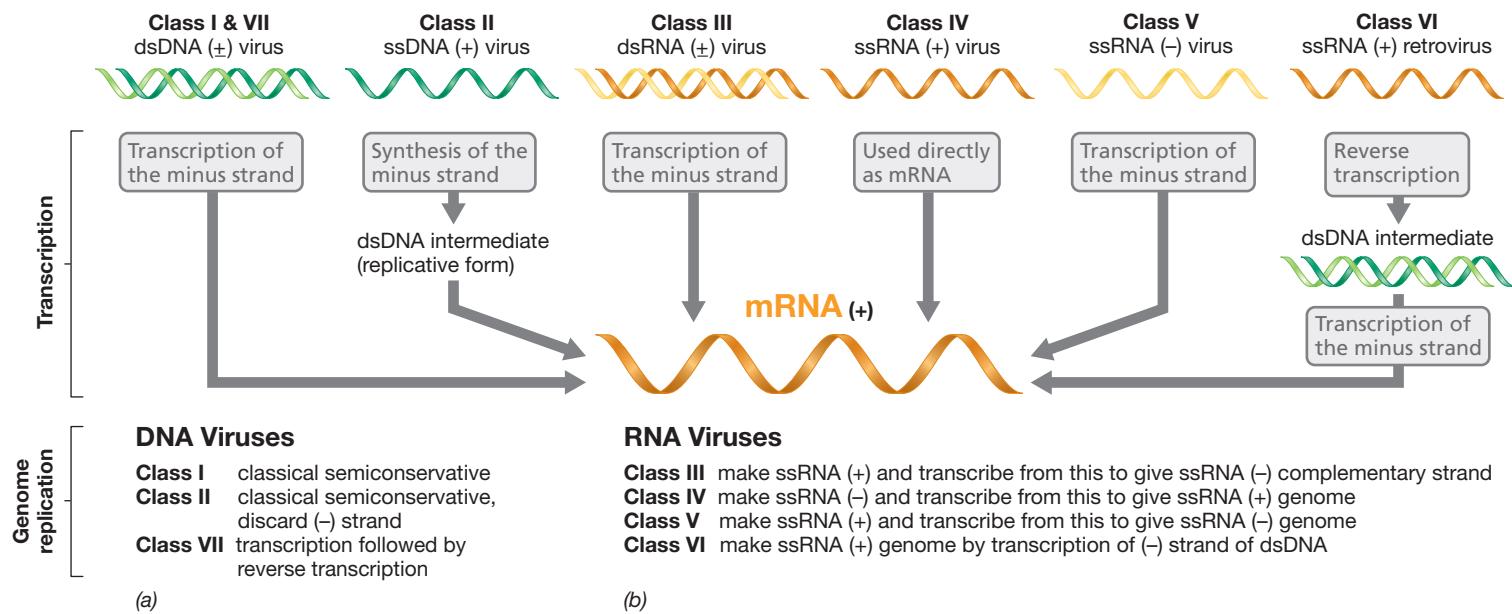

Figure 9.2 The Baltimore classification of viral genomes. Seven classes of viral genomes are known. The genomes can be either (a) DNA or (b) RNA, and either single-stranded (ss) or double-stranded (ds). The path each viral genome takes to form its mRNA and the strategy each uses for replication is shown.

process of copying the information found in RNA into DNA is called **reverse transcription** and is catalyzed by an enzyme called *reverse transcriptase*. Finally, class VII viruses are those highly unusual viruses whose genomes consist of double-stranded DNA but which replicate through an RNA intermediate. As we will see, these viruses also use reverse transcriptase.

Table 9.1 lists a few example viruses in each Baltimore class, and we explore the unique molecular biology of each class as we travel through this chapter.

Viral Protein Synthesis

Once viral mRNA is made (Figure 9.2), viral proteins can be synthesized. In all viruses, these proteins can be grouped into two broad categories: (1) proteins synthesized soon after infection, called *early proteins*, and (2) proteins synthesized later in the infection, called *late proteins*. Both the timing and amount of viral protein synthesis is highly regulated. Early proteins are typically enzymes that act catalytically and are therefore synthesized in relatively small amounts. These include not only nucleic acid polymerases but also proteins

Table 9.1 Some types of viral genomes

Virus	Host	DNA or RNA	Single- or double-stranded	Viral genome		
				Structure	Number of molecules	Size (bases or base pairs) ^a
H-1 parvovirus	Animals	DNA	Single-stranded	Linear	1	5,176
φX174	Bacteria	DNA	Single-stranded	Circular	1	5,386
Simian virus 40 (SV40)	Animals	DNA	Double-stranded	Circular	1	5,243
Poliovirus	Animals	RNA	Single-stranded	Linear	1	7,433
Cauliflower mosaic virus	Plants	DNA	Double-stranded	Circular	1	8,025
Cowpea mosaic virus	Plants	RNA	Single-stranded	Linear	2 different	9,370 (total)
Reovirus type 3	Animals	RNA	Double-stranded	Linear	10 different	23,549 (total)
Bacteriophage lambda	Bacteria	DNA	Double-stranded	Linear	1	48,514
Herpes simplex virus type 1	Animals	DNA	Double-stranded	Linear	1	152,260
Bacteriophage T4	Bacteria	DNA	Double-stranded	Linear	1	168,903
Human cytomegalovirus	Animals	DNA	Double-stranded	Linear	1	229,351

^aThe size is in bases or base pairs depending on whether the virus is single- or double-stranded. The sizes of the viral genomes chosen for this table are known accurately because they have been sequenced. However, this accuracy can be misleading because only a particular strain or isolate of a virus was sequenced. Therefore, the sequence and exact number of bases for other isolates may be slightly different. No attempt has been made to choose the largest and smallest viruses known, but rather to give a fairly representative sampling of the sizes and structures of the genomes of viruses containing both single- and double-stranded RNA and DNA.

that function to shut down host transcription and translation. By contrast, late proteins are typically structural components of the virion and other proteins that are not needed until virion assembly begins, and these are made in much larger amounts (see Section 8.7).

Virus infection upsets the regulatory mechanisms of the host because there is a marked overproduction of viral nucleic acid and protein in the infected cell. Eventually, when the proper proportions of viral genome copies and virion structural components have been synthesized, new virions are assembled and exit the host cell by either lysing and killing it or by a budding process in which the host cell may remain alive.

MINIQUIZ

- Distinguish between a positive-strand RNA virus and a negative-strand RNA virus.
- Contrast mRNA production in the two classes of single-stranded RNA viruses.
- What is unusual about genetic information flow in retroviruses?

9.2 Viral Evolution

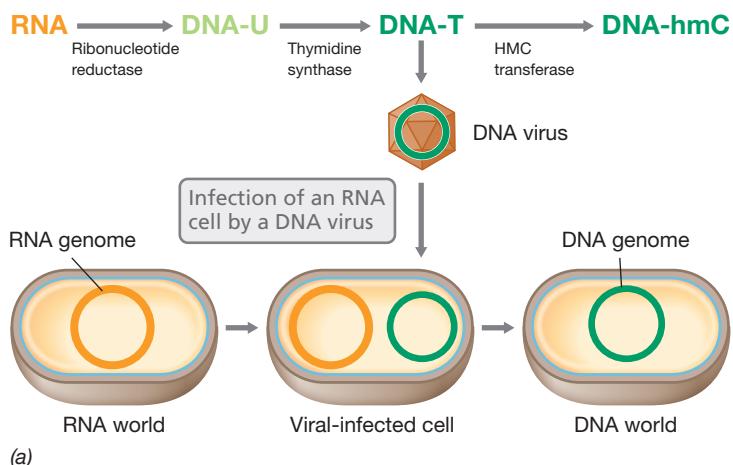

When did viruses first appear on Earth and what is their relationship to cells? All known viruses require a host cell for their replication, and this leads to the natural conclusion that viruses evolved at some time *after* cells first appeared on Earth, nearly 4 billion years ago. Following this line of reasoning, viruses are most likely remnant cell components that evolved an ability to replicate with assistance from the cell. However, other hypotheses for the origin of viruses have been proposed including that viruses are relics of the “RNA world,” a period in evolution where RNA is hypothesized to have been the sole carrier of genetic information (see Section 12.1 and see Figure 9.3), or that viruses were once cells that for some reason, perhaps to economize their genomes, discarded so many genes that they became dependent on a host for most of their replication functions.

Although *how* viruses appeared is an unanswered question, so is the question of *why* viruses appeared. One likely driver of viral evolution was as a mechanism for cells to quickly move genes about in nature. Because viruses have an extracellular form that protects the nucleic acid inside them, they could have been selected as a means of enriching the genetic diversity (and thus fitness) of cells by facilitating gene transfers between them. This function seems especially relevant for prokaryotic cells, where horizontal gene exchange is known to be a major factor in their rapid evolution (see Sections 6.12 and 12.7). Although many viruses kill their host cell, latent viruses do not, and it is possible that the earliest viruses were primarily latent and evolved lytic capacities only later to more rapidly access new hosts.

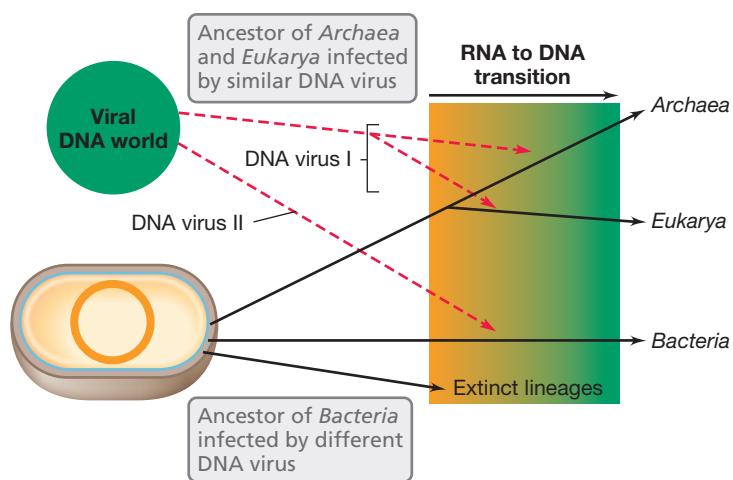

Viruses and the Transition from an RNA to a DNA World

Besides a likely role in facilitating genetic diversity, it is possible that viruses were the first DNA-containing entities. The hypothesis of the RNA world proposes that RNA was the genetic material of the earliest cells and that DNA eventually replaced RNA in this role because DNA is the more stable of the two molecules. Interestingly, a novel hypothesis that accounts for the RNA to DNA transition puts viruses at the center of the story (Figure 9.3).

Viral genome evolution

(a)

(b)

Figure 9.3 Hypothesis of viral origin of DNA. (a) The evolution of DNA-specific enzymes would have allowed RNA viruses to become DNA viruses; DNA-U, DNA with uracil; DNA-T, DNA with thymine; DNA-hmC, DNA with 5-hydroxycytosine. These DNA variants are known from one virus or another. (b) Infection of an RNA cell by a DNA virus could have exposed cells to the more stable chemistry of DNA over RNA. Infection of the ancestors of *Bacteria* with a considerably different DNA virus than those infecting *Archaea* and *Eukarya* could explain why the DNA machinery of *Archaea* and *Eukarya* differs from that of *Bacteria*.

The scenario posits that RNA viruses first evolved DNA as a modification mechanism to protect their genomes from cellular ribonucleases that could destroy them. Because DNA is not RNA and cells in the RNA world would have contained RNA genomes, DNA viruses would have had to evolve their own DNA replication machinery to replicate their genomes. It is further hypothesized that DNA viruses infected the ancestors of the three cellular domains. Gradually, by genetic exchange with the DNA viral genomes, each group of cells obtained the machinery necessary to replicate DNA and eventually converted their genomes from RNA-based to DNA-based chemistry. Furthermore, cells with RNA genomes that were not infected by DNA viruses never evolved DNA genomes, and Darwinian selection would have eventually driven these less fit cells extinct (Figure 9.3b). It is conceivable that an enzyme like reverse transcriptase was a key to the

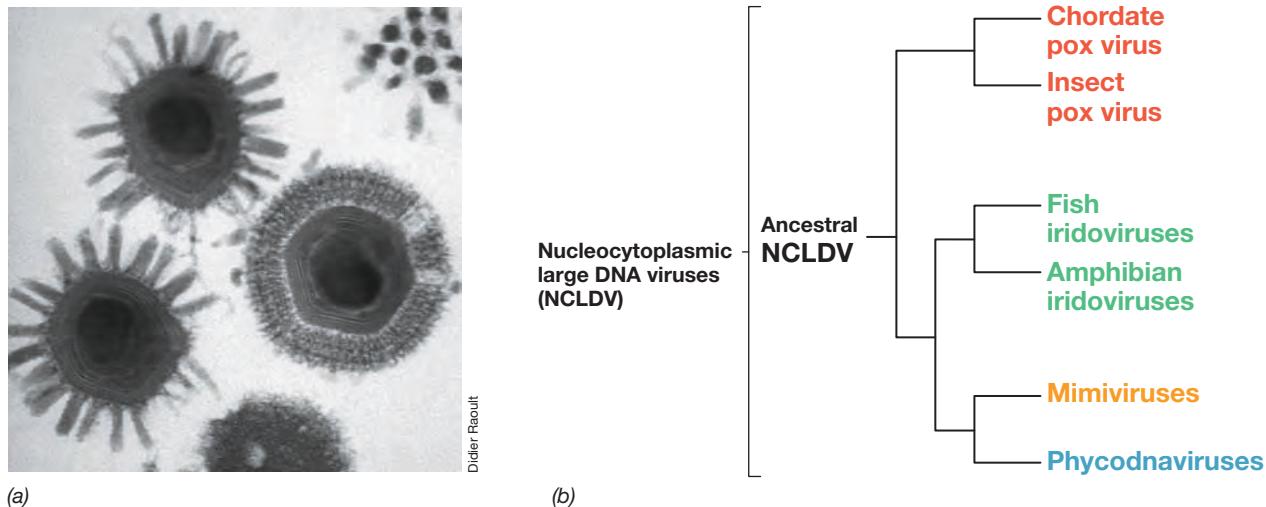

Figure 9.4 Phylogeny of nucleocytoplasmic large DNA viruses (NCLDV). (a) Transmission electron micrograph of Mimivirus, a member of the NCLDV group. A virion is about 0.75 μm in diameter. (b) Phylogeny of major groups of NCLDV based on comparative sequences of several proteins of DNA metabolism.

conversion of RNA into DNA, just as it is in retroviruses today (Section 9.11).

Why is this hypothesis appealing? The three-domain theory shows the *Archaea* and *Eukarya* to be more closely related than either is to the *Bacteria* (Figure 1.6). Although molecular analyses of the machinery required for transcription and translation support the three-domain hypothesis well, analyses of the molecular machinery for DNA replication, recombination, and repair do not. A few DNA-specific processes are similar in *Bacteria* and *Archaea*, whereas most are more similar in *Archaea* and *Eukarya*. The viral DNA scenario accounts for this discrepancy by proposing that although transcription and translation were established processes before the three domains became distinct, DNA-centered events were not. Instead, DNA biochemistry was the result of viral infections. The complement of enzymes of DNA metabolism that we see in cells today is then explained by hypothesizing that the ancestors of the *Archaea* and *Eukarya* were infected by a similar DNA virus that was distinct from the DNA virus that infected the ancestor of *Bacteria* (Figure 9.3).

The viral DNA scenario also explains how DNA originated in cells in the first place and provides a mechanism for how RNA genomes could have gradually been replaced by DNA. If this hypothesis is true, it has one ironic feature. In attempts to stay one step ahead of their hosts, one of the “avoidance maneuvers” of viruses was the evolution of DNA. But in this case, the chemistry of this molecule was such an improvement over that of RNA that cells co-opted the strategy for their own benefit.

Viral Phylogeny

Because the sequence diversity of viral genomes is so enormous—most viral genes retrieved from nature are of unknown function—it has not proven possible to construct an insightful universal phylogenetic tree of viruses like that for cells (Figure 1.6). Only in a few groups of viruses has it been possible to reliably trace phylogenies, and in these cases, trees have been assembled from sequences of a few select genes or proteins shared in

common among the group. One such example is Mimivirus and its relatives, the largest of all known viruses (Figure 9.4).

Mimivirus capsids are multilayered and icosahedral. The virion is surrounded by spikes and is nearly 0.75 μm in diameter, larger than some prokaryotic cells (Figure 9.4a). Mimivirus contains a 1.2-megabase-pair genome consisting of double-stranded DNA. This is over twice that of the next largest known virus, and is larger than the genomes of several prokaryotes (Table 6.1). Mimivirus infects the protozoan *Acanthamoeba* and belongs to a group of giant viruses with large genomes called *nucleocytoplasmic large DNA viruses* (NCLDV) (Figure 9.4b). The NCLDV comprise several virus families, including pox viruses (Section 9.6), iridoviruses, and certain plant viruses. These viruses share a set of highly homologous proteins, most of which function in DNA metabolism. A phylogenetic tree of these viruses constructed from DNA sequences encoding these proteins shows how they have diverged from a common ancestor (Figure 9.4b).

It is thus possible to track the phylogeny of a viral group in some cases. But to do so, one needs to begin with a group that is already known to share a number of properties in common. Other attempts to trace viral phylogeny using the comparative structural biology of capsid proteins have also proven useful with some viral groups (see page 245). Although phylogenetic trees based on cellular genomes have been constructed and support the three-domain hypothesis quite well, evolution has so scrambled viral genomes that it is unlikely that an insightful universal phylogenetic tree of viruses based on comparisons of full viral genome sequences is possible, at least not using currently available computational tools.

MINIQUIZ

- How could viruses have accelerated the evolution of cells?
- Explain how viruses could have “invented” the genetic material found in all cells.
- Give two reasons why a universal phylogenetic tree of viruses may prove hard to construct.

II • Viruses with DNA Genomes

9.3 Single-Stranded DNA Bacteriophages: ϕ X174 and M13

In this section we discuss two well-known single-stranded DNA bacteriophages, ϕ X174 and M13. Many single-stranded DNA plant and animal viruses are also known. However, because these share with bacterial viruses the fact that their genomes are of the plus complementarity ("plus-strand viruses"), many molecular events are similar. Hence, our focus here will be on the phages. Before a single-stranded DNA genome can be transcribed, a complementary strand of DNA must be synthesized, forming the double-stranded replicative form. This can then be used as a source of both mRNA and genome copies.

Phage ϕ X174

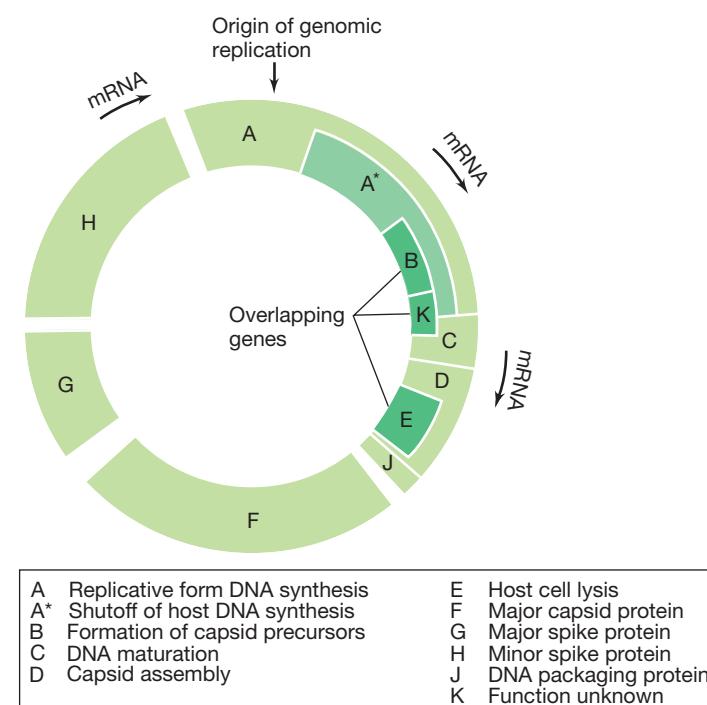

Bacteriophage ϕ X174 contains a circular genome of 5386 nucleotides inside a tiny icosahedral virion, about 25 nm in diameter. Phage ϕ X174 has only a few genes and shows the phenomenon of **overlapping genes**, a condition in which there is insufficient DNA to encode all viral-specific proteins unless parts of the genome are read more than once in different reading frames. For example, in the ϕ X174 genome, gene B resides within gene A and gene K resides within both genes A and C (Figure 9.5). Genes D and E also overlap, gene E being contained completely within gene D. Also, the termination codon of gene D overlaps the initiation codon of gene J (Figure 9.5a).

The distinct gene products from overlapping genes are made by reinitiating transcription *in a different reading frame* within a gene to yield a second (and distinct) transcript. In addition to overlapping genes, a small protein in ϕ X174 called A*, which functions to shut down host DNA synthesis, is synthesized by the reinitiation of *translation* (not transcription) within the mRNA for gene A. The A* protein is read from the same mRNA reading frame as A protein but has a different in-frame start codon and is thus a shorter protein.

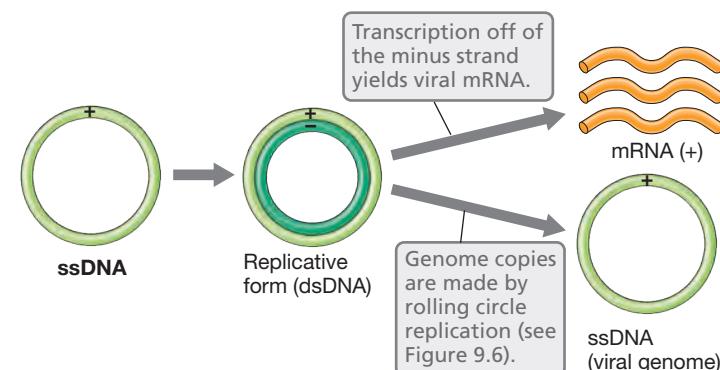

Upon infection of an *Escherichia coli* cell by ϕ X174, the viral DNA is separated from the protein coat and the genome is converted into a double-stranded replicative form by host enzymes. From this, several copies are made by semiconservative replication, and phage-specific transcripts are made by transcription off of the negative strand of the replicative form (Figure 9.5b). The replicative form is also the starting point for making copies of the phage genome by a mechanism we have already seen used in phage lambda (Section 8.8): **rolling circle replication** (Figure 9.6).

In the synthesis of the ϕ X174 genome, the rolling circle facilitates the continuous production of positive strands from the replicative form. To do this, the positive strand of the latter is nicked and the 3' end of the exposed DNA is used to prime synthesis of a new strand (Figure 9.6). Cutting of the plus strand is accomplished by the A protein (Figure 9.5a). Continued rotation of the circle leads to the synthesis of a linear ϕ X174 genome. Note that synthesis differs from semiconservative replication because only the negative strand serves as a template.

When the growing viral strand reaches unit length (5386 residues for ϕ X174), the A protein cleaves it and then ligates the two ends of the newly synthesized single strand to give a single-stranded DNA circle. Ultimately, assembly of mature ϕ X174 virions occurs and cell lysis follows. The E protein (Figure 9.5a) promotes cell lysis by inhibiting the activity of an enzyme in peptidoglycan synthesis (Section 5.4). Because of the resulting weakness in newly synthesized cell wall material, the cell ruptures, releasing the phage virions.

(a) Genetic map of ϕ X 174

(b) Flow of events during ϕ X 174 replication

Figure 9.5 Bacteriophage ϕ X174, a single-stranded DNA phage. (a) Genetic map. Note regions of gene overlap. Protein A* is formed using only part of the coding sequence of gene A by reinitiation of translation. The key indicates the functions of the proteins encoded by each gene. (b) Genetic information flow in ϕ X174. Progeny single-stranded DNA is produced from the replicative form by rolling circle replication (see Figure 9.6).

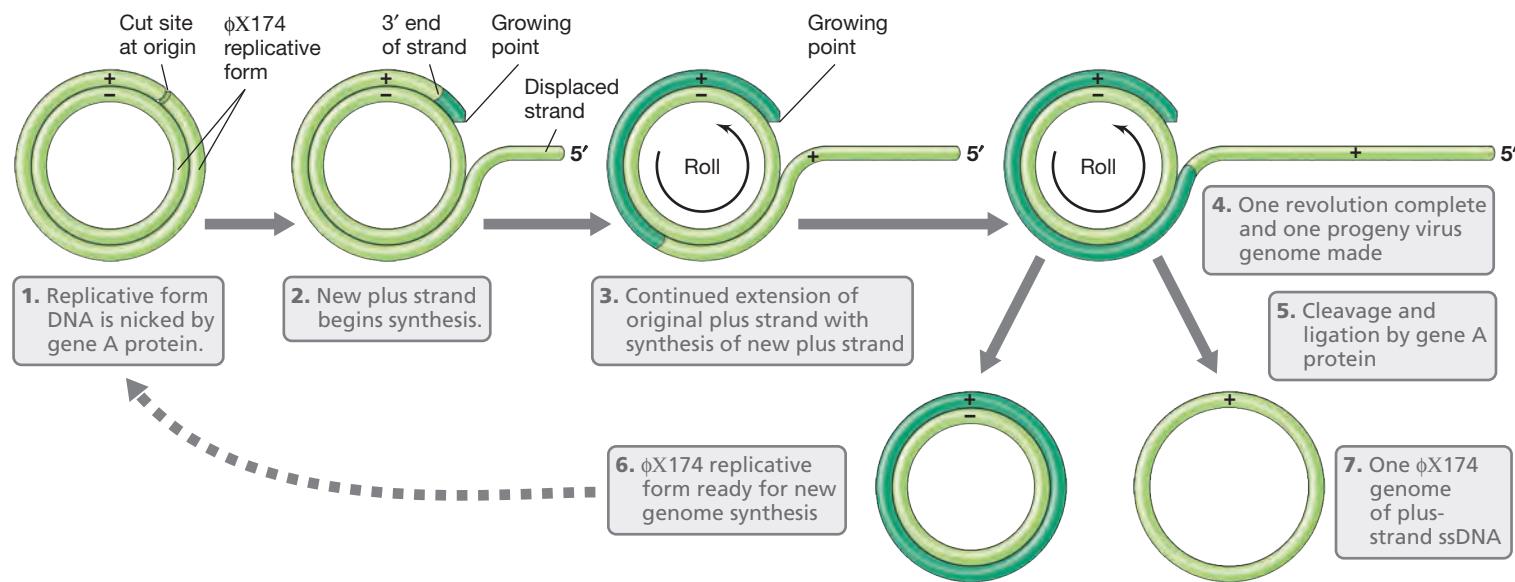

Figure 9.6 Rolling circle replication in phage φX174. Replication begins at the origin of the double-stranded replicative form with the cutting of the plus strand of DNA by gene A protein (both strands of DNA are shown in light green here for simplification). After one new progeny strand has been synthesized (one revolution of the circle), the gene A protein cleaves the new strand and ligates its two ends.

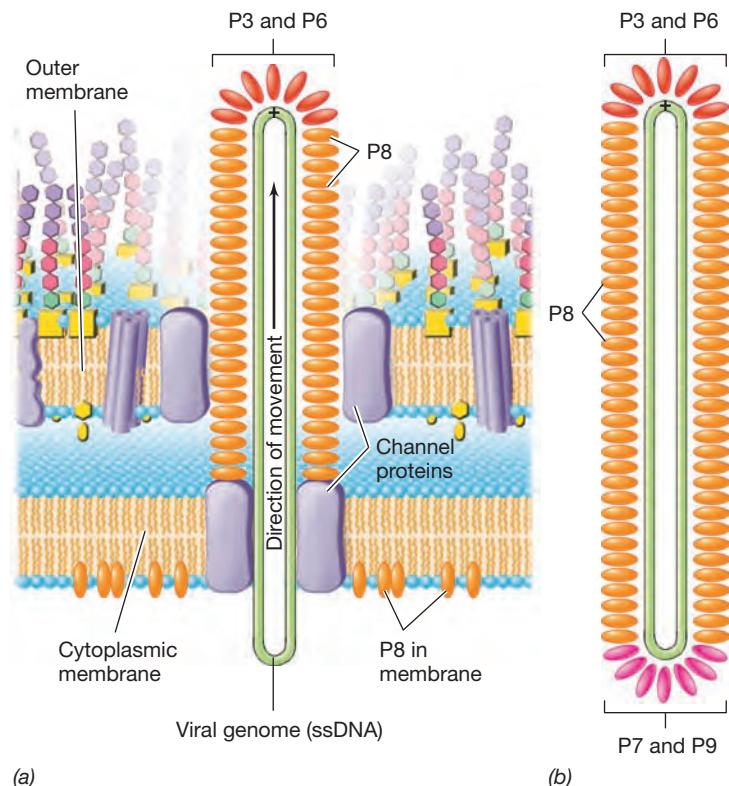

Figure 9.7 Release of phage M13. The virions of phage M13 exit infected cells without lysis. (a) Budding. The virus DNA crosses the cell envelope through a channel constructed from virus-encoded proteins. As this occurs, the DNA is coated with phage proteins that have been embedded in the cytoplasmic membrane. (b) Complete virion. The two ends of the virion are covered with small numbers of the minor coat proteins P3 and P6 (front end) or P7 and P9 (rear end).

Bacteriophage M13

Bacteriophage M13 is a filamentous phage with helical symmetry that has found extensive use in past years as a cloning and DNA-sequencing vector in genetic engineering. The virion of phage M13 is long and thin and attaches to the pilus of its host cell (Section 8.5). Filamentous phages such as M13 have the unusual property of being released without lysing the host cell; infected cells continue to grow and typical plaques are not observed. To facilitate this, M13 DNA is covered with coat proteins as it crosses the cell envelope. Four minor coat proteins cover the tips of the virion while the major coat protein covers the sides (Figure 9.7). Thus with M13, there is no intracellular accumulation of virions as occurs with typical lytic bacteriophages.

Several features of phage M13 make it useful as a cloning and DNA sequencing vehicle. For example, many aspects of DNA replication in M13 are similar to those of φX174 and the genome is very small; this facilitates sequencing efforts. Second, a double-stranded form of genomic DNA essential for cloning purposes is produced naturally when M13 produces its replicative form. Third, as long as infected cells are kept growing, they can be maintained indefinitely, so a continuous source of the cloned DNA is made. And finally, as in phage lambda (Section 8.8), there is a region of the M13 genome that does not encode proteins and can be replaced by foreign DNA. Consequently, phage M13 is an important component of the biotechnologist's toolbox.

MINIQUIZ

- Why is formation of the replicative form of φX174 necessary in order to make phage-specific mRNA?
- In the φX174 genome, describe the difference between how the gene B and gene A* proteins are made.
- How can M13 virions be released without killing the infected host cell?

9.4 Double-Stranded DNA Bacteriophages: T7 and Mu

The double-stranded DNA (dsDNA) bacteriophages are among the best studied of all viruses, and we have already discussed two important ones, T4 and lambda, in Chapter 8. Because of their importance in molecular biology, gene regulation, and genomics, we consider two more such viruses here, T7 and Mu.

Bacteriophage T7

Bacteriophage T7 is a relatively small DNA virus that infects *Escherichia coli* and a few related enteric bacteria. The virion has an icosahedral head and a very short tail, and the T7 genome is a linear double-stranded DNA molecule of about 40 kilobase pairs.

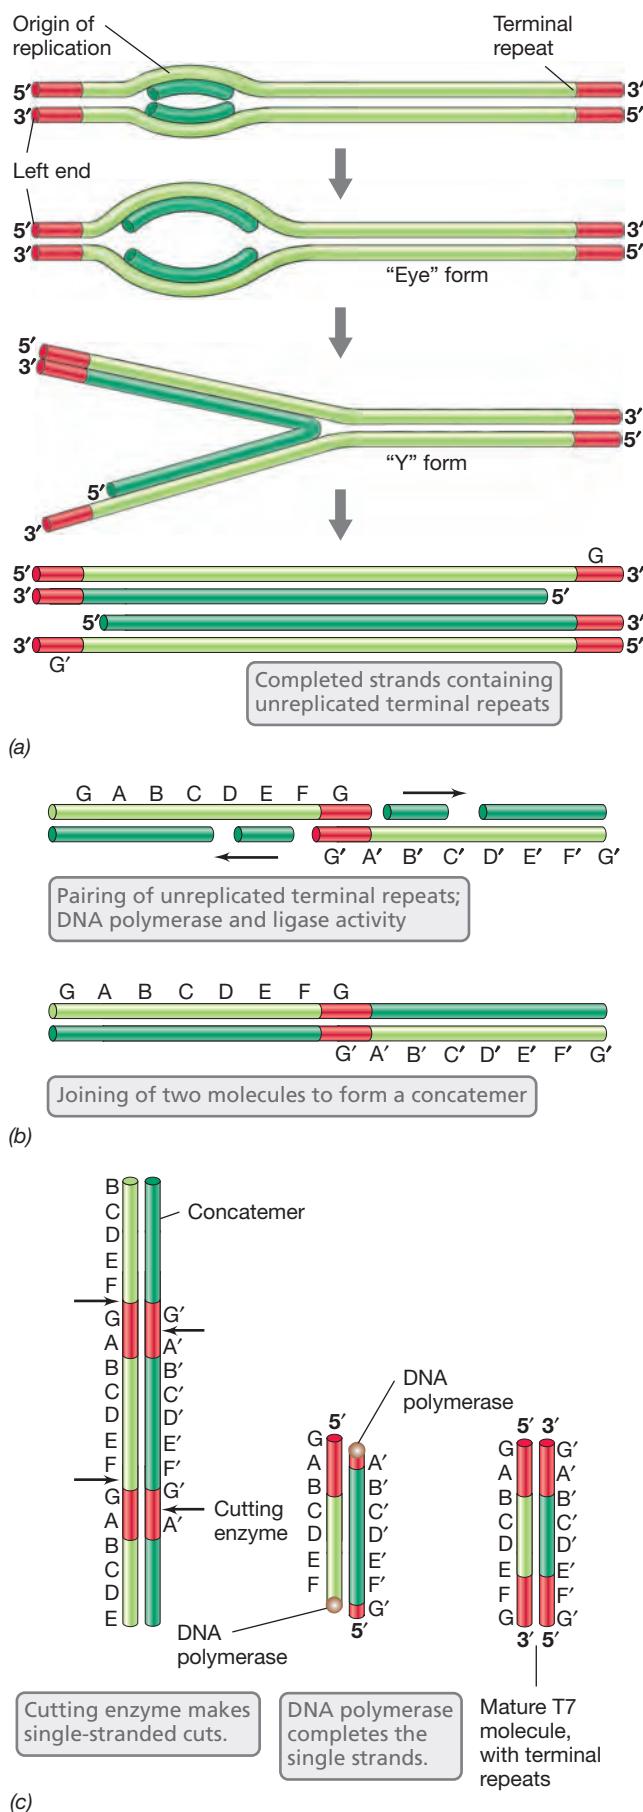

When a T7 virion attaches to a host cell and the DNA is injected, early genes are quickly transcribed by host RNA polymerase and then translated. One of these early proteins inhibits the host restriction system, a mechanism for protecting the cell from foreign DNA (► Section 8.6). This occurs very rapidly, as the T7 anti-restriction protein is made and becomes active before the entire T7 genome has entered the cell. Other early proteins include a T7 RNA polymerase and proteins that inhibit host RNA polymerase activity. T7 RNA polymerase recognizes only T7 gene promoters distributed along the T7 genome. This transcriptional strategy differs from that of phage T4 because T4 uses the host RNA polymerase throughout its replication cycle but modifies it such that it recognizes phage genes only (► Section 8.7).

Genome replication in T7 begins at an origin of replication within the molecule and proceeds bidirectionally from this point (Figure 9.8a). Phage T7 uses its own DNA polymerase, which is a composite protein including one polypeptide encoded by the phage and one by the host. As in phage T4, T7 DNA contains terminal repeats at both ends of the molecule and these are eventually used to form *concatemers* (Figure 9.8b). Continued replication and recombination leads to concatemers of considerable length, but ultimately a phage-encoded endonuclease cuts each concatemer at a specific site, resulting in the formation of linear DNA molecules with terminal repeats that are packaged into phage heads (Figure 9.8c). However, because T7 endonuclease cuts the concatemer at specific sequences, the DNA sequence in each T7 virion is identical. This differs from the situation in phage T4, where DNA concatemers are processed using a “headful mechanism” that generates circularly permuted genomes (► Section 8.6).

Bacteriophage Mu

Bacteriophage Mu is a temperate phage, like lambda (► Section 8.8), but has the unusual property of replicating by *transposition*. Transposable elements are sequences of DNA that can move

Figure 9.8 Replication of the bacteriophage T7 genome. (a) The linear, double-stranded DNA undergoes bidirectional replication, giving rise to intermediate “eye” and “Y” forms (for simplicity, both template strands are shown in light green and both newly synthesized strands in dark green). (b) Formation of concatemers by joining DNA molecules at their unreplicated terminal ends. (c) Production of mature viral DNA molecules from T7 concatemers by activity of the cutting enzyme, an endonuclease.

on their host genome from one location to another as discrete genetic units (Section 10.11); such movements are facilitated by an enzyme called **transposase**. Mu was so named because it generates *mutations* when it integrates into the host cell chromosome, and thus it has been useful in bacterial genetics because it can generate mutants easily.

Bacteriophage Mu has an icosahedral head, a helical tail, and several tail fibers (Figure 9.9a). The genome of Mu consists of linear double-stranded DNA, and most Mu genes encode head and tail proteins, other replication factors such as the Mu transposase, and factors that affect host range. Host range is controlled by the kind of tail fibers that are made, with one type allowing only infection of *Escherichia coli* while the other type allows the phage to infect several other enteric bacteria as well.

Phage Mu replicates in a completely different manner from all other bacteriophages because its genome is replicated as part of a larger DNA molecule (Figure 9.9b). Thus, integration of Mu DNA into the host genome is essential for both lytic and lysogenic development. Integration requires the activity of Mu transposase,

and a 5-base-pair fragment of host DNA is duplicated at the target site where Mu DNA is integrated. This host DNA duplication arises because staggered cuts are made at the point in the host genome where Mu DNA is inserted. The resulting single-stranded segments are converted to the double-stranded form as part of the Mu integration process (Figure 9.9b).

Mu can enter the lytic pathway upon initial infection if the Mu repressor is not made, or it can form a lysogen if the repressor is made. In either case, Mu DNA is replicated by repeated transposition of Mu to multiple sites on the host genome. If the lytic cycle pathway is triggered, only the early genes of Mu are initially transcribed. Then, following expression of a Mu transcriptional activating protein, Mu head and tail proteins are synthesized. Following self-assembly, the cell is lysed and mature Mu virions are released. The lysogenic state in Mu requires that sufficient Mu repressor protein be present to prevent transcription of integrated Mu DNA.

MINIQUIZ

- In what major way does transcription of phage DNA differ in phages T4 and T7?
- What is unusual about the replication mechanism of the Mu genome?

9.5 Viruses of Archaea

Several DNA viruses have been discovered whose hosts are species of *Archaea*, including representatives of both the *Euryarchaeota* and *Crenarchaeota* phyla (Chapter 16). Most viruses that infect species of *Euryarchaeota*, including both methanogenic and halophilic *Archaea*, are of the “head and tail” type, resembling phages that infect enteric bacteria, such as phage T4. One novel archaeal virus infects a halophile and is unusual because it is both enveloped and contains a single-stranded DNA genome. By contrast, all other characterized archaeal DNA viruses contain double-stranded and typically circular DNA genomes.

RNA archaeal viruses have been detected in thermal environments inhabited by *Crenarchaeota*. These are single-stranded plus-sense RNA viruses (positive-strand viruses, Section 9.8), but little else is known about them as they await detailed characterization and laboratory culture. However, as for *Bacteria* and *Eukarya*, it is clear that at least some *Archaea* are infected by viruses with RNA genomes (see page 265).

The most distinctive archaeal viruses infect hyperthermophilic *Crenarchaeota*. For example, the sulfur chemolithotroph *Sulfolobus* is host to several structurally unusual viruses. One such virus, called SSV, forms spindle-shaped virions that often cluster in rosettes (Figure 9.10a). Such viruses are widespread in acidic hot springs worldwide. Virions of SSV contain a circular DNA genome of about 15 kilobase pairs. A second morphological type of *Sulfolobus* virus forms a rigid, helical rod-shaped structure (Figure 9.10b). Viruses in this class, nicknamed SIFV, contain linear DNA genomes about twice the size of that of SSV. Many variations on the spindle- and rod-shaped patterns have been seen in archaeal viral isolation studies.

A spindle-shaped virus that infects the hyperthermophile *Acidianus* displays a novel behavior. The virion, called ATV, contains

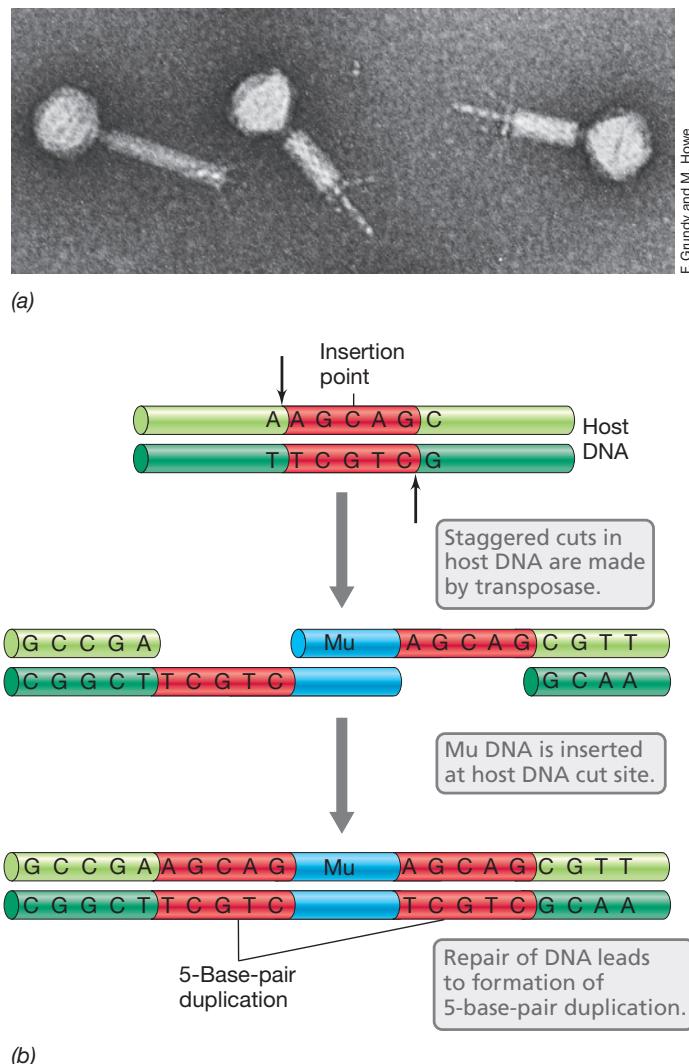

Figure 9.9 Bacteriophage Mu. (a) Electron micrograph of virions of the double-stranded DNA phage Mu. (b) Integration of Mu into the host DNA, showing the generation of a 5-base-pair duplication of host DNA.

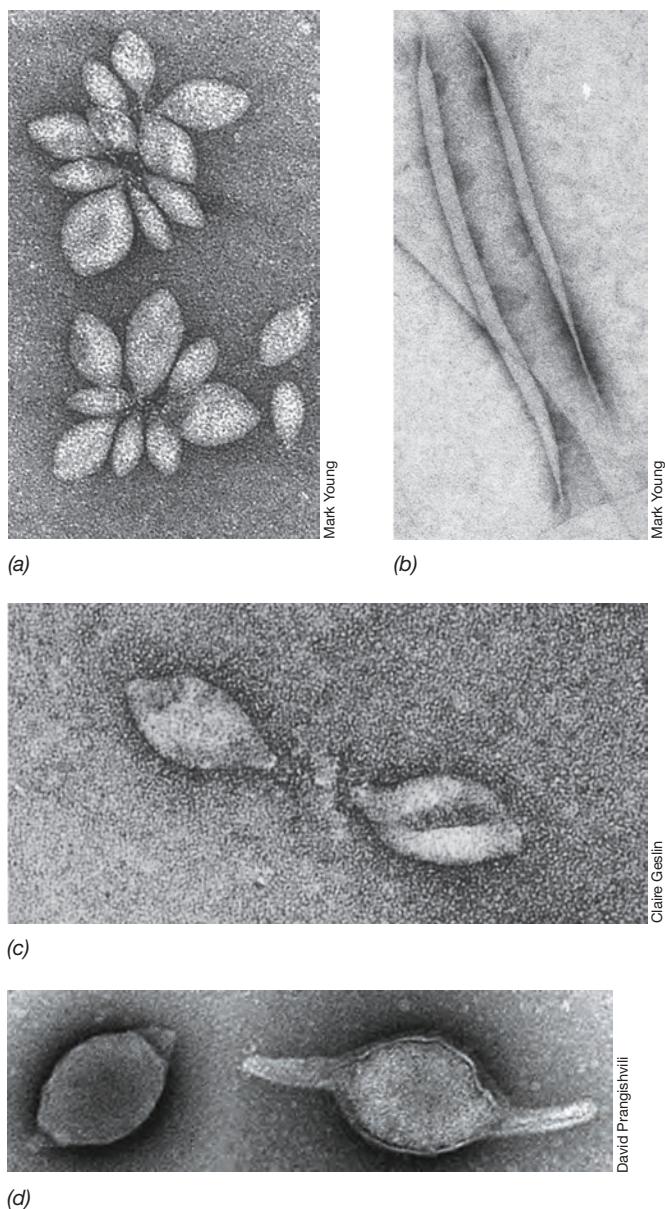

Figure 9.10 Archaeal viruses. Electron micrographs of viruses of *Crenarchaeota* (parts a, b, d), and a virus of a euryarchaeote (part c). (a) Spindle-shaped virus SSV1 that infects *Sulfolobus solfataricus* (virions are 40×80 nm). (b) Filamentous virus SIFV that infects *S. solfataricus* (virions are $50 \times 900\text{--}1500$ nm). (c) Spindle-shaped virus PAV1 that infects *Pyrococcus abyssi* (virions are 80×120 nm). (d) ATV, the virus that infects the hyperthermophile *Acidianus convivator*. When released from the cell the virions are lemon-shaped (left), but they proceed to grow appendages on both ends (right). ATV virions are about 100 nm in diameter.

a circular genome of about 68 kilobase pairs and is lemon-shaped when first released from the host cells. However, shortly after release from its lysed host cell, the virion produces long thin tails, one at each end (Figure 9.10d). The tails are actually tubes, and as they form, the virion becomes thinner and its volume is reduced. Remarkably, this is the first example of virus development in the complete absence of host cell contact. It is thought that the extended tails of ATV help the virus in some way survive in its hot (85°C), acidic (pH 1.5) environment. This unusually shaped virus is also lysogenic, a property rarely seen in other archaeal viruses.

A spindle-shaped virus also infects *Pyrococcus* (*Euryarchaeota*). This virus, named PAV1, resembles SSV but is larger and contains a very short tail (Figure 9.10c). PAV1 has a small circular DNA genome and is released from host cells without cell lysis, probably by a budding mechanism similar to that of the *Escherichia coli* bacteriophage M13 (Section 9.3). *Pyrococcus* has a growth temperature optimum of 100°C , meaning that PAV1 virions must be especially heat-stable. Despite their similar morphologies, genomic comparisons of PAV1 and SSV-type viruses show little sequence similarity, indicating that the two types of viruses do not have common evolutionary roots.

Replication events in the life cycles of archaeal viruses are not yet clear. However, considering that the genomes of most of these viruses are double-stranded DNA, it is unlikely that any major novel modes of replication will be uncovered. However, important molecular details, such as the extent to which viral rather than host polymerases and other enzymes are used in the replication process, await further work on these remarkably tough viruses.

MINIQUIZ

- What type of genome is seen in most archaeal viruses?
- Compared with other archaeal viruses, what are two unusual features of the virus that infects *Acidianus*?

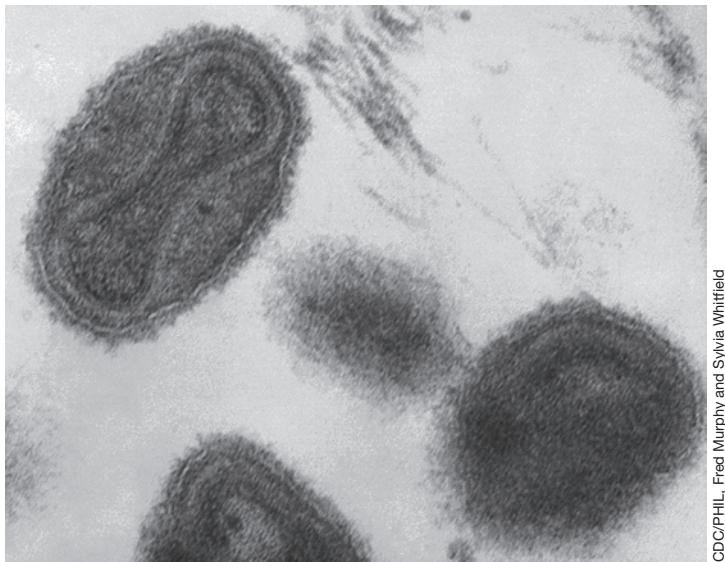

9.6 Uniquely Replicating DNA Animal Viruses

Two groups of double-stranded DNA animal viruses show unusual replication strategies: pox viruses and adenoviruses. Pox viruses are unique because all replication events, including DNA replication, occur in the host *cytoplasm* instead of the nucleus, and adenoviruses are unique because the replication of their genome proceeds in a leading fashion on *both* DNA template strands.

Pox Viruses

Pox viruses have been important historically as well as medically. Smallpox virus was the first virus to be studied in any detail and was the first virus for which a vaccine was developed. Pox viruses are among the largest of all viruses, the brick-shaped vaccinia virions measuring almost 400 nm in diameter (Figure 9.11). Other pox viruses of importance are cowpox and vaccinia virus. Because it closely resembles the smallpox virus but is not pathogenic, vaccinia is used as a smallpox vaccine and a model for smallpox virus molecular biology.

The vaccinia virus genome consists of linear double-stranded DNA about 190 kilobase pairs in length and encoding about 250 genes. Following attachment, vaccinia virions are taken up into host cells and the nucleocapsids (Figure 9.11) are liberated in the cytoplasm; all replication events take place in the cytoplasm. Uncoating of the viral genome requires the activity of a viral protein that is synthesized after infection (the gene encoding this protein is transcribed by a viral RNA polymerase contained within the virion). In addition to this uncoating gene, a number of other viral genes are transcribed, including genes that encode a DNA polymerase that synthesizes copies of the viral genome. These are

CDC/PHL, Fred Murphy and Sylvia Whitfield

Figure 9.11 Smallpox virus. Transmission electron micrograph of a negatively stained thin section of smallpox virus virions. The virions are approximately 350 nm (0.35 μm) long. The dumbbell-shaped structure inside the virion is the nucleocapsid, which contains the double-stranded DNA genome. All pox virus replication functions occur in the host cytoplasm.

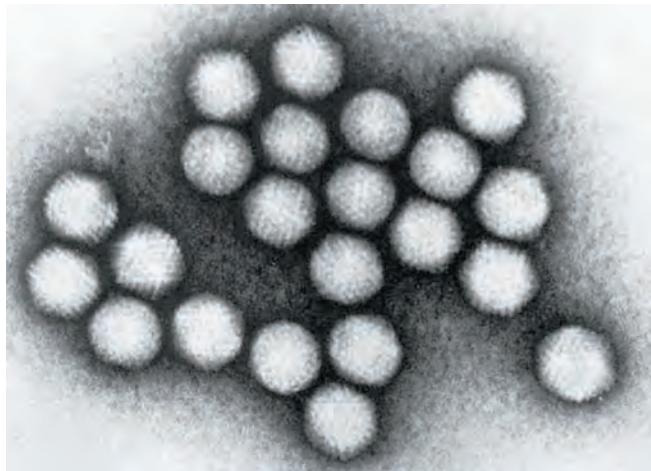

then incorporated into virions that accumulate in the cytoplasm, and the virions are released when the infected cell lyses.

Vaccinia virus has been genetically engineered to contain certain proteins from other viruses for use in vaccines (Section 11.14). A vaccine is a substance capable of eliciting an immune response in an animal that protects the animal from future infection with the same agent. Vaccinia virus causes no serious health effects in humans but elicits a strong immune response. Therefore, as a carrier of proteins from pathogenic viruses, vaccinia virus is a relatively safe and effective tool for stimulating an immune response against these pathogens. Success has been obtained with vaccinia virus vaccines against the viruses that cause influenza, rabies, herpes simplex type 1, and hepatitis B.

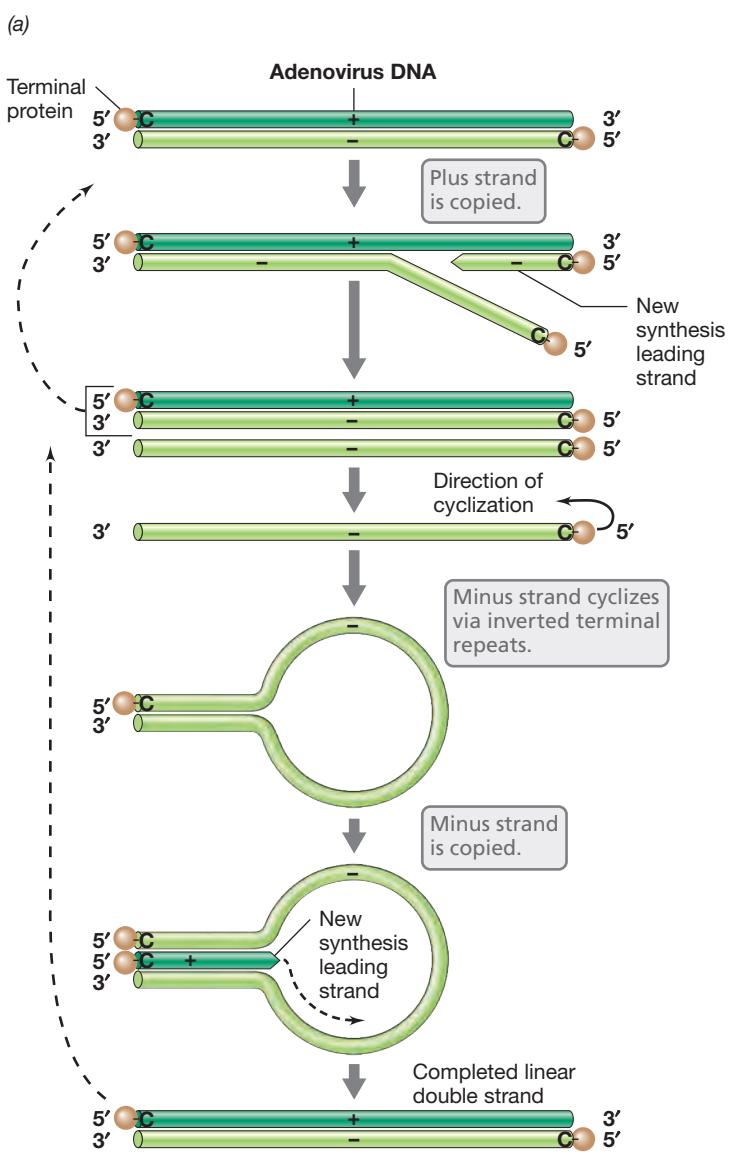

Adenoviruses

Adenoviruses are a group of small and naked icosahedral viruses (Figure 9.12a) that contain linear double-stranded DNA genomes. Adenoviruses are of minor health importance, causing mild respiratory infections in humans, but they have a unique stature in virology because of the mechanism they employ to replicate their genomes. Attached to the 5' end of adenoviral genomic DNA is a protein called the adenoviral *terminal protein*, essential for replication of the DNA. The complementary DNA strands also have inverted terminal repeats that play a role in the replication process (Figure 9.12b).

Following infection, the adenoviral nucleocapsid is released into the host cell nucleus, and transcription of the early genes proceeds by activity of the host RNA polymerase. Most early transcripts encode important replication proteins such as the terminal protein and a viral DNA polymerase. Replication of the adenoviral genome begins at either end of the linear DNA genome and the terminal protein facilitates this process

CDC/PHL, G. William Gary, Jr.

(b)

Figure 9.12 Adenoviruses. (a) Transmission electron micrograph of adenoviral virions. Note the icosahedral structure. (b) Adenoviral genome replication. Because of loop formation (cyclization), there is no lagging strand; DNA synthesis is leading on both strands. A cytosine (C) is attached to the terminal protein.

because it contains a covalently bound cytosine that serves as a primer for DNA polymerase (Figure 9.12b). The products of this initial replication are a completed double-stranded viral genome and a single-stranded minus-sense DNA molecule. At this point, a unique replication event occurs. The single DNA strand cyclizes by means of its inverted terminal repeats, and a complementary (plus-sense) DNA strand is synthesized beginning from its 5' end (Figure 9.12b). This mechanism is unique because double-stranded DNA is replicated without the formation of a lagging strand, as occurs in conventional semiconservative DNA replication (Section 4.5). Once sufficient copies of the adenoviral genome have formed and virion structural components accumulate in the host cell, mature adenoviral virions are assembled and released from the cell following lysis.

MINIQUIZ

- What is unusual about genome replication in pox viruses?
- What is unusual about genome replication in adenoviruses?
- Why is the adenovirus terminal protein essential for replicating its genome?

9.7 DNA Tumor Viruses

Besides catalyzing lytic events or becoming integrated into a genome in a latent state, some DNA animal viruses can induce cancers. These include viruses of the polyomavirus family and some herpesviruses, both of which contain double-stranded DNA genomes.

Polyomavirus SV40

Polyomavirus SV40 is a naked icosahedral virus whose double-stranded DNA genome is circular (Figure 9.13a). The genome is too small to encode its own DNA polymerase (Table 9.1), so host DNA polymerases are used and SV40 DNA is replicated in a bidirectional fashion from a single origin of replication. Because of the small genomes of polyomaviruses, the strategy of overlapping genes, typical of many small bacteriophages (Section 9.3), is also employed here. Transcription of the viral genome occurs in the nucleus and mRNAs are exported to the cytoplasm for protein synthesis. Eventually SV40 virion assembly occurs (in the nucleus) and the cell is lysed to release the new virions.

When SV40 infects a host cell, one of two outcomes can occur, depending on the host cell. In *permissive* hosts, virus infection results in the usual formation of new virions and the lysis of the host cell. In *nonpermissive* hosts, lytic events do not occur; instead, the viral DNA becomes integrated into host DNA, genetically altering the cells in the process (Figure 9.13b). Such cells can show loss of growth inhibition and become malignant, a process called *transformation* (Figure 8.22). As in certain tumor-causing retroviruses (Section 9.11), expression of specific SV40 genes is required to convert the cell to the transformed state. These tumor-inducing proteins bind to and inactivate host cell proteins that control cell division, and in this way, they promote uncontrolled cell development.

(a)

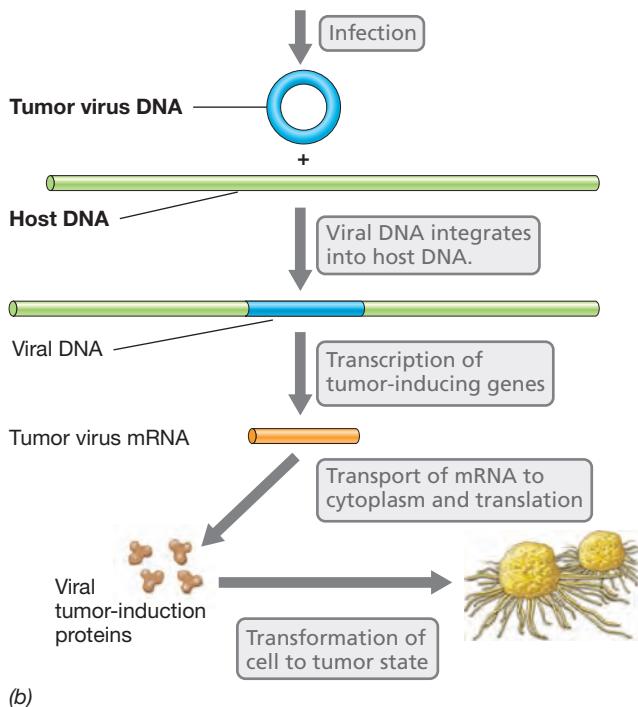

Figure 9.13 Polyomaviruses and tumor induction. (a) Transmission electron micrograph of relaxed (nonsupercoiled) circular DNA from a tumor virus. The contour length of each circle is about 1.5 µm. (b) Events in cell transformation by a polyomavirus such as SV40. Viral DNA becomes incorporated into the host genome. From there, viral genes encoding cell transformation events are transcribed and transported to the cytoplasm for translation.

Herpesviruses

Herpesviruses are a large group of double-stranded DNA viruses that cause a variety of human diseases, including fever blisters (cold sores), venereal herpes, chicken pox, shingles, and infectious mononucleosis. An important group of herpesviruses cause cancer. For example, Epstein–Barr virus causes Burkitt's lymphoma, a tumor endemic in children of central Africa and New Guinea. A widespread herpesvirus is cytomegalovirus (CMV), present in nearly three-quarters of all adults in the United States over 40 years of age. For healthy individuals, infection with CMV comes with no apparent symptoms or long-term health consequences. However, CMV can cause pneumonia, retinitis (an eye

condition), and certain gastrointestinal disorders, as well as serious disease or even death in immune-compromised individuals.

Herpesviruses can remain latent in the body for long periods of time and become active under conditions of stress or when the immune system is compromised. Herpesvirus virions are enveloped and can have many distinct structural layers over the icosahedral nucleocapsid (**Figure 9.14**). Following viral attachment, the host cytoplasmic membrane fuses with the virus envelope, and this releases the nucleocapsid into the cell. The nucleocapsid is transported to the nucleus, where the viral DNA is uncoated and three classes of mRNA are produced: *immediate early*, *delayed early*, and *late* (Figure 9.14). Immediate early mRNA encodes certain regulatory proteins that stimulate the synthesis of the delayed early proteins. Among the key proteins synthesized during the delayed early stage is a viral-specific DNA polymerase and a DNA-binding protein, both of which are needed for viral DNA replication. As for other viruses, late proteins are primarily viral structural proteins.

Herpesvirus DNA replication takes place in the nucleus. After infection, the herpesvirus genome circularizes and replicates by a rolling circle mechanism. Long concatemers are formed that become processed into virus-length genomic DNA during the assembly process (Figure 9.14). Viral nucleocapsids are assembled in the nucleus, and the viral envelope is added via a budding process through the *nuclear* membrane. Mature virions are subsequently released through the endoplasmic reticulum to the outside of the cell. The assembly of herpesvirus virions thus differs from that of other enveloped viruses, which typically receive their envelope from the cytoplasmic membrane.

MINIQUIZ

- How can the outcome of an SV40 viral infection differ in permissive versus nonpermissive hosts?
- Name two common diseases caused by herpesviruses.
- What is unusual about the envelope of a herpesvirus?

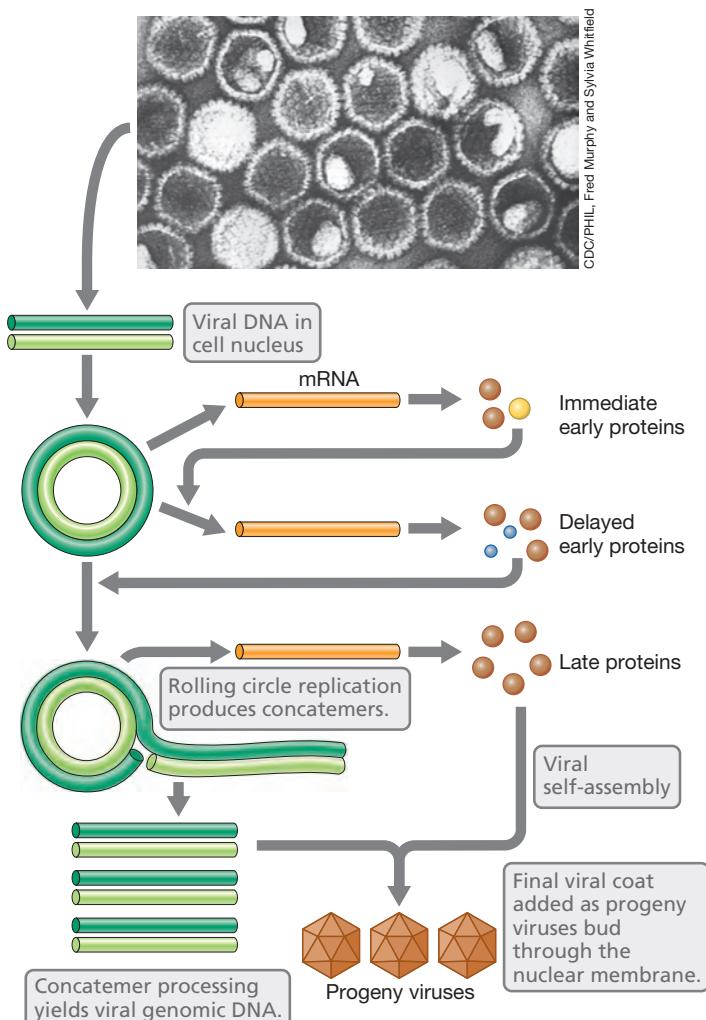

Figure 9.14 **Herpesvirus.** Flow of events in replication of herpes simplex virus starting from a transmission electron micrograph of herpes simplex virus (diameter about 150 nm). Although the viral genome is linear within the virion, it circularizes once inside the host.

III • Viruses with RNA Genomes

9.8 Positive-Strand RNA Viruses

Many viruses contain single-stranded RNA genomes of the plus sense and are therefore *positive-strand RNA viruses*. In these viruses, the sequence of the genome and the mRNA are the same (Figure 9.2). Many positive-strand animal and bacterial viruses are known, so we restrict our coverage here to just a few well-studied cases. We begin with the tiny bacteriophage MS2.

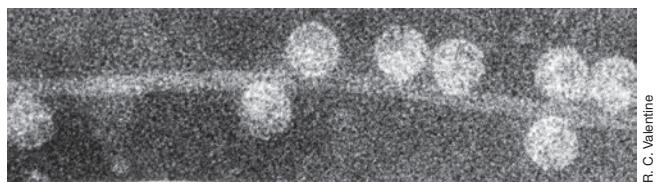

Phage MS2

Bacteriophage MS2 is about 25 nm in diameter and has an icosahedral capsid. The virus infects cells of *Escherichia coli* by attaching to the cell's pilus (**Figure 9.15a**), a structure that normally functions in a form of horizontal gene exchange (conjugation) in bacteria. How MS2 RNA actually gets inside the *E. coli* cell from

the pilus is unknown, but once it has, MS2 replication events begin quickly; the genetic map and major activities of this virus are shown in Figure 9.15b and c.

The MS2 genome encodes only four proteins, including the maturation protein, coat protein, lysis protein, and one subunit of **RNA replicase**, the enzyme that replicates the viral RNA. MS2 RNA replicase is a composite protein, with some subunits encoded by the host genome and one subunit by the viral genome. The gene encoding the MS2 lysis protein overlaps that encoding the coat protein and replicase subunit (Figure 9.15b). We have seen this phenomenon of *overlapping genes* before (Section 9.3) as a strategy for making small genomes more efficient.

Because the genome of phage MS2 is plus-sense RNA, it is translated directly upon entry into the cell by the host RNA polymerase. When RNA replicase is made, it begins synthesis

(a) Electron micrograph of phage MS2

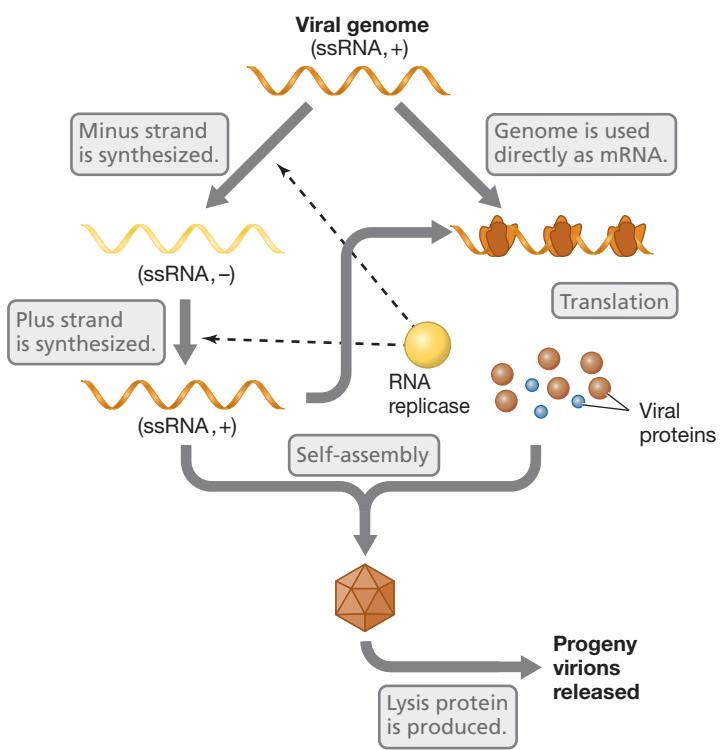

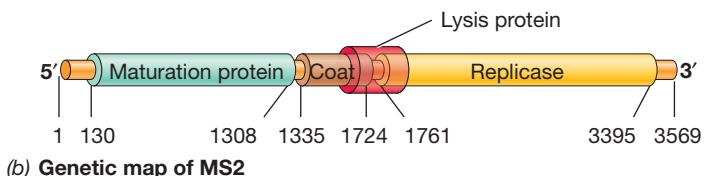

Figure 9.15 A small RNA bacteriophage, MS2. (a) Transmission electron micrograph of the pilus of a donor bacterial cell of *Escherichia coli* showing virions of phage MS2 attached. (c) Flow of events during MS2 replication.

of minus-sense RNA using plus strands as templates. As minus-sense RNA copies accumulate, more plus-sense RNA is made using the minus-sense strands as templates, and some of these are translated for continued synthesis of viral structural proteins.

Phage MS2 regulates synthesis of its proteins by controlling access of host ribosomes to translational start sites on its RNA. MS2 genomic RNA is folded into a complex secondary structure. Of the four AUG translational start sites (Section 4.11) on the MS2 RNA, the most accessible to the cell's translation machinery is that for the coat protein and replicase. Hence, translation begins at these sites very early following infection. However, as

coat protein molecules accumulate, they bind to the RNA around the AUG start site for the replicase protein, effectively turning off synthesis of replicase. Although the gene for the maturation protein is at the 5' end of the RNA, the extensive folding of the RNA limits access to the maturation protein translational start site, and consequently, only a few copies are synthesized. In this way, all MS2 proteins are made in the relative amounts needed for virus assembly. Ultimately, self-assembly of MS2 virions takes place, and virions are released from the cell as a result of cell lysis.

Poliovirus

Several positive-strand RNA animal viruses cause disease in humans and other animals. These include poliovirus, the rhinoviruses that cause many cases of the common cold, the coronaviruses that cause respiratory syndromes, including severe acute respiratory syndrome (SARS), and the hepatitis A virus. We focus here on poliovirus and coronaviruses, both of which have linear RNA genomes.

Poliovirus is one of the smallest of all viruses with an icosahedral structure containing the minimum 60 morphological units per virion (Figure 9.16a, b). At the 5' terminus of the viral RNA is a protein, called the VPg protein, that is attached covalently to the genomic RNA, and at the 3' terminus is a poly(A) tail (Figure 9.16c), a common feature of eukaryotic cell transcripts. The poliovirus genome is also the mRNA, and the VPg protein facilitates binding of the RNA to host ribosomes. Translation yields a **polyprotein**, a single protein that self-cleaves into several smaller proteins including virion structural proteins. Other proteins generated from the polyprotein include the VPg protein, an RNA replicase responsible for synthesis of both minus-strand and plus-strand RNA, and a virus-encoded protease, which carries out the polyprotein cleavage (Figure 9.16c). This mechanism is called *post-translational cleavage* and is common in many animal viruses as well as animal cells.

Poliovirus replication occurs in the host cell cytoplasm. To initiate infection, the poliovirus virion attaches to a specific receptor on the surface of a sensitive cell and enters the cell. Once inside the cell, the virion is uncoated, and the genomic RNA is attached to ribosomes and translated to yield the polyprotein. Replication of viral RNA begins shortly after infection by the poliovirus RNA replicase. Both the positive and negative strands that are made pick up the VPg protein, which also functions as a primer for RNA synthesis (Figure 9.16c). Once poliovirus replication begins, host events are inhibited, and about 5 h postinfection, cell lysis occurs with the release of new poliovirus virions.

Coronaviruses

Coronaviruses are single-stranded plus RNA viruses that, like poliovirus, replicate in the cytoplasm, but differ from poliovirus in their larger size and details of replication. Coronaviruses cause respiratory infections in humans and other animals, including about 15% of common colds and SARS, an occasionally fatal infection of the lower respiratory tract in humans (Section 28.3).

Coronavirus virions are enveloped and contain club-shaped glycoprotein spikes on their surfaces (Figure 9.17a). These give the virus the appearance of having a "crown" (*corona* is Latin for crown). Coronavirus genomes are noteworthy because they

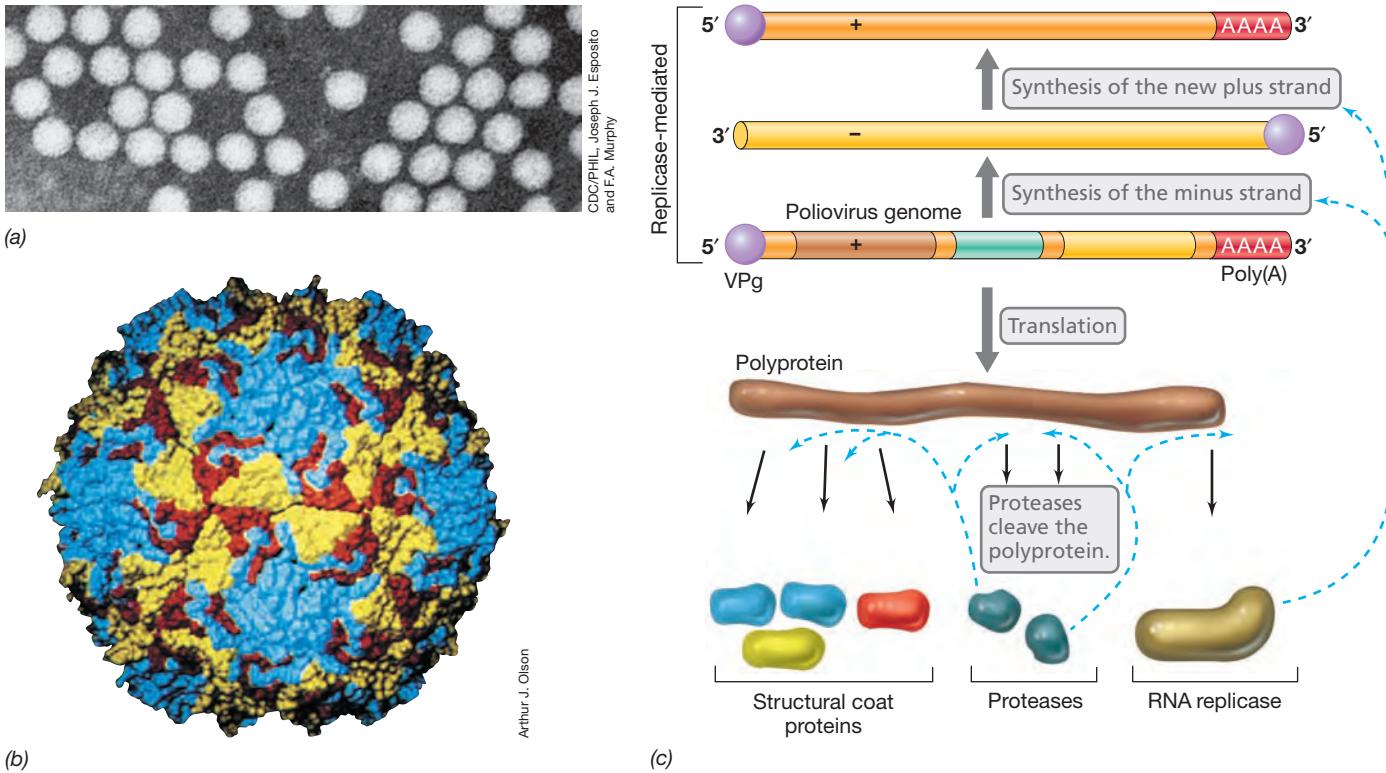

Figure 9.16 Poliovirus. (a) Transmission electron micrograph of poliovirus virions. (b) A computer model of poliovirus virions.

The various structural proteins are shown in distinct colors. (c) The replication and translation of poliovirus. Note the importance of the RNA replicase.

are the largest of any known RNA viruses, about 30 kilobases. Because it is of the plus sense, the coronavirus genome can function directly in the cell as mRNA. Nevertheless, most coronaviral proteins are not made by translating genomic RNA. Instead, upon infection, only a portion of the genome is translated, in particular that which yields the RNA replicase (Figure 9.17b). This enzyme then uses the genomic RNA as a template to produce complementary negative strands from which several mRNAs are produced, and these mRNAs are translated to produce coronaviral proteins (Figure 9.17b). Full-length genomic RNA is also made off of the negative strands. New coronaviral virions are assembled within the Golgi complex, a major secretory organelle in eukaryotic cells (🔗 Section 2.22), and the fully assembled virions are released later from the cell surface.

Coronavirus differs from poliovirus in terms of virion and genome size, lack of the VPg protein, and absence of polyprotein formation and cleavage. Nevertheless, their single-stranded plus-sense RNA genomes dictate that many other molecular events must occur in a similar way.

MINIOUIZ

- How can poliovirus RNA be synthesized in the cytoplasm whereas host RNA must be made in the nucleus?
 - What is present in the poliovirus polyprotein?
 - How are protein synthesis and genomic replication similar or different in poliovirus and the SARS virus?

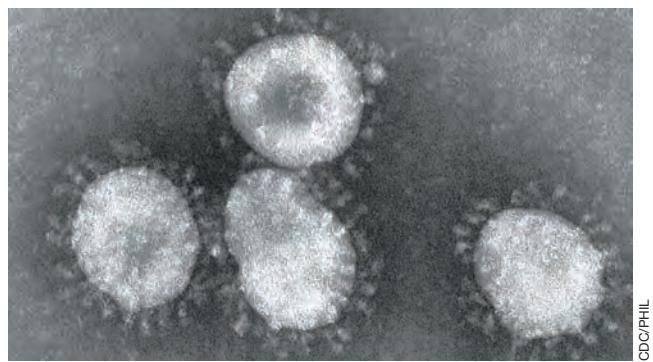

9.9 Negative-Strand RNA Animal Viruses

In contrast to viruses considered in the last section, a number of animal viruses have minus-sense RNA genomes, and thus their genomes are complementary in base sequence to the mRNA. These are the *negative-strand RNA viruses*. We discuss here two important examples: rabies virus and influenza virus. There are no known negative-strand RNA bacteriophages or archaeal viruses.

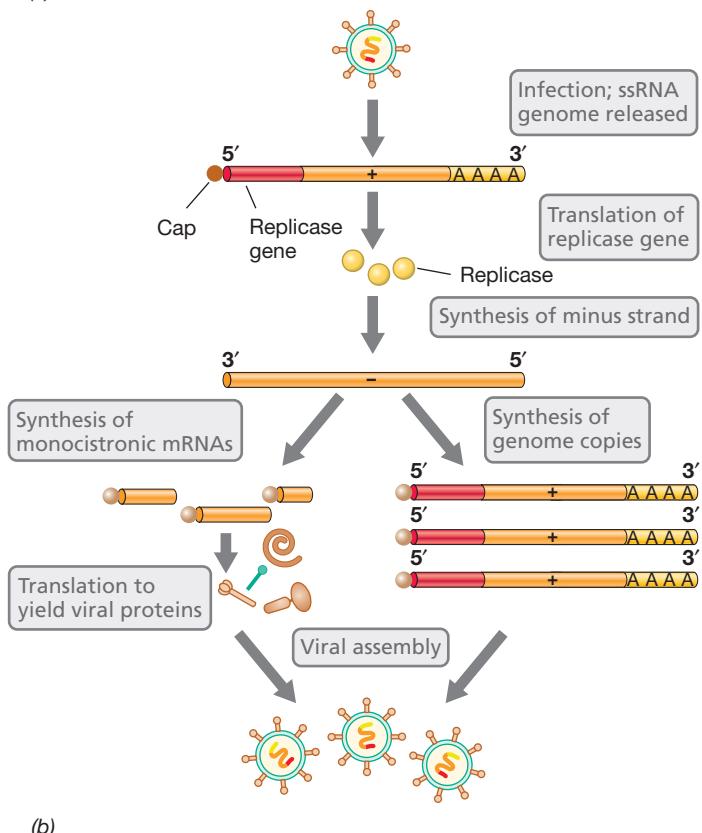

Rabies Virus

Rabies virus, which causes the typically fatal disease rabies (🔗 Section 30.1), is a rhabdovirus, which refers to the characteristic shape of the virion. Rhabdoviruses are commonly bullet-shaped (**Figure 9.18a**) and have an extensive and complex lipid envelope surrounding the helically symmetrical nucleocapsid. A rhabdovirus virion contains several enzymes that are essential for the infection process including an RNA replicase. Unlike positive-strand viruses, a rhabdovirus genome cannot be directly translated but must first be transcribed by the replicase. This occurs in the cytoplasm and generates two classes of RNAs. The first is a series of mRNAs encoding each of the viral proteins, and the second is a complementary copy of the entire viral genome; the latter serves as a template for the synthesis of genomic RNA copies (Figure 9.18b).

Assembly of a rhabdovirus virion is complex. Two different coat proteins are present, nucleocapsid and envelope. The nucleocapsid is formed first by assembly of nucleocapsid protein molecules

(a)

(b)

Figure 9.17 Coronaviruses. (a) Electron micrograph of a coronavirus; a virion is about 150 nm in diameter. (b) Steps in coronavirus replication. The mRNA encoding viral proteins is transcribed from the negative strand made by the RNA replicase using the viral genome as a template.

around the viral RNA genome. The envelope proteins are glycoproteins and they migrate to the cytoplasmic membrane where they are inserted into the membrane. Nucleocapsids then migrate to areas on the cytoplasmic membrane where these virus-specific glycoproteins are embedded and bud through them, becoming coated by the glycoprotein-enriched cytoplasmic membrane in the process. The final result is the release of new virions that can infect neighboring cells.

Influenza Virus

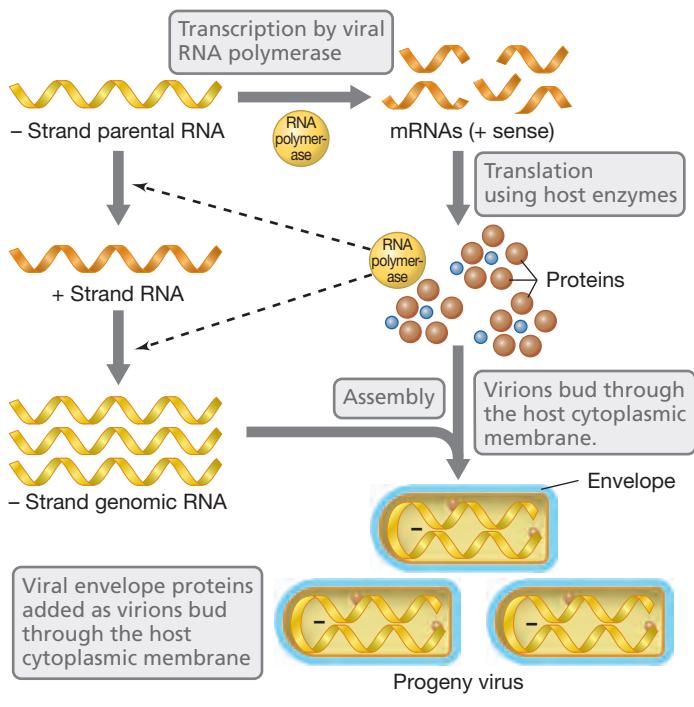

Another group of negative-strand RNA viruses contains the important human pathogen *influenza virus*. Influenza virus has been well studied over many years, beginning with early work

during the 1918 influenza pandemic that killed millions of people worldwide (☞ Sections 28.11 and 29.8). Influenza virus is an enveloped virus in which the viral genome is present in the virion in a number of separate pieces, a condition called a *segmented genome*. In the case of influenza A virus, a common strain, the genome is segmented into eight linear single-stranded molecules ranging in size from 890 to 2341 nucleotides. The nucleocapsid of the virus is of helical symmetry, about 6–9 nm in diameter and about 60 nm long, and is embedded in an envelope that has a number of virus-specific proteins as well as lipid derived from the host cytoplasmic membrane. Because of the way influenza virus buds as it leaves the cell, virions do not have a uniform shape and instead are pleomorphic (Figure 9.19a).

Several proteins on the outside of the influenza virion envelope interact with the host cell surface. One of these is *hemagglutinin*.

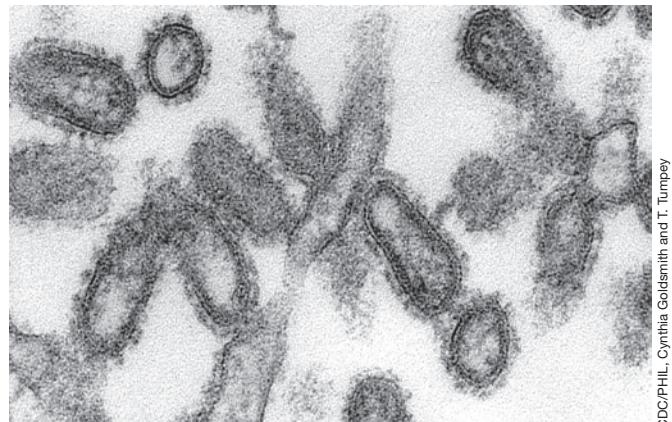

(a)

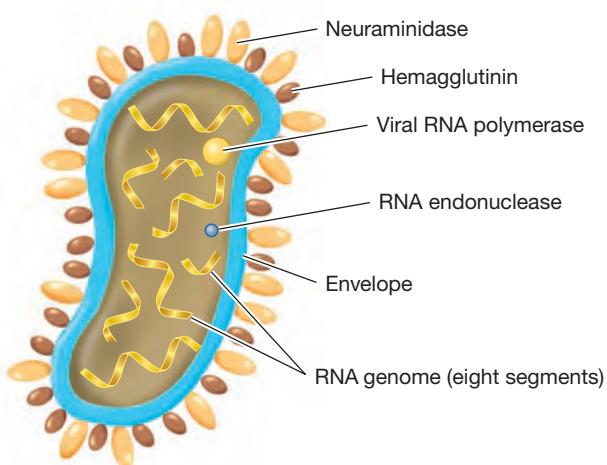

(b)

(a)

(b)

Figure 9.19 Influenza virus. (a) Transmission electron micrograph of thin sections of human influenza virus virions. (b) Some of the major components of the influenza virus, including the segmented genome.

Hemagglutinin is highly immunogenic and antibodies against it prevent the virus from infecting a cell. This is the mechanism by which immunity to influenza is brought about by immunization (Section 29.8). A second important influenza virus surface protein is the enzyme *neuraminidase* (Figure 9.19b). Neuraminidase breaks down sialic acid (a derivative of neuraminic acid) in the host cytoplasmic membrane. Neuraminidase functions primarily in virus assembly, destroying host membrane sialic acid that would otherwise block assembly or become incorporated into the virion. In addition to hemagglutinin and neuraminidase, influenza virions possess two other key enzymes. These include an RNA replicase, which converts the minus-strand genome into a plus strand, and an RNA endonuclease, which cuts the cap from host mRNAs (Section 4.9) and uses them to cap viral mRNAs so they can be translated by the host translational machinery.

After the influenza virion enters the cell, the nucleocapsid separates from the envelope and migrates to the nucleus. Uncoating activates the virus RNA replicase and transcription begins. Ten proteins are encoded by the eight segments of the influenza virus genome. The mRNAs transcribed from six segments each encode a single protein, and the other two segments encode two proteins

each. Some of the viral proteins are needed for influenza virus RNA replication, whereas others are structural proteins of the virion. The overall pattern of genomic RNA synthesis resembles that of the rhabdoviruses (Figure 9.18b), with full-length positive-strand RNA used as a template for making negative-strand genomic RNA. The complete enveloped virion forms by budding, as for the rhabdoviruses.

The segmented genome of the influenza virus has important practical consequences. Influenza virus exhibits a phenomenon called **antigenic shift** in which segments of the RNA genome from two different strains of the virus infecting the same cell are reassorted. This generates hybrid influenza virions that express unique surface proteins unrecognized by the immune system. Antigenic shift is thought to trigger major outbreaks of influenza because immunity to the new forms of the virus is absent from the population. We discuss antigenic shift, and a related phenomenon called *antigenic drift*, in Section 29.8.

MINIQUIZ

- Why is it essential that negative-strand viruses carry an enzyme in their virions?
- What is a segmented genome?
- In influenza virus, what is antigenic shift and how does it occur?

9.10 Double-Stranded RNA Viruses

Viruses with double-stranded RNA genomes infect animals, plants, fungi, and a few bacteria. *Reoviruses* are an important family of animal viruses with double-stranded RNA genomes, 18–30 kilobase pairs in size, and we focus on them here.

Rotavirus is a typical reovirus and is the most common cause of diarrhea in infants 6 to 24 months of age. Other reoviruses cause respiratory infections and some infect plants. Reovirus virions consist of a nucleocapsid 60–80 nm in diameter, surrounded by a double shell of icosahedral symmetry (Figure 9.20a, b). As we have seen with single-stranded RNA viruses, the virions of double-stranded RNA viruses must carry their own enzyme to synthesize their mRNA and replicate their RNA genomes. Like the influenza virus genome, the reoviral genome is segmented, in this case into 10–12 molecules of linear double-stranded RNA.

To initiate infection, a reovirus virion binds to a cellular receptor protein. The attached virus then enters the cell and is transported into lysosomes, where normally it would be destroyed (Section 2.22). However, within the lysosome only the outer coats of the virion are removed by proteolytic enzymes. This reveals the nucleocapsid, which is released into the cytoplasm. This uncoating process activates the viral RNA replicase and initiates virus replication (Figure 9.20c).

Reovirus replication events occur exclusively in the host cytoplasm but *within* the nucleocapsid itself (Figure 9.20c) because the host has enzymes that recognize double-stranded RNA as foreign and would destroy it. The plus strand of the reoviral genome is inactive as mRNA, and thus the first step in replication is the synthesis of plus-sense mRNA by the viral-encoded RNA replicase, using minus-strand RNA as a template. The nucleotide triphosphates necessary for RNA synthesis are supplied by the host

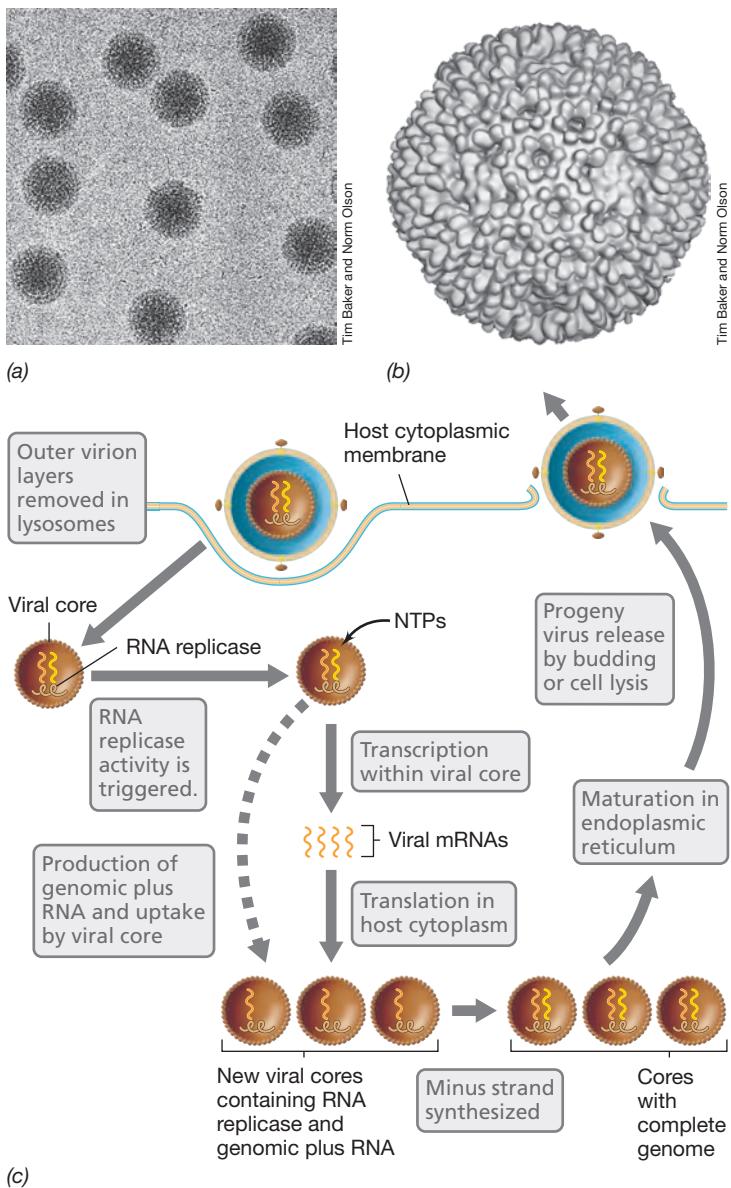

Figure 9.20 Double-stranded RNA viruses: The reoviruses. (a) Transmission electron micrograph showing reovirus virions (diameter, about 70 nm). (b) Three-dimensional computer reconstruction of a reovirus virion calculated from electron micrographs of frozen-hydrated virions. (c) The reovirus life cycle. All replication and transcription steps occur inside the nucleocapsids. NTPs, nucleotide triphosphates.

(Figure 9.20c). The mRNAs are then capped and methylated (as is typical of eukaryotic mRNAs, [Section 4.9](#)) by viral enzymes and exported from the nucleocapsid into the cytoplasm and translated by host ribosomes.

Most RNAs in the reovirus genome encode a single protein, although in a few cases the protein formed is cleaved to yield the final products. However, one of the reovirus mRNAs encodes two proteins but the RNA does not have to be processed in order to translate both of these. Instead, a ribosome occasionally “misses” the start codon for the first gene in this mRNA and travels on to the start codon of the second gene to begin translation. When this occurs, the second protein, needed in small amounts, is made but the first protein is not. This “molecular mistake” can be

viewed as a primitive form of translational control that ensures that viral proteins are made in their proper amounts.

As viral proteins are formed in the host cytoplasm, they aggregate to form new nucleocapsids, trapping copies of RNA replicase inside as they form (Figure 9.20c). Newly formed nucleocapsids then take up the correct complement of genomic (plus-strand) RNA fragments—probably by recognition of specific sequences on each fragment—and as each single-stranded RNA enters a newly formed nucleocapsid, a double-stranded form is produced from it by RNA replicase. Once genomic synthesis is complete, viral coat proteins are added in the host’s endoplasmic reticulum, and the mature reoviral virions are released by budding or cell lysis (Figure 9.20c).

Despite the fact that the reovirus RNA genome is double-stranded, RNA replication in these viruses is actually a *conservative* process rather than the well-known *semiconservative* process typical of cellular DNA replication ([Sections 4.4–4.6](#)). This is because synthesis of mRNA occurs *only* off of the minus strand as a template in the infecting nucleocapsids, whereas synthesis of double-stranded genomic RNA from assimilated plus-strand RNA in progeny virions occurs *only* off of the plus strand as a template (Figure 9.20c). Hence, in addition to having double-stranded RNA genomes, reoviruses also display their unusual molecular biology by employing a unique nucleic acid replication mechanism that is neither semiconservative nor rolling circle (Figure 9.6) in nature.

MINIQUIZ

- What does the reovirus genome consist of?
- How does reovirus genome replication resemble that of influenza virus, and how does it differ?
- Why must reoviral replication events occur within the nucleocapsid?

9.11 Viruses That Use Reverse Transcriptase

Two different classes of viruses use *reverse transcriptase*, and they differ in the type of nucleic acid in their genomes. The retroviruses have RNA genomes, whereas the hepadnaviruses have DNA genomes. Besides their unique biological properties, both classes of viruses include important human pathogens, including HIV (a retrovirus) and hepatitis B (a hepadnavirus).

Retroviruses

Retroviruses have enveloped virions that contain two identical copies of the RNA genome ([Figure 8.23a](#)). The virion also contains several enzymes, including reverse transcriptase, and also a specific viral tRNA. Enzymes for retrovirus replication must be carried in the virion because although the retroviral genome is of the plus sense, it is not used directly as mRNA. Instead, the genome is converted to DNA by reverse transcriptase and integrated into the host genome. The DNA formed is a linear double-stranded molecule and is synthesized within the virion and then released to the cytoplasm. An outline of the steps in reverse transcription is given in [Figure 9.21](#).

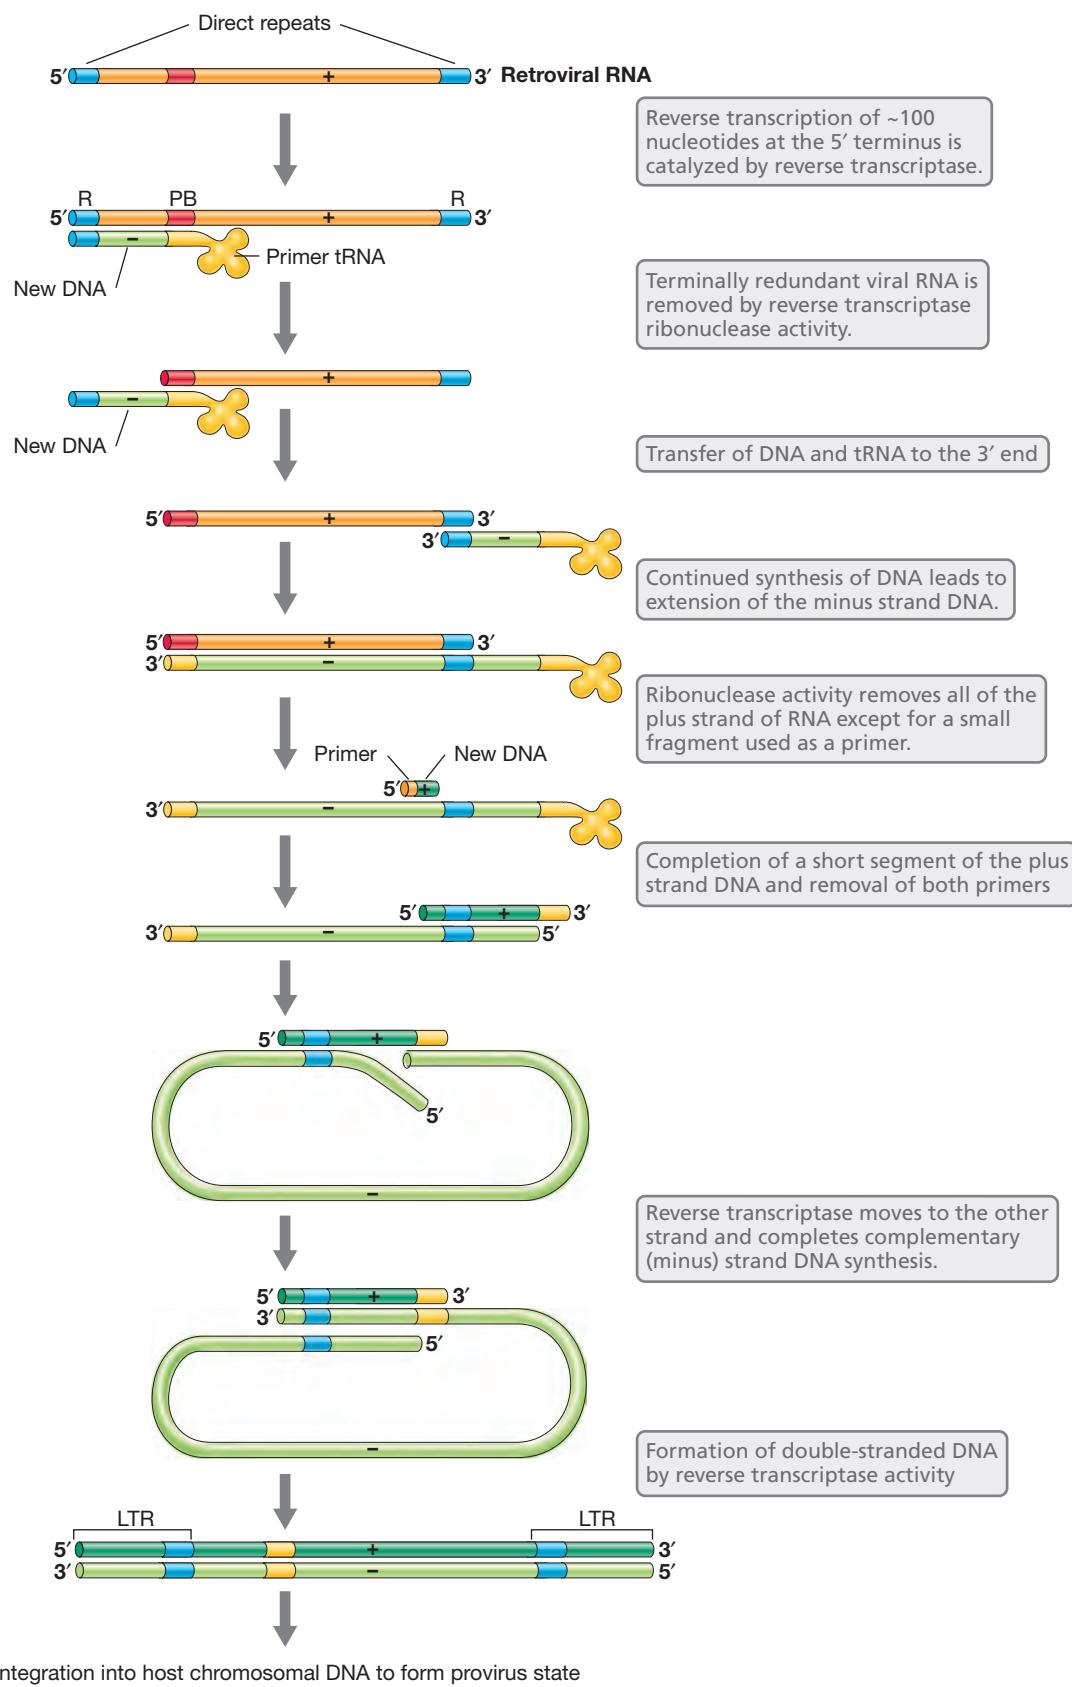

Figure 9.21 Formation of double-stranded DNA from retrovirus single-stranded genomic RNA. The sequences labeled R on the RNA are direct repeats found at either end. The sequence labeled PB is where the primer (tRNA) binds. Note that DNA synthesis yields longer direct repeats on the DNA than were originally on the RNA. These are called long terminal repeats (LTRs).

Reverse transcriptase possesses three enzymatic activities: (1) *reverse transcription* (to synthesize DNA from an RNA template), (2) *ribonuclease activity* (to degrade the RNA strand of an RNA:DNA hybrid), and (3) *DNA polymerase* (to make double-stranded DNA from single-stranded DNA). Reverse transcriptase needs a primer for DNA synthesis and this is the function of the viral tRNA. Using this primer, nucleotides near the 5' terminus of the RNA are reverse-transcribed into DNA. Once reverse transcription reaches the 5' end of the RNA, the process stops. To copy the remaining RNA, a different mechanism comes into play. First, terminally redundant RNA sequences at the 5' end of the molecule are removed by reverse transcriptase. This leads to the formation of a small, single-stranded DNA that is complementary to the RNA segment at the *other end* of the viral RNA. This short, single-stranded piece of DNA then hybridizes with the other end of the viral RNA molecule, where synthesis of DNA begins once again. Continued reverse transcription leads to the formation of a double-stranded DNA molecule with long terminal repeats that assist in integration of the retroviral DNA into the host chromosome (Figure 9.21).

Once integrated, retroviral DNA becomes a permanent part of the host chromosome; the genes may be expressed or they may remain in a latent state indefinitely. However, if induced,

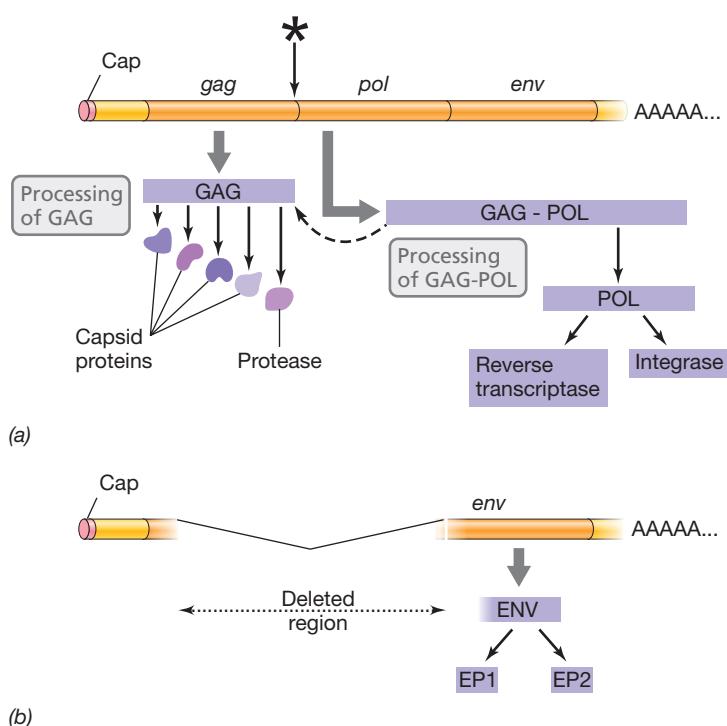

Figure 9.22 Translation of retrovirus mRNA and processing of the proteins. (a) Full-length retroviral mRNA encodes *gag*, *pol*, and *env*. The asterisk shows the site where a ribosome must read through a stop codon or do a precise shift of reading frame to synthesize the GAG-POL polyprotein. The thick gray arrows indicate translation, and the black arrows indicate protein-processing events. One of the *gag* gene products is a protease. The *POL* product is processed to give reverse transcriptase (RT) and integrase (IN). (b) The mRNA has been processed to remove most of the *gag-pol* region. This shortened message is translated to give the ENV polyprotein, which is cleaved into two envelope proteins (EP), EP1 and EP2.

retroviral DNA is transcribed by a cellular RNA polymerase to form RNA transcripts that can be either packaged into virions as genomic RNA or translated to yield retroviral proteins. Translation and processing of retroviral mRNAs is shown in Figure 9.22. All retroviruses have the genes *gag*, *pol*, and *env*, arranged in that order in their genomes (☞ Figure 8.23). The *gag* gene at the 5' end of the mRNA actually encodes several viral structural proteins. These are first synthesized as a single protein (polyprotein) that is subsequently processed by a protease which itself is part of the polyprotein. The structural proteins make up the capsid, and the protease is packaged in the virion.

Next, the *pol* gene is translated into a large polyprotein that also contains the *gag* proteins (Figure 9.22a). Compared to *gag* proteins, *pol* proteins are required in only small amounts. This regulation is achieved because *pol* protein synthesis requires the ribosome to either read through a stop codon at the end of the *gag* gene or switch to a different reading frame in this region. Both of these are rare events and can be considered a form of translational regulation. Once produced, the *pol* gene product is processed to yield *gag* proteins, reverse transcriptase, and integrase; the latter is the protein required for viral DNA integration into the host chromosome. For the *env* gene to be translated, the full-length mRNA is first processed to remove the *gag* and *pol* regions, and

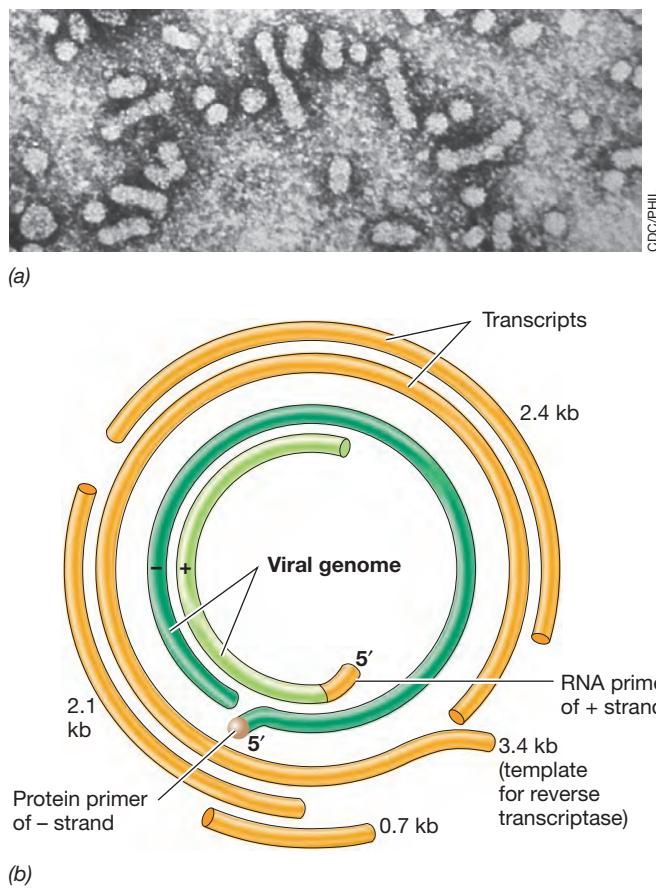

Figure 9.23 Hepadnaviruses. (a) Electron micrograph of hepatitis B virions. (b) Hepatitis B genome. The partially double-stranded genome is shown in green. The sizes of the transcripts are also shown; all of the genes in the hepatitis B virus overlap. Reverse transcriptase produces the DNA genome from a single genome-length mRNA made by host RNA polymerase.

then the *env* product is made and immediately processed into two distinct envelope proteins by the viral-encoded protease (Figure 9.22b). Retroviral assembly occurs on the inner side of the host cytoplasmic membrane and virions are released across the membrane by budding (☞ Figure 8.24).

Hepadnaviruses

The life cycles of viruses show a variety of unusual genome structures and replication schemes, but none is more unusual than that of the **hepadnaviruses**, such as human hepatitis B virus (Figure 9.23a). The tiny DNA genomes of hepadnaviruses are unusual because they are *partially* double-stranded. Despite their small size (3–4 kilobase pairs), the hepadnavirus genomes encode several proteins by employing overlapping genes, a common strategy in very small viruses (Section 9.3).

Like the retroviruses, hepadnaviruses use reverse transcriptase in their replication cycle. Besides the usual activities of this enzyme, hepadnaviral reverse transcriptase also functions as a protein primer for synthesis of one of its own DNA strands. In terms of its role in replication events, however, reverse transcriptase plays different roles in retroviral and hepadnaviral genome replication. In hepadnaviruses, the *DNA* genome is replicated through an *RNA* intermediate, whereas in retroviruses, the *RNA* genome is replicated through a *DNA* intermediate (Figures 9.21 and 9.23).

Upon infection, the hepadnavirus nucleocapsid enters the host nucleus where the partial genomic DNA strand is completed to form a complete double-stranded molecule. Transcription by host RNA polymerase yields four size classes of viral mRNAs (Figure 9.23b), which are subsequently translated to yield the hepadnaviral proteins. The largest of these transcripts is slightly larger than the viral genome and together with reverse transcriptase, associates with viral proteins in the host cytoplasm to form new virions. Reverse transcriptase then forms single-stranded DNA off of this large transcript inside the virion to form the DNA genome minus-sense strand and uses this as a template to form a partial plus-sense strand, yielding the incomplete double-stranded genome characteristic of hepadnaviruses (Figure 9.23b). Once mature virions are produced, these associate with membranes in the endoplasmic reticulum and Golgi complex, from which they are exported across the cytoplasmic membrane by budding.

MINIQUIZ

- Why are protease inhibitors an effective treatment for human AIDS?
- Contrast the genomes of HIV and hepatitis B virus.
- How does the role of reverse transcriptase in the replication cycles of retroviruses and hepadnaviruses differ?

IV • Subviral Agents

We conclude our genomic tour of the viral world by considering two *subviral* agents: the viroids and the prions. These are infectious agents that resemble viruses but which lack either nucleic acid or protein and are thus not viruses.

9.12 Viroids

Viroids are infectious RNA molecules that differ from viruses in that they lack protein. Viroids are small, circular, single-stranded RNA molecules that are the smallest known pathogens. They range in size from 246 to 399 nucleotides and show a considerable degree of sequence homology to each other, suggesting that they have common evolutionary roots. Viroids cause a number of important plant diseases and can have a severe agricultural impact (Figure 9.24). A few well-studied viroids include coconut cadang-cadang viroid (246 nucleotides) and potato spindle tuber viroid (359 nucleotides). No viroids are known that infect animals or microorganisms.

Viroid Structure and Function

The extracellular form of a viroid is naked RNA; there is no protein capsid of any kind. Although the viroid RNA is a single-stranded, covalently closed circle, its extensive secondary structure makes it resemble a hairpin-shaped double-stranded molecule with closed ends (Figure 9.25). This apparently makes the viroid sufficiently stable to exist outside the host cell. Because it lacks a capsid, a viroid does not use a receptor to enter the host cell. Instead, the viroid enters a plant cell through a wound, as from insect or other

Figure 9.24 **Viroids and plant diseases.** Photograph of healthy tomato plant (left) and one infected with potato spindle tuber viroid (PSTV) (right). The host range of most viroids is quite restricted. However, PSTV infects tomatoes as well as potatoes, causing growth stunting, a flat top, and premature plant death.

mechanical damage. Once inside, viroids move from cell to cell via plasmodesmata, which are the thin strands of cytoplasm that link plant cells (Figure 9.26).

Viroid RNA does not encode proteins and thus the viroid is totally dependent on its host for replication. Plants have several RNA polymerases, one of which has RNA replicase activity, and this is the enzyme that replicates the viroid. The replication

Yijun Qi and Biao Ding

Figure 9.25 **Viroid structure.** Viroids consist of single-stranded circular RNA that forms a seemingly double-stranded structure by intra-strand base pairing.

mechanism itself resembles the rolling circle mechanism used for genome synthesis by some small viruses (Sections 9.3 and 9.7). The result is a large RNA molecule containing many viroid units joined end to end. The viroid has ribozyme (catalytic RNA) activity and this is used for self-cleavage of the large RNA molecule, releasing individual viroids.

Viroid Disease

Viroid-infected plants can be symptomless or develop symptoms that range from mild to lethal, depending on the viroid (Figure 9.24). Most disease symptoms are growth related, and it is believed that viroids mimic or in some way interfere with plant small regulatory RNAs. In fact, viroids could themselves be derived from regulatory RNAs that have evolved away from carrying out beneficial roles in the cell to inducing destructive events. Viroids are known to yield small interfering RNAs (siRNAs) as a side product during replication. It has been proposed that these siRNAs may then function by way of the RNA interference silencing pathway to suppress the expression of plant genes that show some homology to the viroid RNA, and in this way induce disease symptoms.

MINIQUIZ

- If viroids are circular molecules, why are they depicted as hairpins?
- How might viroids cause disease in plants?

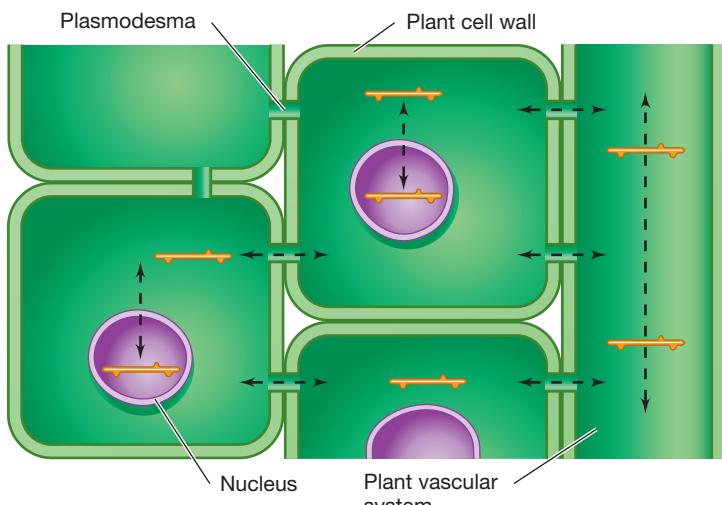

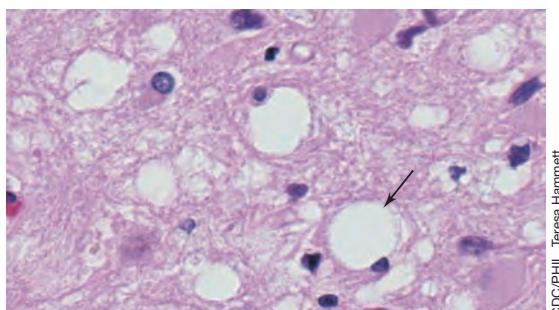

Figure 9.26 **Viroid movement inside plants.** After entry into a plant cell, viroids (orange) replicate either in the nucleus or the chloroplast. Viroids can move between plant cells via the plasmodesmata (thin threads of cytoplasm that penetrate the cell walls and connect plant cells). In addition, on a larger scale, viroids can move around the plant via the plant vascular system.

9.13 Prions

Prions represent the opposite extreme from that of viroids. Prions are infectious agents whose extracellular form consists entirely of protein. That is, a prion lacks both DNA and RNA. Prions cause several neurological diseases such as scrapie in sheep, bovine spongiform encephalopathy (BSE or “mad cow disease”) in cattle, chronic wasting disease in deer and elk, and kuru and variant Creutzfeldt–Jakob disease in humans. No prion diseases of plants are known, although prions have been found in yeast. Collectively, animal prion diseases are known as *transmissible spongiform encephalopathies*.

Prion Proteins and the Prion Infectious Cycle

If prions lack nucleic acid, how is prion protein encoded? The answer to this conundrum is that the host cell itself encodes the

(a)

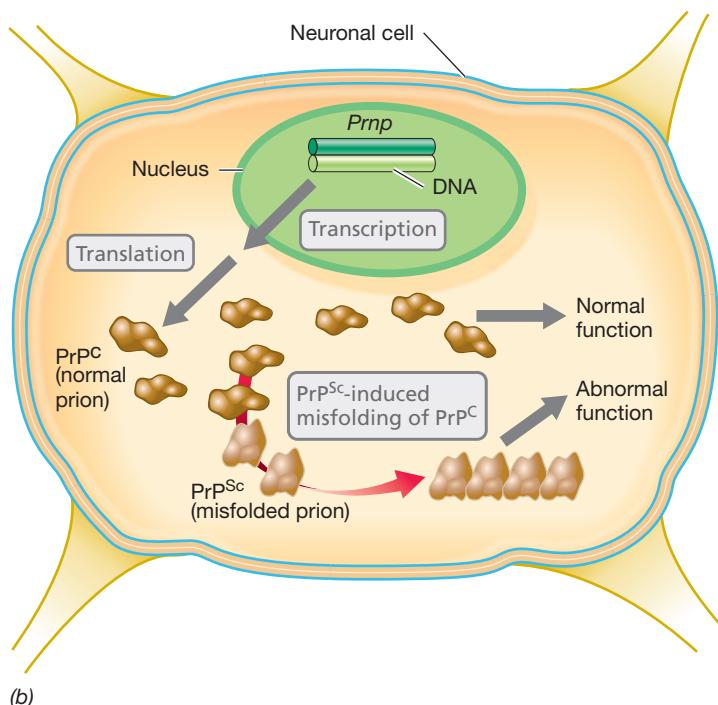

Figure 9.27 **Prions.** (a) Section through brain tissue of a human with variant Creutzfeldt–Jakob disease. Note the spongy nature of the tissue (clearings, arrow) where neural tissue has been lost. (b) Mechanism of prion misfolding. Neuronal cells produce the native form of the prion protein. The pathogenic form catalyzes the refolding of native prions into the pathogenic form. The pathogenic form is protease resistant, insoluble, and forms aggregates in neural cells. This eventually leads to destruction of neural tissues (see part a) and neurological symptoms.

prion. The host contains a gene, *Prnp* ("Prion protein"), which encodes the native form of the prion, known as *PrP^C* (Prion Protein Cellular). This is primarily found in the neurons of healthy animals, especially in the brain (Figure 9.27a). The pathogenic form of the prion protein is designated *PrP^{Sc}* (prion protein Scrapie), because the first prion disease to be discovered was that of scrapie in sheep. *PrP^{Sc}* is identical in amino acid sequence to *PrP^C* from the same species, but has a different conformation. For example, native prion proteins are largely α -helical, whereas the pathogenic forms contain less α -helix and more β -sheet secondary structure. Prion proteins from different species of mammals are similar but not identical in amino acid sequence, and host range is linked in some way to protein sequence. For example, *PrP^{Sc}* from BSE-diseased cattle can infect humans, whereas *PrP^{Sc}* from scrapie-infected sheep apparently cannot.

When the *PrP^{Sc}* form enters a host cell that is expressing *PrP^C*, it promotes the conversion of *PrP^C* into the pathogenic form (Figure 9.27b). That is, the pathogenic prion "replicates" by converting preexisting native prions into the pathogenic form. As the pathogenic prions accumulate, they form insoluble aggregates in the neural cells (Figure 9.27a). This leads to disease symptoms including the destruction of brain and other nervous tissue. *PrP^C* functions in the cell as a cytoplasmic membrane glycoprotein, and it has been shown that membrane attachment of pathogenic prions is necessary before disease symptoms commence. Mutant versions of *PrP^{Sc}* that can no longer attach to nerve cell cytoplasmic membranes still aggregate but no longer cause disease.

Nonmammalian Prions

Many vertebrates, including amphibians and fish, contain genes homologous to the *Prnp* gene of mammals that are also expressed in nervous tissue. However, the proteins encoded by these genes do not have misfolded pathogenic versions and are therefore not prions. Certain fungi have proteins that fit the prion definition of an inherited self-perpetuating change in protein structure, although these proteins do not cause noticeable disease. Instead they adapt the fungal cells to altered nutritional conditions. In yeast, for example, the [URE3] prion is a protein that regulates the transcription of genes encoding certain nitrogen metabolism functions. The normal, soluble form of this protein represses genes encoding proteins that metabolize certain nitrogen sources. However, when the [URE3] prion accumulates, it forms insoluble aggregates, just as for mammalian prion protein. When this occurs, transcription of the genes for the normally repressed form of nitrogen metabolism is derepressed and the expression of these genes commences.

MINIQUIZ

- On what basis can prions be differentiated from all other infectious agents?
- What is the difference between the native and pathogenic forms of the prion protein?
- How does a prion differ from a viroid?

BIG IDEAS

9.1 • Viral genomes can be single-stranded or double-stranded DNA or RNA and vary from a few to hundreds of kilobases in size. Viral mRNA is always of the plus configuration by definition, but single-stranded genomes can be of the plus or minus configuration. Viruses with RNA genomes must either carry an RNA replicase in their virions or encode this enzyme in their genomes in order to synthesize RNA from an RNA template.

9.2 • Viruses may have evolved as agents of gene transfer in cells, or they may be degenerate cells that became dependent on a host cell for replication. Viruses may have been the first microorganisms on Earth with DNA genomes and could have conveyed this property to cells during a transition from an RNA to a DNA world. Universal viral phylogenies are not yet possible, but phylogenetic trees of various groups can be constructed.

9.3 • Single-stranded DNA viruses contain DNA of the plus configuration, and a double-stranded replicative form is necessary for transcription and genome replication. The genome of the virus ϕ X174 is so small that some of its genes overlap, and the genome replicates by a rolling circle mechanism. Some related viruses, such as M13, have filamentous virions that are released from the host cell without lysis.

9.4 • The head-and-tail bacteriophage T7 contains a double-stranded DNA genome that encodes both early genes, transcribed by the host RNA polymerase, and late genes, transcribed by a virus-encoded RNA polymerase. Replication of the T7 genome employs T7 DNA polymerase and involves terminal repeats and concatemers. Bacteriophage Mu is a temperate virus that is also a transposable element. Mu replicates by transposition in the host chromosome.

9.5 • Several double-stranded DNA viruses infect cells of *Archaea*, most of which inhabit extreme environments. Many of these genomes are circular in contrast to the linear double-stranded DNA genomes of bacteriophages. Although head-and-tail-type viruses are known, many archaeal viruses have an unusual spindle-shaped morphology.

9.6 • Pox viruses are large double-stranded DNA viruses that replicate entirely in the cytoplasm and are responsible for several human diseases, including smallpox. Adenoviruses are double-stranded DNA viruses whose genome replication employs protein primers and a mechanism that occurs without lagging-strand synthesis.

9.7 • Some double-stranded DNA viruses cause cancer in humans. SV40 is such a tumor virus and has a tiny genome containing overlapping genes. The virus can trigger cell transformation (tumor induction) from the activity of certain genes. Some herpesviruses also cause cancer but most cause various human infectious diseases. Herpesviruses can maintain themselves in a latent state in the host indefinitely, initiating viral replication periodically.

9.8 • In single-stranded plus-sense RNA viruses, the genome is also the mRNA, and a negative strand is synthesized to produce more mRNA and genome copies. The tiny bacteriophage MS2 contains only four genes, one of which encodes a subunit of its RNA replicase. In poliovirus, the viral RNA is translated directly, producing a polyprotein that is cleaved into several small viral proteins. Coronaviruses are large RNA viruses that resemble poliovirus in some but not all of their replication features.

9.9 • In negative-strand viruses, the virus RNA is not mRNA but must first be copied to form mRNA by RNA replicase present in the virion. The positive strand is the template for production of genome copies. Important pathogenic negative-strand viruses include rabies virus and influenza virus.

9.10 • Reoviruses contain segmented linear double-stranded RNA genomes. Like negative-strand RNA viruses, reoviruses contain an RNA-dependent RNA polymerase within the virion. All replication events occur within newly forming virions.

9.11 • Some viruses employ reverse transcriptase, including retroviruses (HIV) and hepadnaviruses (hepatitis B). Retroviruses have single-stranded RNA genomes and use reverse transcriptase to make a DNA copy. Hepadnaviruses contain partially complete DNA genomes and use reverse transcriptase to make a single strand of genomic DNA from a full-length complementary strand of RNA.

9.12 • Viroids are circular single-stranded RNA molecules that do not encode proteins and are dependent on host-encoded enzymes for replication. Unlike viruses, viroid RNA is not enclosed within a capsid, and all known viroids are plant pathogens.

9.13 • Prions consist of protein but have no nucleic acid of any kind. Prions exist in two conformations, the native cellular form and the pathogenic form, which takes on a different protein structure. The pathogenic form “replicates” itself by converting native prion proteins, encoded by the host cell, into the pathogenic conformation.

REVIEW OF KEY TERMS

Antigenic shift in influenza virus, major changes in viral proteins (antigens) due to gene reassortment

Hepadnavirus a virus whose DNA genome replicates by way of an RNA intermediate

Negative strand a nucleic acid strand that has the opposite sense to (is complementary to) the mRNA

Overlapping genes two or more genes in which part or all of one gene is embedded in the other

Polypeptide a large protein expressed from a single gene and subsequently cleaved to form several individual proteins

Positive strand a nucleic acid strand that has the same sense as the mRNA

Prion an infectious protein whose extracellular form lacks nucleic acid

Replicative form a double-stranded molecule that is an intermediate in the replication of viruses with single-stranded genomes

Retrovirus a virus whose RNA genome has a DNA intermediate as part of its replication cycle

Reverse transcription the process of copying genetic information found in RNA into DNA

RNA replicase an enzyme that can produce RNA from an RNA template

Rolling circle replication a mechanism, used by some plasmids and viruses, of replicating circular DNA, which starts by nicking and unrolling one strand. For a single-stranded genome, the still-circular strand is used as a template for DNA synthesis; for a double-stranded genome, the unrolled strand is used as a template for DNA synthesis

Transposase an enzyme that catalyzes the insertion of DNA segments into other DNA molecules

Viroid an infectious RNA whose extracellular form lacks protein

REVIEW QUESTIONS

- How much larger is the *Escherichia coli* genome than the bacteriophage T4 or T7 genomes? (Section 9.1)
- Describe the classes of viruses based on their genomic characteristics. For each class, describe how viral mRNA is made and how the viral genome is replicated. (Section 9.1)
- How might viruses help explain the differences observed in the DNA replication machinery of cells of the three domains? (Section 9.2)
- What are overlapping genes? Give examples of viruses that have overlapping genes. (Sections 9.3 and 9.8)
- Describe how the genome of bacteriophage φX174 is transcribed and translated. (Section 9.3)
- Why can it be said that transcription of the bacteriophage T7 genome requires two enzymes? (Section 9.4)
- Why is bacteriophage Mu mutagenic? What features are necessary for Mu to insert into DNA? (Section 9.4)
- List three unusual features of the archaeal virus that infects *Acidianus* that distinguish it from bacteriophage T7. (Section 9.5)
- Of all the double-stranded DNA animal viruses, pox viruses stand out concerning one unique aspect of their DNA replication process. What is this unique aspect and how can this be accomplished without special enzymes being packaged in the virion? (Section 9.6)
- Explain why it can be said that adenoviruses are unique in biology. (Section 9.6)
- List two common infectious diseases and one very serious rare disease cause by a herpesvirus. (Section 9.7)
- If the MS2 or poliovirus virions did not contain a specific enzyme, explain why these viruses could not replicate. (Section 9.8)
- What is the function of the VPg protein of poliovirus, and how can coronaviruses replicate without a VPg protein? (Section 9.8)
- Describe two ways in which the genomes of poliovirus and influenza virus differ. (Sections 9.8 and 9.9)
- Rabies virus and poliovirus both have single-stranded RNA genomes, but only in poliovirus can the genome be translated directly. Explain. (Sections 9.8 and 9.9)
- Compare the reovirus genome to those of influenza virus and bacteriophage MS2. (Section 9.10)
- Why do both hepadnaviruses and retroviruses require reverse transcriptase when their genomes are double-stranded DNA and single-stranded RNA, respectively? (Section 9.11)
- What are the similarities and differences between viruses and viroids? (Section 9.12)
- What are the similarities and differences between prions and viruses? (Section 9.13)
- What are the similarities and differences between viroids and prions? (Sections 9.12 and 9.13)

APPLICATION QUESTIONS

1. Not all proteins are made from the RNA genome of bacteriophage MS2 in the same amounts. Can you explain why? One of the proteins functions very much like a repressor, but it functions at the translational level. Which protein is it and how does it function?
2. Replication of both strands of DNA in adenoviruses occurs in a continuous (leading) fashion. How can this happen without violating the rule that DNA synthesis always occurs in a $5' \rightarrow 3'$ direction?
3. Imagine that you are a researcher at a pharmaceutical company charged with developing new drugs against human RNA viral pathogens. Describe at least two types of drugs you might pursue, what class of virus they would affect, and why you feel that the drugs would not harm the patient.
4. Reoviruses contain genomes that are unique in all of biology. Why? Why can't reovirus replication occur in the host cytoplasm? Contrast reovirus genomic replication events with those of a cell. Why can it be said that reovirus genome replication is not semiconservative even though the reovirus genome consists of complementary strands?

10 • Genetics of *Bacteria* and *Archaea*

microbiologynow

Defunct Viruses or Secret Agents of Gene Transfer?

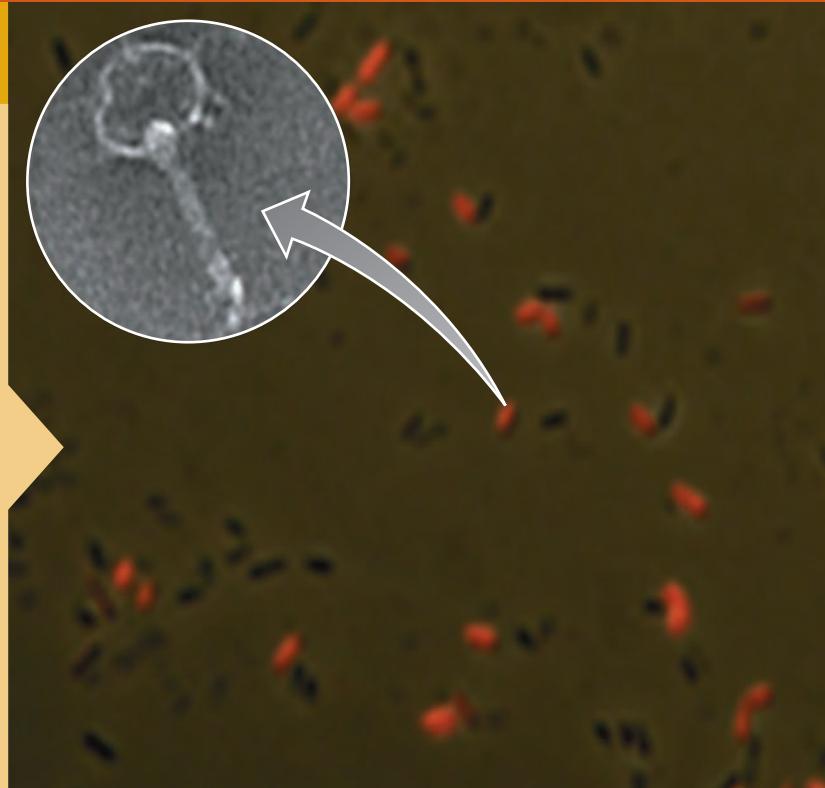

How do *Bacteria* and *Archaea* acquire new and exciting characteristics that translate into the vast diversity of the microbial world? In contrast to eukaryotic organisms, several mechanisms of horizontal gene exchange occur in prokaryotes. This genetic exchange is the foundation for niche adaptation and plays a powerful role in evolution.

One example of this genetic exchange is through *gene transfer agents* (GTAs)—products of an unusual host–virus interaction. GTAs are the result of microbial cells hijacking defective viruses and using them specifically for DNA exchange. GTAs resemble tiny tailed bacteriophages (photo inset) and contain random small pieces of host DNA. They are not considered true viruses because they do not contain genes encoding their own production and do not produce characteristic viral plaques.

GTAs have been isolated from a myriad of prokaryotes including sulfate-reducing *Bacteria* and methanogenic *Archaea* and are particularly prevalent in marine prokaryotes. It is thus likely that GTAs are fairly widespread in nature. Microbial geneticists have determined that a subset of cells of the phototrophic bacterium *Rhodobacter capsulatus* produce and release GTAs during stationary phase and nutrient fluctuations.¹ This was documented by linking the promoter of a gene essential for GTA production to a reporter gene encoding a red fluorescent protein; cells making GTA turned red (photo).

While bacteriophages are considered the most abundant entities on Earth, the number of these that might actually be GTAs instead of viruses is unknown. GTAs may help explain the robust nature of DNA transfer between prokaryotes, especially those inhabiting the oceans. It also posits another question: Do GTAs play a role in the prevalence of other common genetic phenomena, such as bacterial antibiotic resistance?

- I Mutation 292
- II Gene Transfer in *Bacteria* 299
- III Gene Transfer in *Archaea* and Other Genetic Events 309

Numerous examples of microbial diversity are described throughout this book. How does this diversity arise? While prokaryotes reproduce asexually, they also possess mechanisms for exchanging genes. This gene exchange along with genetic innovations that arise from random changes in the genetic blueprint can confer an advantage that ultimately drives genetic diversity.

In this chapter we discuss the mechanisms by which *Bacteria* and *Archaea* can change their genome. We first describe how

alterations arise in the genome, and then we consider how genes can be transferred from one microorganism to another by *horizontal gene transfer*. While bacterial genetics is key for microbial diversity and habitat adaptation, microorganisms also possess mechanisms to maintain genomic stability, and we finish up the chapter by considering these. Taken together, both genomic change and genomic stability are important to the evolution of an organism and its competitive success in nature.

I • Mutation

All organisms contain a specific sequence of nucleotide bases in their genome, their genetic blueprint. A **mutation** is a *heritable* change in the base sequence of that genome, that is, a change that is passed from the mother cell to progeny cells. Mutations can lead to changes—some good, some bad, but mostly neutral in effect—in the properties of an organism. Although the rate of spontaneous mutation is low (Section 10.3), the speed at which many prokaryotes divide and their exponential growth ensure that mutations accumulate surprisingly fast. Whereas mutation usually brings about only a very small amount of genetic change in a cell, genetic recombination typically generates much larger changes. Taken together, mutation and recombination fuel the evolutionary process.

We begin by considering the molecular mechanism of mutation and the properties of mutant microorganisms.

10.1 Mutations and Mutants

In all cells, the genome consists of double-stranded DNA. In viruses, by contrast, the genome may consist of single- or double-stranded DNA or RNA. A strain of any cell or virus carrying a change in nucleotide sequence is called a **mutant**. A mutant by definition differs from its parental strain in its **genotype**, the nucleotide sequence of the genome. In addition, the observable properties of the mutant—its **phenotype**—may also be altered relative to its parent. This altered phenotype is called a *mutant phenotype*. It is common to refer to a strain isolated from nature as a **wild-type strain**. The term “wild-type” may be used to refer to a whole organism or just to the status of a particular gene that is under investigation. Mutant derivatives can be obtained either directly from wild-type strains or from other strains previously derived from the wild type, for example, another mutant.

Genotype versus Phenotype

Depending on the mutation, a mutant strain may or may not differ in phenotype from its parent. By convention in bacterial genetics, the **genotype** of an organism is designated by three lowercase letters followed by a capital letter (all in italics) indicating a particular gene. For example, the *hisC* gene of *Escherichia coli* encodes a protein called HisC that functions in biosynthesis of the amino acid histidine. Mutations in the *hisC* gene would be designated as *hisC1*, *hisC2*, and so on, the numbers referring to the order of isolation of the mutant strains. Each *hisC* mutation would be different, and each *hisC* mutation might affect the HisC protein in different ways.

The **phenotype** of an organism is designated by a capital letter followed by two lowercase letters, with either a plus or minus superscript to indicate the presence or absence of that property. For example, a *His⁺* strain of *E. coli* is capable of making its own histidine, whereas a *His⁻* strain is not. The *His⁻* strain would require a histidine supplement for growth. A mutation in the *hisC* gene will lead to a *His⁻* phenotype if it eliminates the function of the HisC protein.

Isolation of Mutants: Screening versus Selection

Virtually any characteristic of an organism can be changed by mutation. Some mutations are *selectable*, conferring some type of advantage on organisms possessing them, whereas others are nonselectable, even though they may lead to a very clear change in the phenotype of an organism. A selectable mutation confers a clear advantage on the mutant strain under certain environmental conditions, so the progeny of the mutant cell are able to outgrow and replace the parent. A good example of a selectable mutation is drug resistance: An antibiotic-resistant mutant can grow in the presence of an antibiotic that inhibits or kills the parent (Figure 10.1a) and is thus selected under these conditions. It is relatively easy to detect and isolate selectable mutants by choosing the appropriate environmental conditions. **Selection** is therefore an extremely powerful genetic tool, allowing the isolation of a single mutant from a population containing millions or even billions of parental cells.

An example of a nonselectable mutation is color loss in a pigmented organism (Figure 10.1b, c). Nonpigmented cells usually have neither an advantage nor a disadvantage over the pigmented parent cells when grown on agar plates, although pigmented organisms may have a selective advantage in nature. We can detect such mutations only by examining large numbers of colonies and looking for the “different” ones, a process called **screening**.

Isolation of Nutritional Auxotrophs

Although screening is more tedious than selection, methods are available for screening large numbers of colonies for certain types of mutations. For instance, nutritionally defective mutants can be detected by the technique of *replica plating* (Figure 10.2). A colony from a master plate can be transferred onto an agar plate lacking the nutrient by using a sterile loop, toothpick, or even a robotic arm. Parental colonies will grow normally, whereas those of the mutant will not. Thus, the inability of a colony to grow on medium lacking the nutrient signals that it is a mutant. The

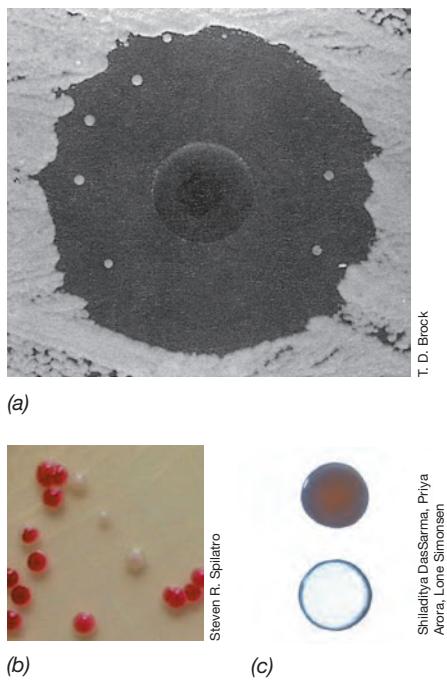

Figure 10.1 Selectable and nonselectable mutations. (a) Development of antibiotic-resistant mutants, a type of easily selectable mutation, within the inhibition zone of an antibiotic assay disc. (b) Nonselectable mutations. UV-radiation-induced nonpigmented mutants of *Serratia marcescens*. The wild type has a dark red pigment. The white or colorless mutants make no pigment. (c) Colonies of mutants of a species of *Halobacterium*, a member of the Archaea. The wild-type colonies are white. The orangish-brown colonies are mutants that lack gas vesicles (Section 2.15). The gas vesicles scatter light and mask the color of the colony.

colony on the master plate corresponding to the vacant spot on the replica plate can then be picked, purified, and characterized. A mutant with a nutritional requirement for growth is called an **auxotroph**, and the parent from which it was derived is called a **prototroph**. (A prototroph may or may not be the wild type. An auxotroph may be derived from the wild type or from a mutant derivative of the wild type.) For instance, mutants of *E. coli* with a His⁻ phenotype are histidine auxotrophs. Examples of common classes of mutants and the means by which they are detected are listed in **Table 10.1**.

MINIQUIZ

- Distinguish between a mutation and a mutant.
- Distinguish between screening and selection.

10.2 Molecular Basis of Mutation

Mutations can be either spontaneous or induced. **Induced mutations** are those that are due to agents in the environment and include mutations made deliberately by humans. They can result from exposure to natural radiation (cosmic rays, and so on) that alters the structure of bases in the DNA. In addition, a variety of chemicals, including oxygen radicals (Section 5.16), can chemically modify DNA. For example, oxygen radicals can convert guanine into 8-hydroxyguanine, and this causes mutations. **Spontaneous mutations** are those that occur without external intervention. The bulk of spontaneous mutations result from occasional errors in the pairing of bases by DNA polymerase during DNA replication.

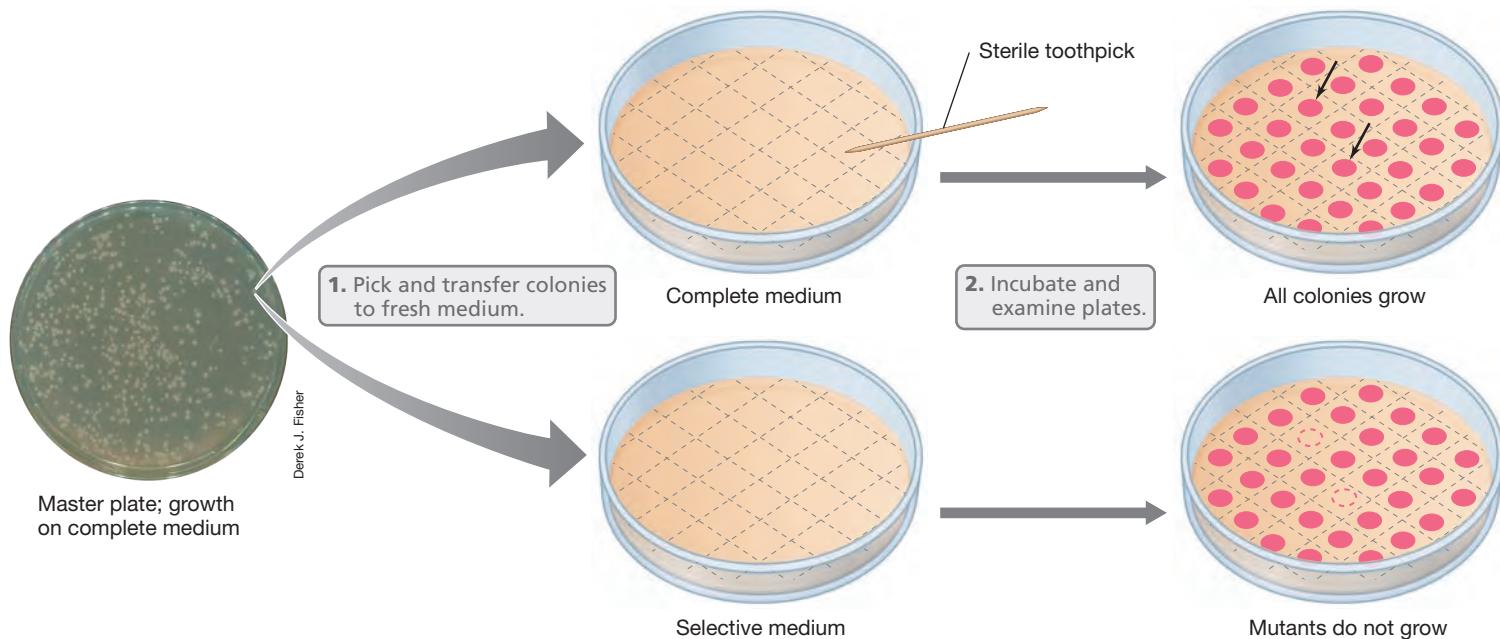

Figure 10.2 Screening for nutritional auxotrophs. The replica-plating method can be used for the detection of nutritional mutants. Colonies from the master plate are transferred to a gridded plate containing different media for selection. The colonies not appearing on the selective medium are indicated with arrows. The selective medium lacked one nutrient (leucine) present in the master plate. Therefore, the colonies indicated with arrows on the master plate are leucine auxotrophs.

Table 10.1 Kinds of mutants

Phenotype	Nature of change	Detection of mutant
Auxotroph	Loss of enzyme in biosynthetic pathway	Inability to grow on medium lacking the nutrient
Temperature-sensitive	Alteration of an essential protein so it is more heat-sensitive	Inability to grow at a high temperature that normally supports growth
Cold-sensitive	Alteration of an essential protein so it is inactivated at low temperature	Inability to grow at a low temperature that normally supports growth
Drug-resistant	Detoxification of drug or alteration of drug target or permeability to drug	Growth on medium containing a normally inhibitory concentration of the drug
Rough colony	Loss or change in lipopolysaccharide layer	Granular, irregular colonies instead of smooth, glistening colonies
Nonencapsulated	Loss or modification of surface capsule	Small, rough colonies instead of larger, smooth colonies
Nonmotile	Loss of flagella or nonfunctional flagella	Compact instead of flat, spreading colonies; lack of motility by microscopy
Pigmentless	Loss of enzyme in biosynthetic pathway leading to loss of one or more pigments	Presence of different color or lack of color
Sugar fermentation	Loss of enzyme in degradative pathway	Lack of color change on agar containing sugar and a pH indicator
Virus-resistant	Loss of virus receptor	Growth in presence of large amounts of virus

Mutations that change only one base pair are called **point mutations**. Point mutations are caused by base-pair substitutions in the DNA or by the loss or gain of a single base pair. Most point mutations do not actually cause any phenotypic change, as discussed below. However, as for all mutations, any phenotypic change that results from a point mutation depends on exactly where the mutation occurs and what type of nucleotide change occurs.

Base-Pair Substitutions

If a point mutation is within the region of a gene that encodes a polypeptide, any change in the phenotype of the cell is most likely the result of a change in the amino acid sequence of the polypeptide. The error in the DNA is transcribed into mRNA, and the erroneous mRNA in turn is translated to yield a polypeptide. **Figure 10.3** shows the consequences of various base-pair substitutions.

In interpreting the results of a mutation, we must first recall that the genetic code is degenerate (➡ Section 4.11 and Table 4.5). Consequently, not all mutations in the base sequence encoding a polypeptide will change the polypeptide. This is illustrated in Figure 10.3, which shows several possible results when the DNA that encodes a single tyrosine codon in a polypeptide is mutated. First, a change in the RNA from UAC to UAU would have no apparent effect because UAU is also a tyrosine codon. Although they do not affect the sequence of the encoded polypeptide, such changes in the DNA are considered one type of **silent mutation**; that is, a mutation that does not affect the phenotype of the cell. Note that silent mutations in coding regions are almost always in the third base of the codon (arginine and leucine can also have silent mutations in the first position).

Changes in the first or second base of the codon more often lead to significant changes in the amino acid sequence of the polypeptide. For instance, a single base change from *UAC* to *AAC* (Figure 10.3) results in an amino acid change within the polypeptide from tyrosine to asparagine at a specific site. This is called a **missense mutation** because the informational “sense” (precise sequence of amino acids) in the polypeptide

has changed. If the change is at a critical location in the polypeptide chain, the protein could be inactive or have reduced activity. However, not all missense mutations necessarily lead to nonfunctional proteins. The outcome depends on where the substitution lies in the polypeptide chain and on how it affects protein folding and activity. For example, mutations in the active site of an enzyme are more likely to destroy activity than mutations in other regions of the protein.

Another possible outcome of a base-pair substitution is the formation of a nonsense (stop) codon. This results in premature

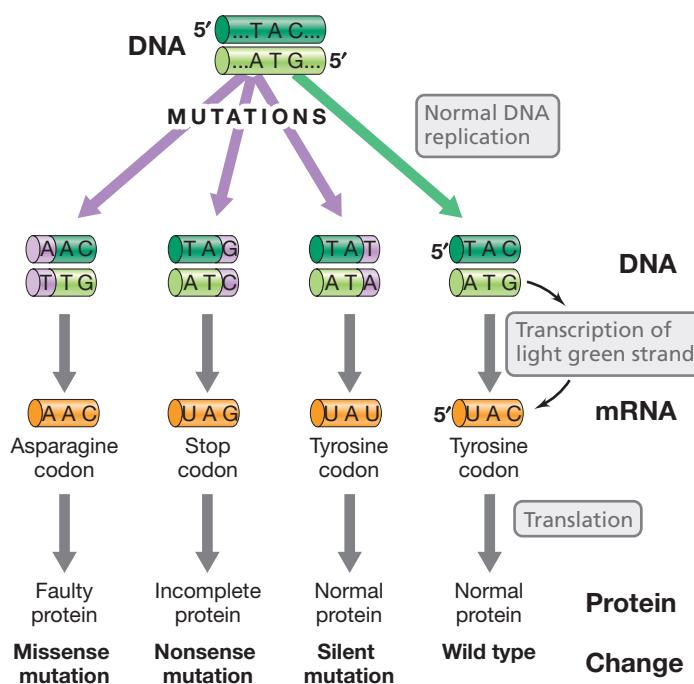

Figure 10.3 Possible effects of base-pair substitution in a gene encoding a protein. Three different protein products are possible from changes in the DNA for a single codon.

termination of translation, leading to an incomplete polypeptide (Figure 10.3). Mutations of this type are called **nonsense mutations** because the change is from a sense (coding) codon to a nonsense codon (➡ Table 4.5). Unless the nonsense mutation is very near the end of the gene, the product is considered *truncated* or incomplete. Truncated proteins are completely inactive or, at the very least, lack normal activity.

Other terms are common in microbial genetics to describe the type of base substitution in a point mutation. **Transitions** are mutations in which one purine base (A or G) is substituted for another purine, or one pyrimidine base (C or T) is substituted for another pyrimidine. **Transversions** are point mutations in which a purine base is substituted for a pyrimidine base, or vice versa.

Frameshifts and Other Insertions or Deletions

Because the genetic code is read from one end of the nucleic acid in consecutive blocks of three bases (codons), any deletion or insertion of a single base pair results in a shift in the reading frame. These **frameshift mutations** often have serious consequences. Single base insertions or deletions change the primary sequence of the encoded polypeptide, typically in a major way (Figure 10.4). Such microinsertions or microdeletions can result from replication errors. Insertion or deletion of two base pairs also causes a frameshift; however, insertion or deletion of three base pairs adds or removes a whole codon. This results in addition or deletion of a single amino acid in the polypeptide sequence. Although this may well be deleterious to protein function, it is usually not as bad as a frameshift, which scrambles the entire polypeptide sequence after the mutation point.

Insertions or deletions can also result in the gain or loss of hundreds or even thousands of base pairs. Such changes inevitably result in complete loss of gene function. Some deletions are so large that they may include several genes. If any of the deleted genes are essential, the mutation will be lethal. Such deletions cannot be restored through further mutations, but only through genetic recombination. Larger insertions and deletions may arise

as a result of errors during genetic recombination. In addition, many large insertion mutations are due to the insertion of specific identifiable DNA sequences called *transposable elements* (Section 10.11). The effect of transposable elements on the evolution of bacterial genomes is discussed further in Section 6.12.

MINIQUIZ

- Do missense mutations occur in genes encoding tRNA? Why or why not?
- Why do frameshift mutations generally have more serious consequences than missense mutations?

10.3 Reversions and Mutation Rates

The rates at which different kinds of mutations occur vary widely. Some types of mutations occur so rarely that they are almost impossible to detect, whereas others occur so frequently that they present difficulties for an experimenter trying to maintain a genetically stable stock culture. Sometimes a second mutation can reverse the effect of an initial mutation. Furthermore, all organisms possess a variety of systems for DNA repair. Consequently, the observed mutation rate depends not only on the frequency of DNA changes but also on the efficiency of DNA repair.

Reversions (Back Mutations)

Point mutations are typically reversible, a process known as **reversion**. A revertant is a strain in which the original phenotype that was changed in the mutant is restored by a second mutation. Revertants can be of two types, same site or second site. In *same-site revertants*, the mutation that restores activity is at the same site as the original mutation. If the back mutation is not only at the same site but also restores the original sequence, it is called a *true revertant*.

In *second-site revertants*, the mutation is at a different site in the DNA. Second-site mutations can restore a wild-type phenotype if they function as *suppressor mutations*—mutations that compensate for the effect of the original mutation. Several classes of suppressor mutations are known. These include (1) a mutation somewhere else in the same gene that restores enzyme function, such as a second frameshift mutation near the first that restores the original reading frame; (2) a mutation in another gene that restores the function of the original mutated gene; and (3) a mutation in another gene that results in the production of an enzyme that can replace the mutated one.

An interesting class of suppressor mutations are those that result in base sequence changes in tRNAs. Nonsense mutations can be suppressed by changing the anticodon sequence of a tRNA molecule so that it now recognizes a stop codon (Figure 10.5). Such an altered tRNA is called a *suppressor tRNA* and will insert the amino acid it carries at the stop codon that it now reads. Suppressor tRNA mutations would be lethal unless a cell has more than one tRNA for a particular codon. One tRNA may then be mutated into a suppressor, while the other performs the original function. Most cells have multiple tRNAs and so suppressor mutations are reasonably common, at least in microorganisms. Sometimes the amino acid inserted by the suppressor tRNA is identical to

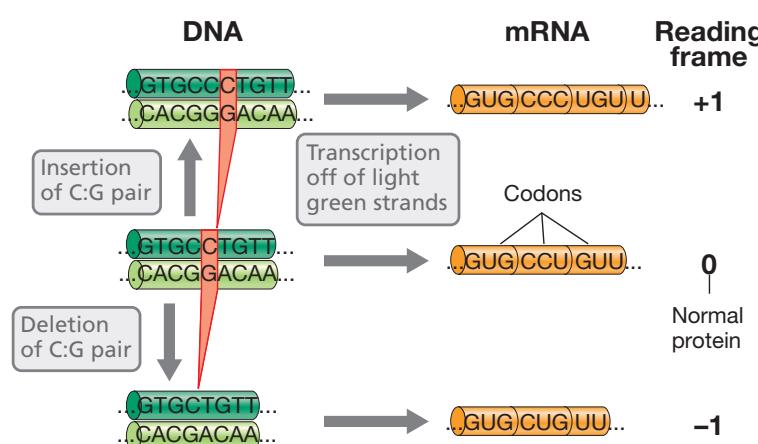

Figure 10.4 Shifts in the reading frame of mRNA caused by insertions or deletions. The reading frame in mRNA is established by the ribosome, which begins at the 5' end (toward the left in the figure) and proceeds by units of three bases (codons). The normal reading frame is referred to as the 0 frame, that missing a base the -1 frame, and that with an extra base the $+1$ frame.

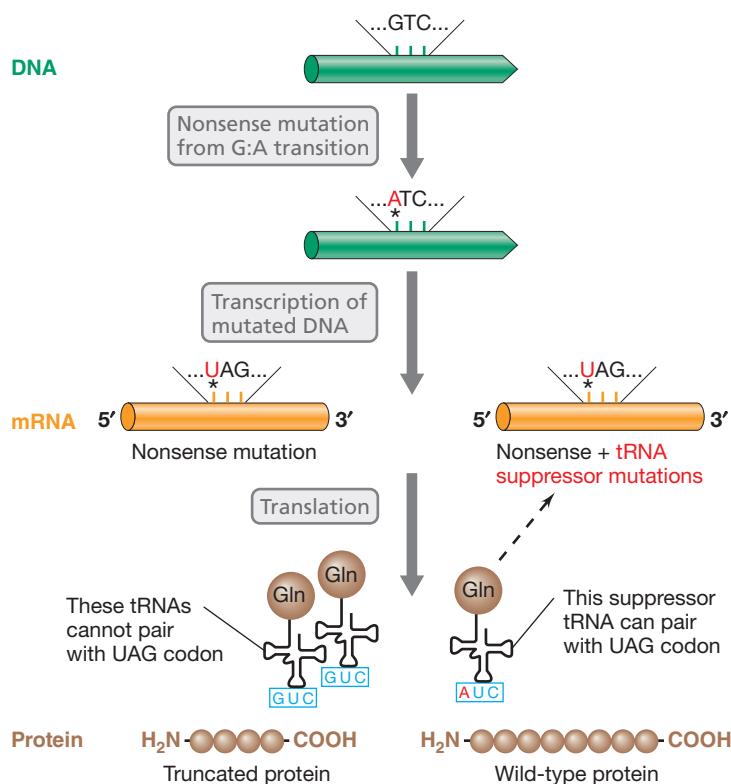

Figure 10.5 Suppression of nonsense mutations. Introduction of a nonsense mutation in a gene encoding a protein results in the incorporation of a stop codon (indicated by the *) in the corresponding mRNA. This single mutation leads to the production of a truncated polypeptide. The mutation is suppressed if a second mutation occurs in the anticodon of a tRNA, a tRNA charged with glutamine in this example, which allows the mutated tRNA or suppressor tRNA to bind to the nonsense codon.

the original amino acid and the protein is fully restored. In other cases, a different amino acid is inserted and a partially active protein may be produced.

The Ames Test

The *Ames test* (named for the biochemist Bruce Ames who developed the test) makes practical use of detecting revertants in large populations of mutant bacteria to test the mutagenicity of potentially hazardous chemicals. A standard way to test chemicals for mutagenesis in the Ames test is to look for an increased rate of back mutations (reversion) in auxotrophic strains of bacteria (**Figure 10.6**). The Ames test assays for *back* mutations instead of *forward* mutations (generating auxotrophs from the wild type) because revertants can be more easily selected.

It is important that the auxotrophic strain used in the Ames test carry a point mutation so that the reversion rate is measurable. Cells of such an auxotroph do not grow on a medium lacking the required nutrient (for example, an amino acid), and even very large populations of cells can be spread on the plate without the formation of visible colonies. However, if revertants (back mutants) are present, those cells form colonies. Thus, if 10^8 cells are spread on the surface of a single plate, even as few as 10–20 revertants can be detected by the 10–20 colonies they form (**Figure 10.6**, left photo). However, if the reversion rate is increased

by the presence of a chemical mutagen, the number of revertant colonies is even greater. After overnight incubation, the mutagenicity of the compound can be detected by looking for a halo of back mutations in the area around the paper disc (**Figure 10.6**).

A wide variety of chemicals have been subjected to the Ames test, and it has become one of the most useful screens for determining the potential mutagenicity of a compound. Since some mutagens can cause cancer in animals, the Ames test doubles as a means of screening for potential carcinogens as well.

Mutation Rates

For most microorganisms, errors in DNA replication occur at a frequency of 10^{-6} to 10^{-7} per thousand bases during a single round of replication. A typical gene has about 1000 base pairs. Therefore, the frequency of a mutation *in a given gene* is also in the range of 10^{-6} to 10^{-7} per round of replication. For instance, in a bacterial culture having 10^8 cells/ml, there are likely to be a number of different mutants for any given gene in each milliliter of culture. Eukaryotes with very large genomes tend to have replication error rates about 10-fold lower than typical bacteria, whereas DNA viruses, especially those with very small genomes, may have error rates 100-fold to 1000-fold higher than those of cellular organisms. RNA viruses have even higher error rates due to less proofreading (☞ Section 4.6) and the lack of RNA repair mechanisms.

Single base errors during DNA replication are more likely to lead to missense mutations than to nonsense mutations because most single base substitutions yield codons that encode other amino acids (☞ Table 4.5). The next most frequent type of codon change caused by a single base change leads to a silent mutation. This is because for the most part alternate codons for a given amino acid differ from each other by a single base change in the “silent” third position. A given codon can be changed to any of 27 other codons by a single base substitution, and on average, about two of these will be silent mutations, about one a nonsense mutation, and the rest will be missense mutations. There are also some DNA sequences, typically sequences containing short repeats,

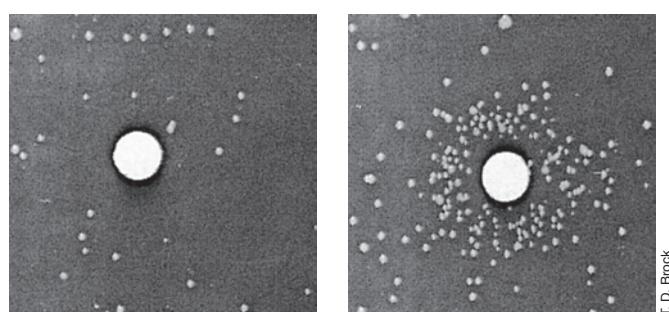

Figure 10.6 The Ames test for assessing the mutagenicity of a chemical. Two plates were inoculated with a culture of a histidine-requiring mutant of *Salmonella enterica*. The medium does not contain histidine, so only cells that revert back to wild type can grow. Spontaneous revertants appear on both plates, but the chemical on the filter-paper disc in the test plate (right) has caused an increase in the mutation rate, as shown by the large number of colonies surrounding the disc. Revertants are not seen very close to the test disc because the concentration of mutagen is lethally high there. The plate on the left was the negative control; its filter-paper disc had only water added.

that are hot spots for mutations because the error frequency of DNA polymerase is relatively high there. The error rate at hot spots is affected by the base sequence in the vicinity.

Unless a mutation can be selected for, its experimental detection is difficult, and much of the skill of the microbial geneticist requires increasing the efficiency of mutation detection. This can most readily be done by increasing the pool of mutations. As we see in the next section, it is possible to greatly increase the mutation rate by treatment with mutagenic agents. In addition, the mutation rate may change in certain situations, such as when cells are placed under high-stress conditions.

MINIQUIZ

- Why does the Ames test measure the rate of reversion rather than the rate of forward mutation?
- Which class of mutation, missense or nonsense, is more common, and why?

10.4 Mutagenesis

The spontaneous rate of mutation is very low, but a variety of chemical, physical, and biological agents can increase the mutation rate and are therefore said to induce mutations. These agents are called **mutagens**. We discuss some of the major categories of mutagens and their activities here.

Chemical Mutagens

An overview of some of the major chemical mutagens and their modes of action is given in **Table 10.2**. Several classes of chemical mutagens exist. The *nucleotide base analogs* are molecules that resemble the purine and pyrimidine bases of DNA in structure yet display faulty pairing properties (**Figure 10.7**). If a base analog is incorporated into DNA in place of the natural base, the DNA may replicate normally most of the time. However, DNA replication errors occur at higher frequencies at these sites due to incorrect base pairing. The result is the incorporation of a mismatched base into the new strand of DNA and thus introduction of a mutation. During subsequent segregation of this strand in cell division, the mutation is revealed.

Other chemical mutagens induce *chemical modifications* in one base or another, resulting in faulty base pairing or related changes (Table 10.2). For example, alkylating agents (chemicals that react with amino, carboxyl, and hydroxyl groups by substituting them with alkyl groups) such as nitrosoguanidine are powerful mutagens and generally induce mutations at higher frequency than base analogs. Unlike base analogs, which have an effect only when incorporated during DNA replication, alkylating agents can introduce changes even in nonreplicating DNA. Both base analogs and alkylating agents tend to induce base-pair substitutions (Section 10.2).

Another group of chemical mutagens, the acridines, are planar molecules that function as *intercalating agents*. These mutagens become inserted between two DNA base pairs and push them apart. During replication, this abnormal conformation can lead to single base insertions or deletions in acridine-containing DNA. Thus, acridines typically induce frameshift mutations (Section 10.2).

Table 10.2 Chemical and physical mutagens and their modes of action

Agent	Action	Result
<i>Base analogs</i>		
5-Bromouracil	Incorporated like T; occasional faulty pairing with G	AT GC and occasionally GC AT
2-Aminopurine	Incorporated like A; faulty pairing with C	AT GC and occasionally GC AT
<i>Chemicals reacting with DNA</i>		
Nitrous acid (HNO_2)	Deaminates A and C	AT GC and GC AT
Hydroxylamine (NH_2OH)	Reacts with C	GC AT
<i>Alkylating agents</i>		
Monofunctional (for example, ethyl methanesulfonate)	Puts methyl on G; faulty pairing with T	GC AT
Bifunctional (for example, mitomycin, nitrogen mustards, nitrosoguanidine)	Cross-links DNA strands; faulty region excised by DNase	Both point mutations and deletions
<i>Intercalating agents</i>		
Acridines, ethidium bromide	Inserts between two base pairs	Microinsertions and microdeletions
<i>Radiation</i>		
Ultraviolet (UV)	Pyrimidine dimer formation	Repair may lead to error or deletion
Ionizing radiation (for example, X-rays)	Free-radical attack on DNA, breaking chain	Repair may lead to error or deletion

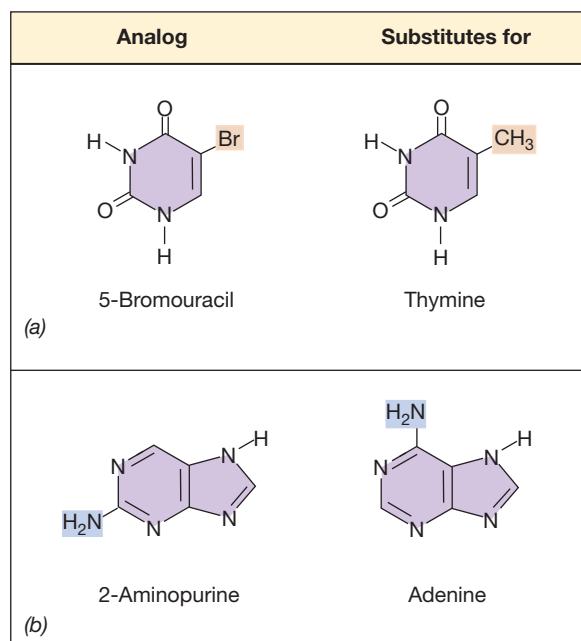

Figure 10.7 Nucleotide base analogs. Structure of two common nucleotide base analogs used to induce mutations and the normal nucleic acid bases for which they substitute. (a) 5-Bromouracil can base-pair with guanine, causing AT to GC substitutions. (b) 2-Aminopurine can base-pair with cytosine, causing AT to GC substitutions.

Ethidium bromide, which is often used to detect DNA in gel electrophoresis, is also an intercalating agent and therefore a mutagen.

Radiation

Several forms of radiation are highly mutagenic. We can divide mutagenic electromagnetic radiation into two main categories, *nonionizing* and *ionizing* (Figure 10.8). Although both kinds of radiation are used to generate mutations, nonionizing radiation such as ultraviolet (UV) radiation has the widest use.

The purine and pyrimidine bases of nucleic acids absorb UV radiation strongly, and the absorption maximum for DNA and RNA is at 260 nm. Killing of cells by UV radiation is due primarily to its effect on DNA. Although several effects are known, one well-established effect is the production of *pyrimidine dimers*, in which two adjacent pyrimidine bases (cytosine or thymine) on the same strand of DNA become covalently bonded to one another. This either greatly impedes DNA polymerase activity or greatly increases the probability of DNA polymerase misreading the sequence at this point.

Ionizing radiation is more powerful than UV radiation and includes short-wavelength radiation such as X-rays, cosmic rays, and gamma rays (Figure 10.8). These rays cause water and other substances to ionize, resulting in the formation of free radicals such as the hydroxyl radical, OH (➡ Section 5.16). Free radicals react with and damage macromolecules in the cell, including DNA. This causes double-stranded and single-stranded breaks that may lead to rearrangements or large deletions. At low doses of ionizing radiation only a few “hits” on DNA occur, but at higher doses, multiple hits cause fragmentation of DNA that sometimes cannot be repaired and thus leads to the death of the cell.

DNA Repair and the SOS System

By definition, a mutation is a *heritable* change in the genetic material. Therefore, if damaged DNA can be corrected before the

cell divides, no mutation will occur. Cells have a variety of different DNA repair processes to correct mistakes or repair damage. While most of these DNA repair systems are virtually error-free, some are error-prone and the repair process itself introduces the mutation. Some types of DNA damage, especially large-scale damage from highly mutagenic chemicals or large doses of radiation, may cause lesions that interfere with replication. If such lesions are not removed before replication occurs, DNA replication will stall and lethal breaks in the chromosome will result. Stalled replication as well as certain types of major DNA damage activate the **SOS repair system**. The SOS system initiates a number of DNA repair processes, some of which are error-free. However, the SOS system also allows DNA repair to occur without a template, that is, with random incorporation of dNTPs. As might be expected, this results in many errors and hence many mutations. However, mutations may be less detrimental to cell survival than breaks in the chromosome, as mutations can often be corrected while chromosome breaks usually cannot.

In *Escherichia coli* the SOS repair system regulates the transcription of approximately 40 genes located throughout the chromosome that participate in DNA damage tolerance and DNA repair. In DNA damage tolerance, DNA lesions remain in the DNA, but are bypassed by specialized DNA polymerases that can move past DNA damage—a process known as translesion synthesis. Even if no template is available to allow insertion of the correct bases, it is less dangerous to cell survival to fill the gap than to let it remain. Consequently, translesion synthesis generates many errors. In *E. coli*, in which the process of mutagenesis has been studied in great detail, the two error-prone repair polymerases are DNA polymerase V, an enzyme encoded by the *umuCD* genes (Figure 10.9), and DNA polymerase IV, encoded by *dinB*. Both are induced as part of the SOS repair system.

The SOS system is regulated by two proteins, LexA and RecA. LexA is a repressor that normally prevents expression of the SOS system. The RecA protein, which normally functions in genetic recombination (Section 10.5), is activated by the presence of DNA damage, in particular by the single-stranded DNA that results when replication stalls (Figure 10.9). The activated form of RecA stimulates LexA to inactivate itself by self-cleavage. This leads to derepression of the SOS system and results in the coordinate expression of a number of proteins that take part in DNA repair. Because some of the DNA repair mechanisms of the SOS system are inherently error-prone, many mutations arise. Once the original DNA damage has been repaired, the SOS regulon is repressed and further mutagenesis ceases.

Changes in Mutation Rate and Their Evolutionary Consequence

High fidelity (low error frequency) in DNA replication is essential if organisms are to remain genetically stable. On the other hand, perfect fidelity is counterproductive because it would prevent evolution. The fact that organisms as phylogenetically distant as *Archaea* and *Bacteria* have about the same mutation rate might suggest that evolutionary pressure has selected organisms with the lowest possible mutation rates. However, this is not so. For example, mutants of some organisms that are hyperaccurate in DNA replication and repair have been selected in the laboratory.

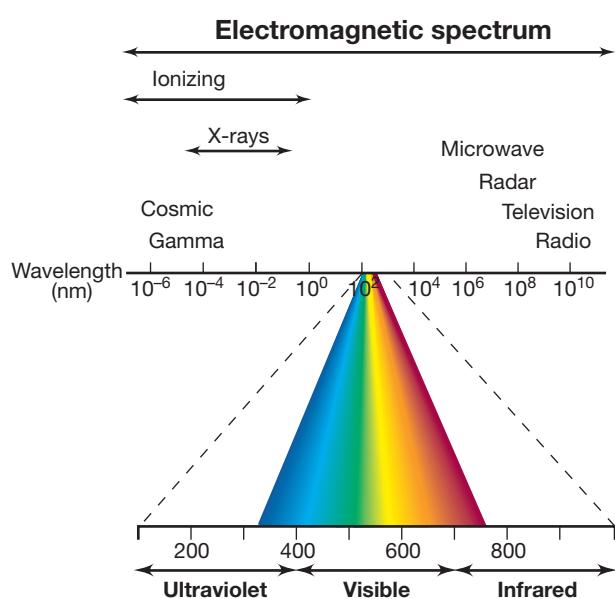

Figure 10.8 Wavelengths of radiation. Ultraviolet radiation consists of wavelengths just shorter than visible light. For any electromagnetic radiation, the shorter the wavelength, the higher the energy. DNA absorbs strongly at 260 nm.

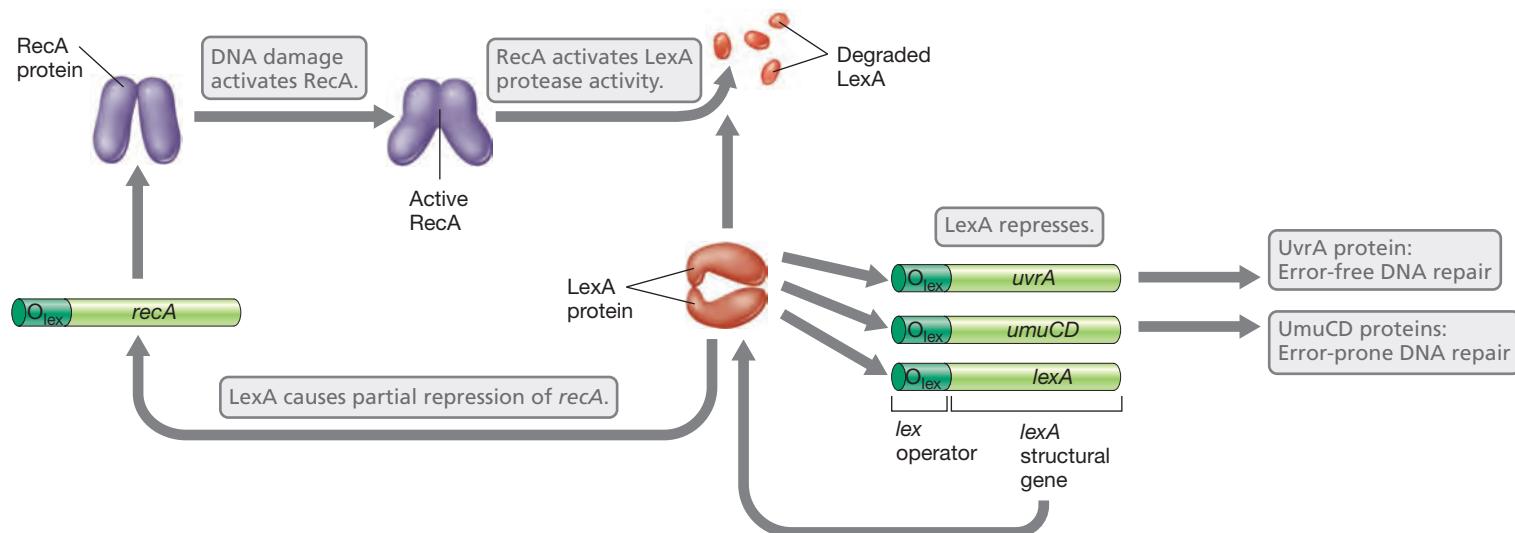

Figure 10.9 Mechanism of the SOS response. DNA damage activates RecA protein, which in turn activates the protease activity of LexA. The LexA protein then cleaves itself. LexA protein normally represses the activities of the *recA* gene and the DNA repair genes *uvrA* and *umuCD* (the UmuCD proteins are part of DNA polymerase V). However, repression is not complete. Some RecA protein is produced even in the presence of LexA protein. With LexA inactivated, these genes become highly active.

However, in these strains, the improved proofreading and repair mechanisms result in slower growth; thus, hyperaccurate mutants might well be at a disadvantage in the natural environment.

In contrast to hyperaccuracy, some organisms actually benefit from an increased mutation rate. DNA repair systems are themselves genetically encoded and thus subject to mutation. For example, the protein subunit of DNA polymerase III required for proofreading (Section 4.6) is encoded by *dnaQ*. Certain mutations in *dnaQ* lead to mutants that are still viable but have an increased rate of mutation. These are known as **hypermutable** or **mutator strains**. Mutations leading to a mutator phenotype are known in several other DNA repair systems as well. The mutator phenotype is apparently selected for in complex and changing environments because strains of bacteria with mutator phenotypes appear to be more abundant under these conditions. Presumably, whatever disadvantage an increased mutation rate may have in such environments is offset by the ability to generate greater numbers of

useful mutations. These mutations ultimately increase evolutionary fitness of the population and make the organism more successful in its ecological niche.

As indicated earlier, a mutator phenotype may be induced in wild-type strains by stressful situations. For instance, the SOS repair system includes error-prone repair. Therefore, when the SOS repair system is activated, the mutation rate increases. In some cases this is merely an inevitable by-product of DNA repair, but in other cases, the increased mutation rate may itself be of selective value to the organism for survival purposes.

- Why might a mutator phenotype be successful in an environment experiencing rapid changes?
- What is meant by “error-prone” DNA repair?

II • Gene Transfer in Bacteria

Comparative genomic analyses of closely related microorganisms that exhibit different phenotypes have revealed distinct genome differences. Often these idiosyncratic differences result from *horizontal gene transfer*, the movement of genes between cells that are not direct descendants of one another (Section 6.12). Horizontal gene transfer allows cells to quickly acquire new characteristics and drives metabolic diversity.

Three mechanisms of genetic exchange are known in prokaryotes: (1) *transformation*, in which free DNA released from one cell is taken up by another (Section 10.6); (2) *transduction*, in which DNA transfer is mediated by a virus (Section 10.7); and (3) *conjugation*, in which DNA transfer requires cell-to-cell contact

and a conjugative plasmid in the donor cell (Sections 10.8 and 10.9). These processes are contrasted in Figure 10.10, and it should be noted that DNA transfer typically occurs in only one direction, from donor to recipient.

Before discussing the mechanisms of transfer, we consider the fate of transferred DNA. Whether it is transferred by transformation, transduction, or conjugation, DNA that enters the cell by horizontal gene transfer faces three possible fates: (1) It may be degraded by restriction enzymes; (2) it may replicate by itself (but only if it possesses its own origin of replication, such as a plasmid or phage genome); or (3) it may recombine with the host chromosome.

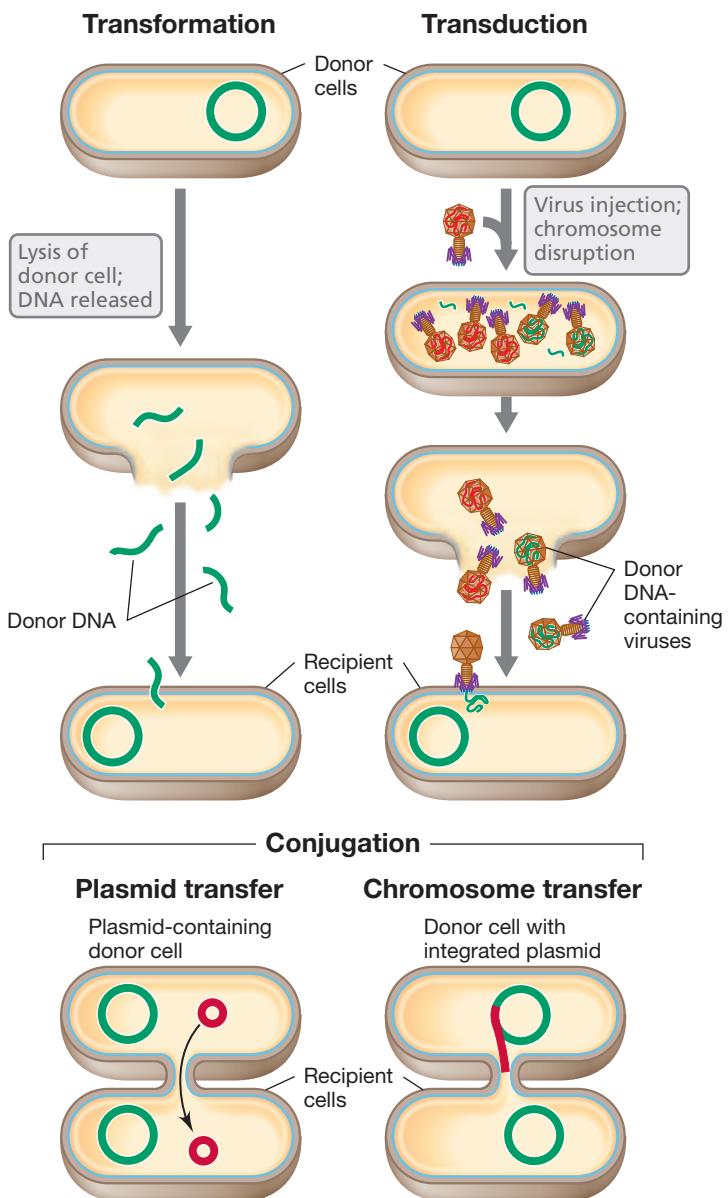

Figure 10.10 Processes by which DNA is transferred from donor to recipient bacterial cell. Just the initial steps in transfer are shown.

10.5 Genetic Recombination

Recombination is the physical exchange of DNA between *genetic elements* (structures that carry genetic information). In this section we focus on *homologous recombination*, a process that results in genetic exchange between homologous DNA sequences from two different sources. Homologous DNA sequences are those that have nearly the same sequence; therefore, bases can pair over an extended length of the two DNA molecules. This type of recombination drives the process of “crossing over” in classical genetics.

Molecular Events in Homologous Recombination

The RecA protein, previously mentioned in regard to the SOS repair system (Section 10.4 and Figure 10.9), is the key to homologous recombination. RecA is essential in nearly every homologous

recombination pathway. RecA-like proteins have been identified in all bacteria examined, as well as in the *Archaea* and most *Eukarya*.

A molecular mechanism for homologous recombination between two DNA molecules is shown in Figure 10.11. An enzyme that cuts DNA in the middle of a strand, called an *endonuclease*, begins the process by nicking one strand of the donor DNA molecule. This nicked strand is separated from the other strand by proteins with helicase activity (➡ Section 4.5). The resulting single-stranded segment binds single-strand binding protein (➡ Section 4.5) and then RecA. This results in a complex that promotes base pairing with the complementary sequence in the recipient DNA molecule. This base pairing in turn displaces the other strand of the recipient DNA molecule (Figure 10.11) and is appropriately called *strand invasion*.

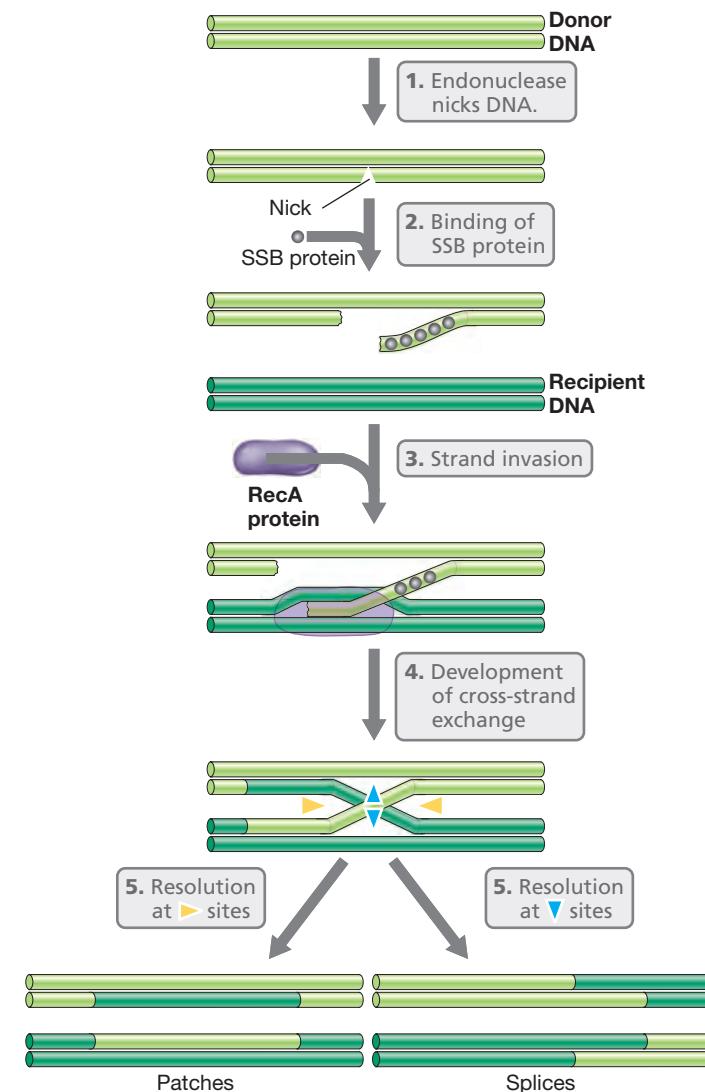

Figure 10.11 A simplified version of homologous recombination.

Homologous DNA molecules pair and exchange DNA segments. The mechanism requires breakage and reunion of paired segments. Two of the participating proteins, single-strand binding (SSB) protein and the RecA protein, are shown. The other participating proteins are not shown. The diagram is not to scale: Pairing may occur over hundreds or thousands of bases. Resolution occurs by cutting and rejoining the cross-linked DNA molecules. Note that there are two possible outcomes, patches or splices, depending on where strands are cut during the resolution process.

The base pairing of one strand from each of the two DNA molecules over long stretches generates recombination intermediates containing long **heteroduplex** regions, where each strand has originated from a different chromosome. Finally the linked molecules are separated (resolved) by resolvase enzymes that cut and rejoin the previously unbroken strands of both original DNA molecules. Depending on the orientation of the junction during resolution, two types of products, referred to as “patches” or “splices,” are formed that differ in the conformation of the heteroduplex regions remaining after resolution (Figure 10.11).

Effect of Homologous Recombination on Genotype

For homologous recombination to generate new genotypes, the two homologous sequences must be related but genetically distinct. This is obviously the case in a diploid eukaryotic cell, which has two sets of chromosomes, one from each parent. In prokaryotes, genetically distinct but homologous DNA molecules are brought together in different ways. Genetic recombination in prokaryotes occurs after fragments of homologous DNA from a donor chromosome are transferred to a recipient cell by transformation, transduction, or conjugation. It is only after the transfer event, when the DNA fragment from the donor is in the recipient cell, that homologous recombination occurs. In prokaryotes, only part of a chromosome is transferred; therefore, if recombination does not occur, the DNA fragment will be lost because it cannot replicate independently. Thus, in prokaryotes, transfer is just the first step in generating recombinant organisms.

To detect physical exchange of DNA segments, the cells resulting from recombination must be phenotypically different from both parents (Figure 10.12). Genetic crosses in bacteria usually depend on using recipient strains that lack some selectable character that the recombinants will gain. For instance, the recipient may be unable to grow on a particular medium, and genetic recombinants are selected that can. Various kinds of selectable markers, such as drug resistance and nutritional requirements,

were discussed in Section 10.1. The exceedingly great sensitivity of the selection process allows even a few recombinant cells to be detected in a large population of nonrecombinant cells and thus selection is an important tool for the microbial geneticist.

Complementation

In all three methods of bacterial gene transfer, only a portion of the donor chromosome enters the recipient cell. Therefore, unless recombination takes place with the recipient chromosome, the donor DNA will be lost because it cannot replicate independently in the recipient. Nonetheless, it is possible to stably maintain a state of partial diploidy for use in bacterial genetic analysis. A bacterial strain that carries *two copies* of any particular chromosomal segment is known as a partial diploid, or *merodiploid*. In general, one copy is present on the chromosome itself and the second copy on another genetic element, such as a plasmid or a bacteriophage.

Consequently, if the chromosomal copy of a gene is defective due to a mutation, it is possible to supply a functional (wild-type) copy of the gene on a plasmid or phage. For example, if one of the genes for biosynthesis of the amino acid tryptophan has a mutation resulting in a nonfunctional enzyme, this will give a Trp^- phenotype. That is, the mutant strain will be a tryptophan auxotroph and will require tryptophan for growth. However, if a copy of the wild-type gene is introduced into the same cell on a plasmid or viral genome, this gene will encode the necessary protein and restore the wild-type phenotype. This process is called *complementation* because the wild-type gene is said to *complement* the mutation, in this case converting the Trp^- cell into Trp^+ (Figure 10.12).

- Explain the fate of transferred chromosomal DNA if recombination does not occur in prokaryotes.
- What is a merodiploid?

10.6 Transformation

Transformation is a genetic transfer process by which *free DNA* is incorporated into a recipient cell and brings about genetic change. Several prokaryotes are naturally transformable, including certain species of both gram-negative and gram-positive *Bacteria* and also some species of *Archaea* (Section 10.10). Because the DNA of prokaryotes is present in the cell as a large single molecule, when a cell is gently lysed, its DNA pours out. Bacterial chromosomes break easily because of their extreme length (1700 μm in *Bacillus subtilis*, for example). Even after gentle extraction, the *B. subtilis* chromosome of 4.2 megabase pairs is converted to fragments of about 10 kilobase pairs each. Because the DNA that corresponds to an average gene is about 1000 nucleotides, each of the fragments of *B. subtilis* DNA contains about ten genes. This is a typical transformable size. A single cell usually incorporates only one or a few DNA fragments, so only a small proportion of the genes of one cell can be transferred to another in a single transformation event.

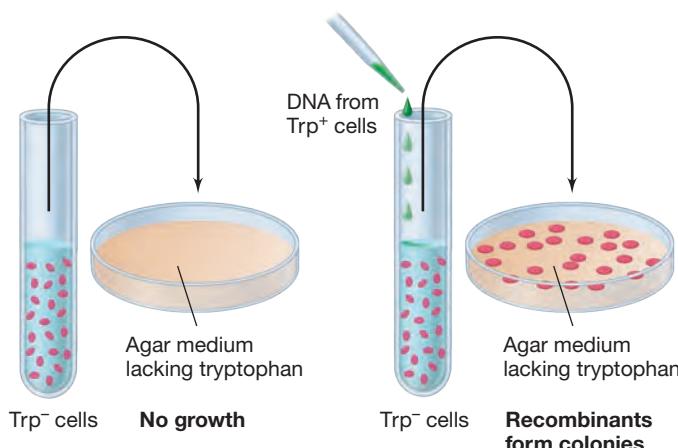

Figure 10.12 Using a selective medium to detect rare genetic recombinants.

On the selective medium only the rare recombinants form colonies even though a very large population of bacteria was plated. Procedures such as this, which offer high resolution for genetic analyses, can ordinarily be used only with microorganisms. The type of genetic exchange being illustrated is transformation, but a similar outcome could result from any of the other forms of horizontal gene transfer.

Competence in Transformation

A cell that is able to take up DNA and be transformed is said to be *competent*, and this capacity is genetically determined. Competence in most naturally transformable bacteria is regulated, and special proteins play a role in the uptake and processing of DNA. These competence-specific proteins include a membrane-associated DNA-binding protein, a cell wall autolysin, and various nucleases. One pathway of natural competence in *B. subtilis*—an easily transformed species—is regulated by quorum sensing, a regulatory system that responds to cell density (Section 7.9). Cells produce and excrete a small peptide during growth, and the accumulation of this peptide to high concentrations induces the cells to become competent. But not all cells become competent. In *Bacillus*, roughly 20% of the cells in a culture become competent and stay that way for several hours. However, in *Streptococcus*, 100% of the cells can become competent, but only for a brief period during the growth cycle.

High-efficiency, natural transformation is rare among *Bacteria*. For example, *Acinetobacter*, *Bacillus*, *Streptococcus*, *Haemophilus*, *Neisseria*, and *Thermus* are naturally competent and easy to transform. By contrast, many *Bacteria* are poorly transformed, if at all, under natural conditions. For example, *Escherichia coli* and many other gram-negative bacteria fall into this category. However, if cells of *E. coli* are treated with high concentrations of Ca^{2+} and then chilled, they become adequately competent. Cells treated in this manner take up double-stranded DNA, and therefore transformation of *E. coli* by plasmid DNA can be relatively efficient. This is important because getting DNA into *E. coli*—the workhorse of genetic engineering—is critical for biotechnology, as we will see in Chapter 11.

Electroporation is a physical technique that is used to get DNA into organisms that are difficult to transform, especially those with thick cell walls. In electroporation, cells are mixed with DNA and then exposed to brief high-voltage electrical pulses. This makes the cell envelope permeable and allows entry of the DNA. Electroporation is a quick process and works for most types of cells, including *E. coli*, most other *Bacteria*, some members of the *Archaea*, and even yeast and certain plant cells.

Uptake of DNA in Transformation

During natural transformation, competent bacteria reversibly bind DNA. Soon, however, the binding becomes irreversible. Competent cells bind much more DNA than do noncompetent cells—as much as 1000 times more. As noted earlier, the sizes of the transforming fragments are much smaller than that of the whole genome, and the fragments are further degraded during the uptake process. In *Streptococcus pneumoniae* each cell can bind only about ten molecules of double-stranded DNA of 10–15 kbp each. However, as these fragments are taken up, they are converted into single-stranded pieces of about 8 kb, with the complementary strand being degraded. The DNA fragments in the mixture compete with each other for uptake and thus the probability of a transformant taking up DNA that confers an advantage or a selectable marker decreases.

Interestingly, transformation in *Haemophilus influenzae* requires the DNA fragment to have a particular 11-bp sequence for irreversible binding and uptake to occur. This sequence is found at an unexpectedly high frequency in the *Haemophilus* genome. Evidence such as this, and the fact that certain bacteria become competent in their natural environment, suggests that transformation is not a laboratory artifact but plays an important role in horizontal gene transfer in nature. By promoting new combinations of genes, naturally transformable bacteria increase the diversity and fitness of the microbial community as a whole.

Integration of Transforming DNA

During transformation, transforming DNA is bound at the cell surface by a DNA-binding protein (Figure 10.13). Next, either the entire double-stranded fragment is taken up, or a nuclease degrades one strand and the remaining strand is taken up, depending on the organism. After uptake, the DNA is bound by a competence-specific protein. This protects the DNA from nuclease attack until it reaches the chromosome, where the RecA protein takes over. The DNA is integrated into the genome of the recipient by recombination (Figures 10.13 and 10.11). If single-stranded DNA is integrated, a heteroduplex DNA is formed. During the next round of chromosomal replication, one parental

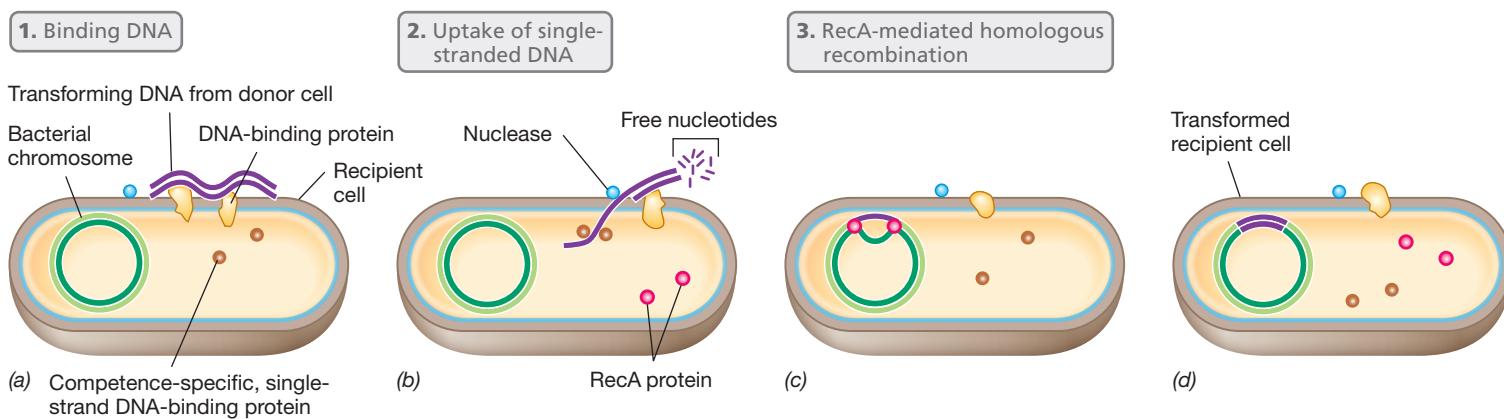

Figure 10.13 Mechanism of transformation in a gram-positive bacterium. (a) Binding of double-stranded DNA by a membrane-bound DNA-binding protein. (b) Passage of one of the two strands into the cell while nuclease activity degrades the other strand. (c) The single strand in the cell is bound by specific proteins, and recombination with homologous regions of the bacterial chromosome is mediated by RecA protein. (d) Transformed cell.

and one recombinant DNA molecule are generated. On segregation at cell division, the recombinant molecule is present in the transformed cell, which is now genetically altered compared to its parent. The preceding applies only to small pieces of linear DNA. Many naturally transformable *Bacteria* are transformed only poorly by plasmid DNA because the plasmid must remain double-stranded and circular in order to replicate.

MINIQUIZ

- During transformation a cell usually incorporates only one or a few fragments of DNA. Explain.
- Even in naturally transformable cells, competence is usually inducible. What does this mean?

10.7 Transduction

In **transduction**, a bacterial virus (bacteriophage) transfers DNA from one cell to another. Viruses can transfer host genes in two ways. In the first, called *generalized transduction*, DNA derived from virtually any portion of the host genome is packaged inside the mature virion in place of the virus genome. In the second, called *specialized transduction*, DNA from a specific region of the host chromosome is integrated directly into the virus genome—usually replacing some of the virus genes. This occurs only with certain temperate viruses such as phage lambda (► Section 8.8).

In generalized transduction, the bacterial donor genes cannot replicate independently and are not part of a viral genome. Thus, unless the donor genes recombine with the recipient bacterial chromosome, they will be lost. In specialized transduction, homologous recombination may also occur. However, since the donor bacterial DNA is actually a part of a temperate phage genome, it may be integrated into the host chromosome during lysogeny (► Section 8.8).

Transduction occurs in a variety of *Bacteria*, including the genera *Desulfovibrio*, *Escherichia*, *Pseudomonas*, *Rhodococcus*,

Rhodobacter, *Salmonella*, *Staphylococcus*, and *Xanthobacter*, as well as *Methanothermobacter thermotrophicus*, a species of *Archaea*. Not all phages can transduce, and not all bacteria are transducible, but with bacteriophage abundance estimated to outnumber prokaryotic cells by 10-fold in nature, the phenomenon plays an important role in gene transfer in the environment. Examples of genes transferred by transducing bacteriophages include multiple antibiotic resistance genes among strains of *Salmonella enterica* serovar Typhimurium, Shiga-like toxin genes in *Escherichia coli*, virulence factors in *Vibrio cholerae*, and genes encoding photosynthetic proteins in cyanobacteria.

While transduction plays a role in horizontal transfer of DNA in nature, microbial geneticists use both generalized and specialized transducing bacteriophages to deliver DNA to target bacterial cells. Transduction can be used to deliver DNA to strains in which transformation and conjugation are not efficient. Bacteriophages can also be used to deliver large pieces of DNA to host cells. A typical tailed phage that contains double-stranded DNA can package up to 40 kilobase pairs of DNA. The bacteriophages used for transduction in the laboratory are usually nonlytic because bacterial genes have replaced all or some necessary viral genes. To select for a transduction event, a transducing phage must infect a donor host that has a selectable marker.

Generalized Transduction

In generalized transduction, virtually any gene on the donor chromosome can be transferred to the recipient, forming a *transductant*. Generalized transduction was first discovered and extensively studied in the bacterium *Salmonella enterica* with phage P22 and has also been studied with phage P1 in *Escherichia coli*. An example of how transducing particles are formed is given in Figure 10.14. When a bacterial cell is infected with a phage, the lytic cycle may occur. However, during lytic infection, the enzymes responsible for packaging viral DNA into the bacteriophage sometimes package host DNA accidentally. The result is called a *transducing particle*. These cannot lead to a viral infection because they contain no viral

Lytic cycle

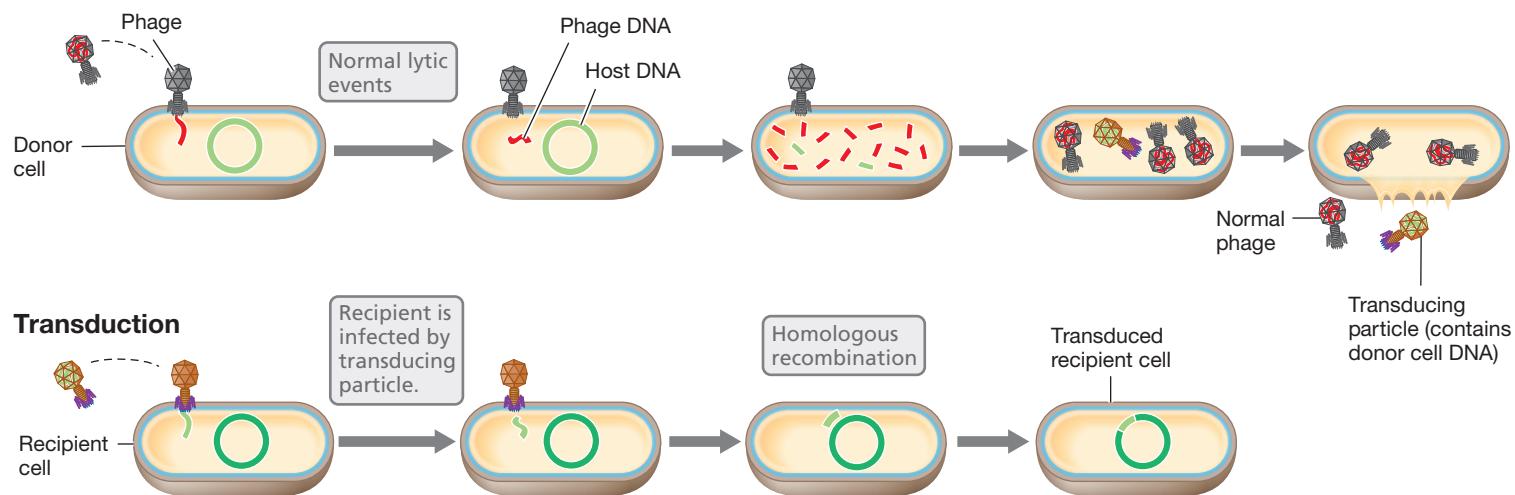

Figure 10.14 Generalized transduction. Note that “normal” virions contain phage genes, whereas a transducing particle contains host genes.

DNA, and are said to be *defective*. On lysis of the cell, the transducing particles are released along with normal virions that contain the virus genome. Consequently, the lysate contains a mixture of normal virions and transducing particles.

When this lysate is used to infect a population of recipient cells, most of the cells are infected with normal virus. However, a small proportion of the population receives transducing particles that inject the DNA they packaged from the previous host bacterium. Although this DNA cannot replicate, it can recombine with the DNA (Section 10.5) of the new host. Because only a small proportion of the particles in the lysate are defective, and each of these contains only a small fragment of donor DNA, the probability of a given transducing particle containing a particular gene is quite low. Typically, only about 1 cell in 10^6 to 10^8 is transduced for a given gene.

Lysogeny and Specialized Transduction

Generalized transduction allows the transfer of any gene from one bacterium to another, but at a low frequency. In contrast, specialized transduction allows extremely efficient transfer, but is selective and transfers only a small region of the bacterial chromosome. In the first case of specialized transduction to be discovered, genes for galactose catabolism were transduced by the temperate phage lambda of *E. coli*.

When lambda lysogenizes a host cell, the phage genome is integrated into the *E. coli* chromosome at a specific site (➡ Section 8.8). This site is next to the cluster of genes that encode the enzymes for galactose utilization. After insertion, viral DNA replication is under control of the bacterial host chromosome. Upon induction, the viral DNA separates from the host DNA by a process that is the reverse of integration (Figure 10.15). Usually the lambda DNA is excised precisely, but occasionally the phage genome is excised incorrectly. Some of the adjacent bacterial genes to one side of the prophage (for example, the galactose operon) are excised along with phage DNA. At the same time, some phage genes are left behind (Figure 10.15b). This transducing particle can subsequently transfer genes for galactose utilization to a recipient cell. This transfer can only be detected if a galactose-negative (Gal^-) strain is infected with such a transducing particle and Gal^+ transductants are selected.

For a lambda virion to be infectious, there is a limit to the amount of phage DNA that can be replaced with host DNA. Sufficient phage DNA must be retained to encode the phage protein coat and other phage proteins needed for lysis and lysogeny. However, if a helper phage is used together with a defective phage in a mixed infection, then far fewer phage-specific genes are needed in the defective phage. Only the *att* (attachment) region, the *cos* site (cohesive ends, for packaging), and the replication origin of the lambda genome (➡ Figure 8.17a) are necessary.

Phage Conversion

Alteration of the phenotype of a host cell by lysogenization is called *phage conversion*. When a normal (that is, nondefective) temperate phage lysogenizes a cell and becomes a prophage, the cell becomes immune to further infection by the same type of phage. Such immunity may itself be regarded as a change in phenotype. However, other phenotypic changes unrelated to phage immunity are often observed in phage conversion of lysogenized cells.

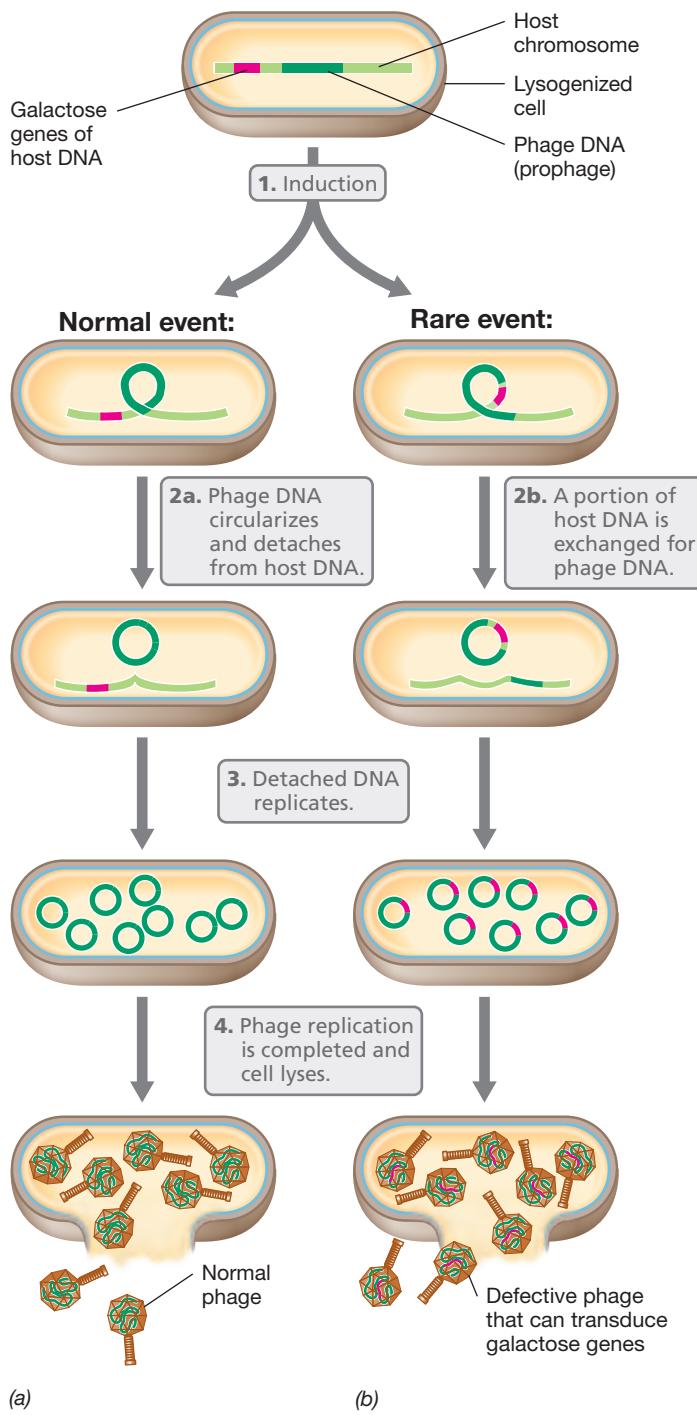

Figure 10.15 Specialized transduction. In an *Escherichia coli* cell containing a lambda prophage, (a) normal lytic events and (b) the production of particles transducing the galactose genes. Only a short region of the circular host chromosome is shown in the figure.

Two cases of phage conversion have been especially well studied. One results in a change in structure of a polysaccharide on the cell surface of *Salmonella enterica* serovar Anatum on lysogenization with bacteriophage ϵ^{15} . The second results in the conversion of non-toxin-producing strains of *Corynebacterium diphtheriae* (the bacterium that causes the disease diphtheria) to toxin-producing (pathogenic) strains following lysogeny

with bacteriophage β (Section 29.3). In both cases, the genes responsible for the changes are an integral part of the phage genome and hence are automatically transferred to the cell upon infection by the phage and lysogenization.

Lysogeny likely carries strong selective value for the host cell because it confers resistance to infection by viruses of the same type. Phage conversion may also be of considerable evolutionary significance because it results in genetic alteration of host cells. Many bacteria isolated from nature are natural lysogens, and thus it is likely that lysogeny is essential for survival of many host cells in nature.

MINIQUIZ

- How does a transducing particle differ from an infectious bacteriophage?
- What is the major difference between generalized transduction and transformation?
- Why is phage conversion considered beneficial to host cells?

10.8 Conjugation

Bacterial **conjugation** (mating) is a form of horizontal gene transfer that requires cell-to-cell contact. Conjugation is a plasmid-encoded mechanism that can mediate DNA transfer between unrelated cells, even between different genera. Conjugative plasmids use this mechanism to transfer copies of themselves and the genes they encode, such as those for antibiotic resistance, to new host cells.

The process of conjugation requires a *donor* cell, which contains the conjugative plasmid, and a *recipient* cell, which does not. In addition, genetic elements that cannot transfer themselves can sometimes be *mobilized* or transferred during conjugation. These other genetic elements can be other plasmids or the host chromosome itself. Indeed, conjugation was discovered because the F plasmid of *Escherichia coli* can mobilize the host chromosome (see Figure 10.21). Transfer mechanisms may differ depending on the participating plasmid, but most plasmids in gram-negative *Bacteria* employ a mechanism similar to that used by the F plasmid.

F Plasmid

The F plasmid (F stands for “fertility”) is a circular DNA molecule of 99,159 bp. Figure 10.16 shows a genetic map of the F plasmid. One region of the plasmid contains genes that regulate DNA replication. It also contains a number of transposable elements (Section 10.11) that allow the plasmid to integrate into the host chromosome. In addition, the F plasmid has a large region of DNA, the *tra* region, containing genes that encode transfer functions. Many genes in the *tra* region participate in mating pair formation, and most of these have to do with the synthesis of a surface structure, the sex pilus (Section 2.13). Only donor cells produce these pili. Different conjugative plasmids may have slightly different *tra* regions, and the pili may vary somewhat in structure. The F plasmid and its relatives encode F pili.

Pili allow specific pairing to take place between the donor and recipient cells. All conjugation in gram-negative *Bacteria*

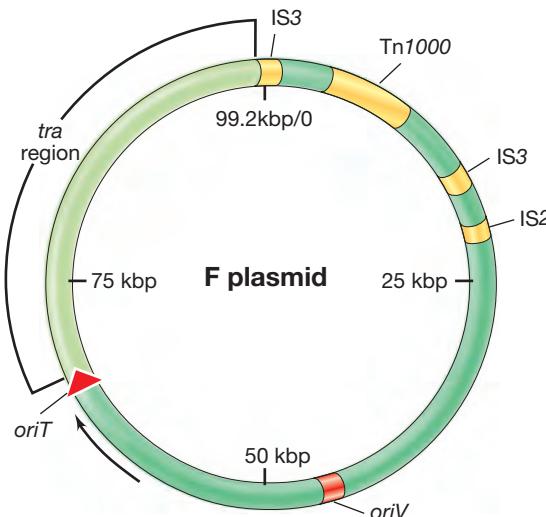

Figure 10.16 Genetic map of the F (fertility) plasmid of *Escherichia coli*. The numbers on the interior show the size in kilobase pairs (the exact size is 99,159 bp). The region in dark green at the bottom of the map contains genes primarily responsible for the replication and segregation of the F plasmid. The origin of vegetative replication is *oriV*. The light green *tra* region contains the genes needed for conjugative transfer. The origin of transfer during conjugation is *oriT*. The arrow indicates the direction of transfer (the *tra* region is transferred last). Insertion sequences are shown in yellow. These may recombine with identical elements on the bacterial chromosome, which leads to integration and the formation of different Hfr strains.

is thought to depend on cell pairing brought about by pili. The pilus makes specific contact with a receptor on the recipient cell and then is retracted by disassembling its subunits. This pulls the two cells together (Figure 10.17). Following this process, donor and recipient cells remain in contact by binding proteins located in the outer membrane of each cell. DNA is then transferred from donor to recipient cell through this conjugation junction.

Mechanism of DNA Transfer during Conjugation

DNA synthesis is necessary for DNA transfer by conjugation. This DNA is synthesized not by normal bidirectional replication

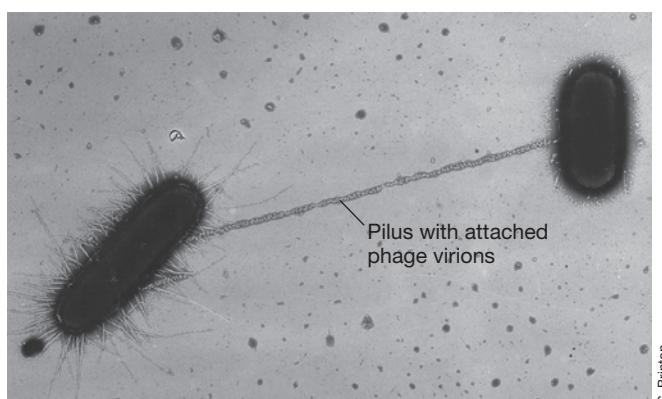

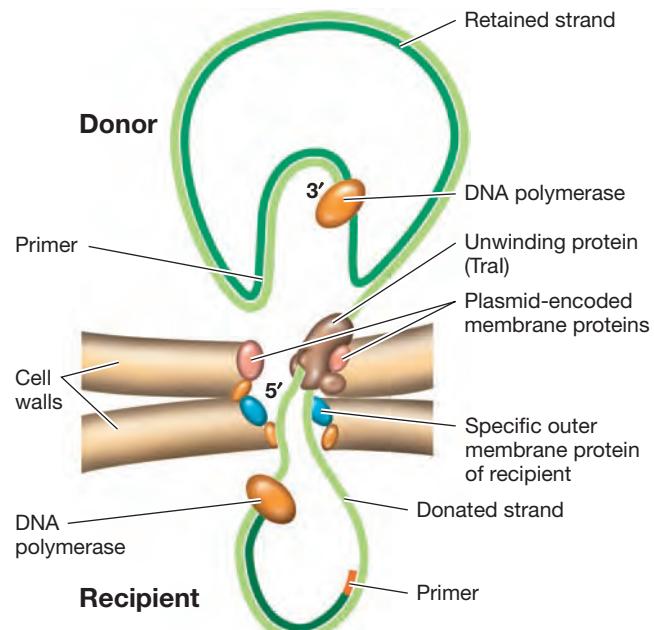

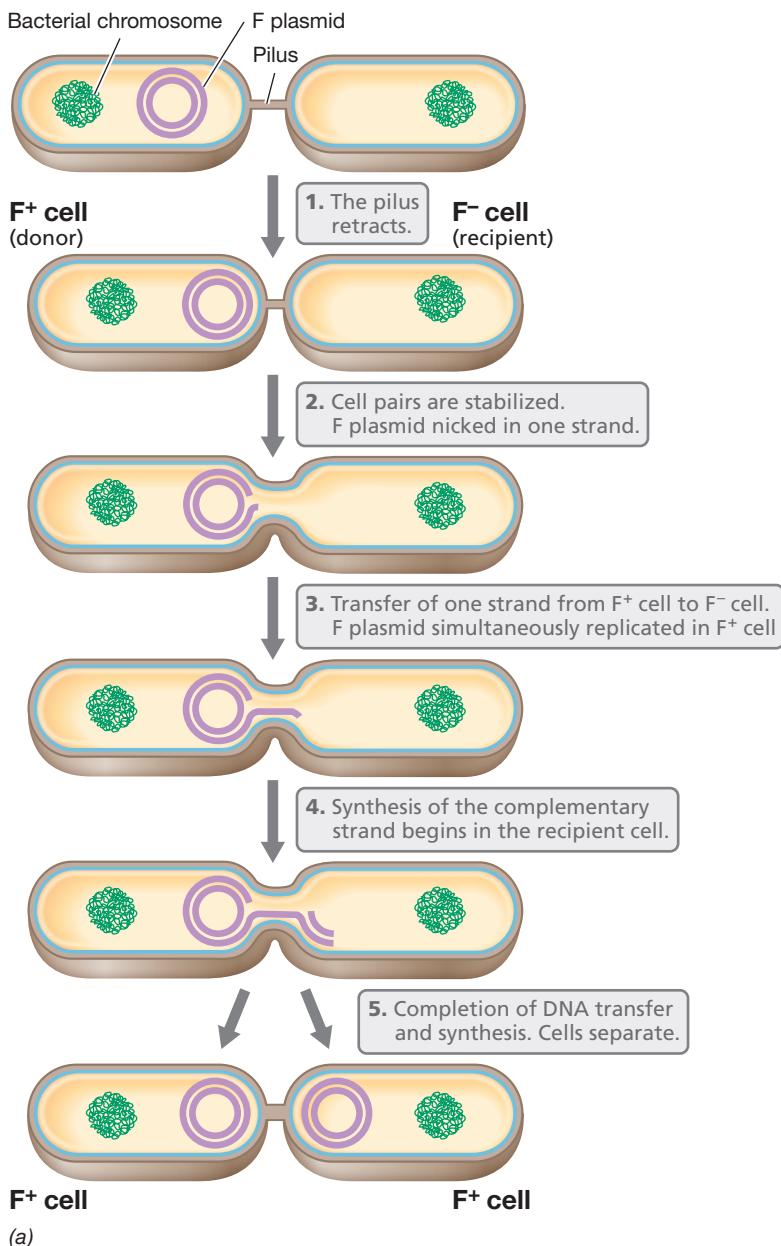

Figure 10.17 Formation of a mating pair. Direct contact between two conjugating bacteria is first made via a pilus. The cells are then drawn together to form a mating pair by retraction of the pilus, which is achieved by depolymerization. Certain small phages (F-specific bacteriophages) use the sex pilus as a receptor and can be seen here attached to the pilus.

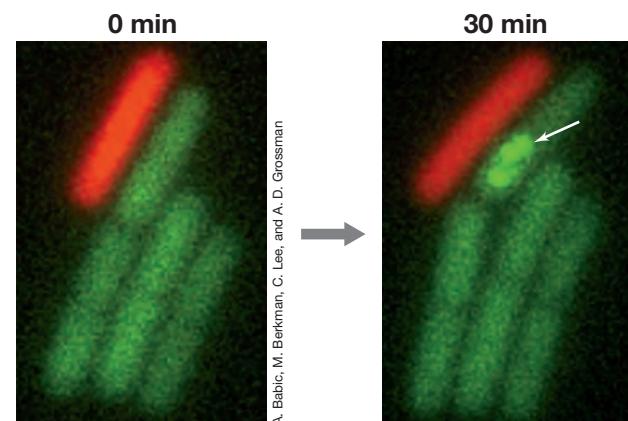

(Section 4.6), but by **rolling circle replication**, a mechanism also used by some viruses (Sections 8.8 and 9.3) and shown in Figure 10.18. DNA transfer is triggered by cell-to-cell contact, at which time one strand of the circular plasmid DNA is nicked and is transferred to the recipient. The nicking enzyme required to initiate the process, TraI, is encoded by the *tra* operon of the F plasmid. TraI also has helicase activity and thus also unwinds the strand to be transferred. As this transfer occurs, DNA synthesis by the rolling circle mechanism replaces the transferred strand in the donor, while a complementary DNA strand is being made in

the recipient. Therefore, at the end of the process, both donor and recipient possess complete plasmids. For transfer of the F plasmid, if an F-containing donor cell, which is designated F⁺, mates with a recipient cell lacking the plasmid (F⁻), the result is two F⁺ cells (Figure 10.18).

Transfer of plasmid DNA is efficient and rapid; under favorable conditions virtually every recipient cell that pairs with a donor acquires a plasmid. Transfer of the F plasmid, comprising approximately 100 kilobase pairs of DNA, takes about 5 minutes. If the plasmid genes can be expressed in the recipient, the recipient itself

(b)

Red donor cell containing a plasmid with the *lacO* region makes contact with green recipient cell.
LacI-GFP in the recipient cell binds to the *lacO* region on the transferred plasmid after conjugation.

Figure 10.18 Transfer of plasmid DNA by conjugation. (a) The transfer of the F plasmid converts an F⁻ recipient cell into an F⁺ cell. Note the mechanism of rolling circle replication. (b) Details of the replication and transfer process. (c) Visualization of DNA transfer by conjugation in *Bacillus subtilis* using fluorescent microscopy. The donor cell constitutively expresses a red fluorescent protein, while the recipient cells fluoresce green due to green fluorescent protein (GFP) fused to LacI (Figure 7.15). The DNA transferred from the donor contains a *lacO* operator region that binds LacI-GFP. Arrows indicate focal points in the recipient cell where LacI-GFP is bound to the *lacO* region obtained from conjugation.

becomes a donor and can transfer the plasmid to other recipients. In this fashion, conjugative plasmids can spread rapidly among bacterial populations, behaving much like infectious agents. This is of major ecological significance because conjugative plasmids have been found in many *Bacteria* and some *Archaea* (Section 10.10), and a few plasmid-containing cells introduced into a population of recipients can convert the entire population into plasmid-bearing (and thus donating) cells in a short time.

MINIQUIZ

- In conjugation, how are donor and recipient cells brought into contact with each other?
- Explain how rolling circle DNA replication allows both donor and recipient to end up with a complete copy of plasmids transferred by conjugation.
- Why does F have two different origins of replication?

10.9 The Formation of Hfr Strains and Chromosome Mobilization

Chromosomal genes can be transferred by plasmid-mediated conjugation. As mentioned above, the F plasmid of *Escherichia coli* can, under certain circumstances, mobilize the chromosome for transfer during cell-to-cell contact. The F plasmid is an *episome*, a plasmid that can integrate into the host chromosome. When the F plasmid is integrated, chromosomal genes can be transferred along with the plasmid. Following genetic recombination between donor and recipient DNA, horizontal transfer of chromosomal genes by this mechanism can be very extensive.

Cells possessing a nonintegrated F plasmid are called F⁺. Those with an F plasmid integrated into the chromosome are called **Hfr cells** (for *high frequency of recombination*). This term refers to the high rates of genetic recombination between genes on the donor and recipient chromosomes. Both F⁺ and Hfr cells are donors, but unlike conjugation between an F⁺ and an F⁻, conjugation between an Hfr donor and an F⁻ leads to transfer of genes from the host chromosome. This is because the chromosome and plasmid now form a single molecule of DNA. Consequently, when rolling circle replication is initiated by the F plasmid, replication continues on into the chromosome. Thus, the chromosome is also replicated and transferred. Hence, integration of a conjugative plasmid provides a mechanism for mobilizing a cell's genome.

Overall, the presence of the F plasmid results in three distinct alterations in a cell: (1) the ability to synthesize the F pilus (Figure 10.17), (2) the mobilization of DNA for transfer to another cell, and (3) the alteration of surface receptors so the cell can no longer act as a recipient in conjugation and is unable to take up a second copy of the F plasmid or genetically related plasmids.

Integration of F and Chromosome Mobilization

The F plasmid and the chromosome of *E. coli* both carry several copies of mobile elements called *insertion sequences* (IS; Section 10.11). These provide regions of sequence homology between chromosomal and F plasmid DNA. Consequently, homologous recombination between an IS on the F plasmid and a corresponding IS on the chromosome results in integration of the F plasmid

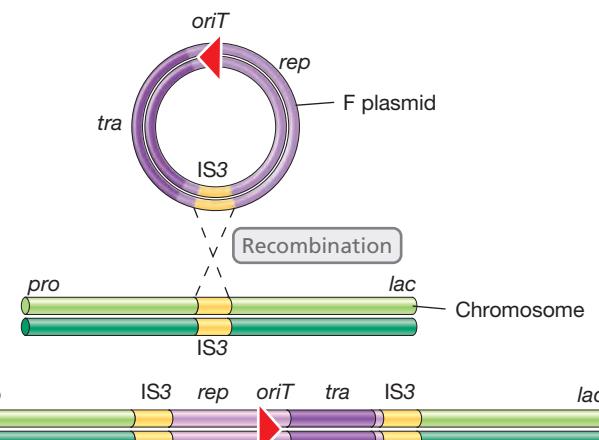

Figure 10.19 The formation of an Hfr strain. Integration of the F plasmid into the chromosome may occur at a variety of specific sites where IS elements are located. The example shown here is an IS3 located between the chromosomal genes *pro* and *lac*. Some of the genes on the F plasmid are shown. The arrow indicates the origin of transfer, *oriT*, with the arrow as the leading end. Thus, in this Hfr *pro* would be the first chromosomal gene to be transferred and *lac* would be among the last.

into the host chromosome, as shown in Figure 10.19. Once integrated, the plasmid no longer replicates independently, but the *tra* operon still functions normally and the strain synthesizes pili. When a recipient is encountered, conjugation is triggered just as in an F⁺ cell, and DNA transfer is initiated at the *oriT* (origin of transfer) site. However, because the plasmid is now part of the chromosome, after part of the plasmid DNA is transferred, chromosomal genes begin to be transferred (Figure 10.20). As in the case of conjugation with just the F plasmid itself (Figure 10.18), chromosomal DNA transfer also requires replication.

Because the DNA strand typically breaks during transfer, only part of the donor chromosome is transferred. Consequently, the recipient does not become Hfr (or F⁺) because only part of the

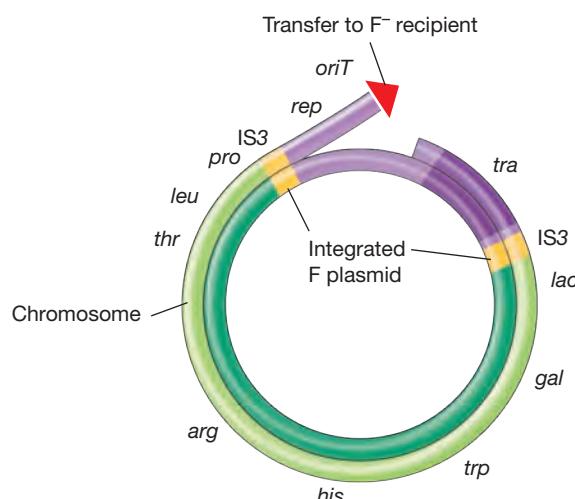

Figure 10.20 Transfer of chromosomal genes by an Hfr strain. The Hfr chromosome breaks at the origin of transfer within the integrated F plasmid. The transfer of DNA to the recipient begins at this point. DNA replicates during transfer as for a free F plasmid (Figure 10.18). This figure is not to scale; the inserted F plasmid is actually less than 3% of the size of the *Escherichia coli* chromosome.

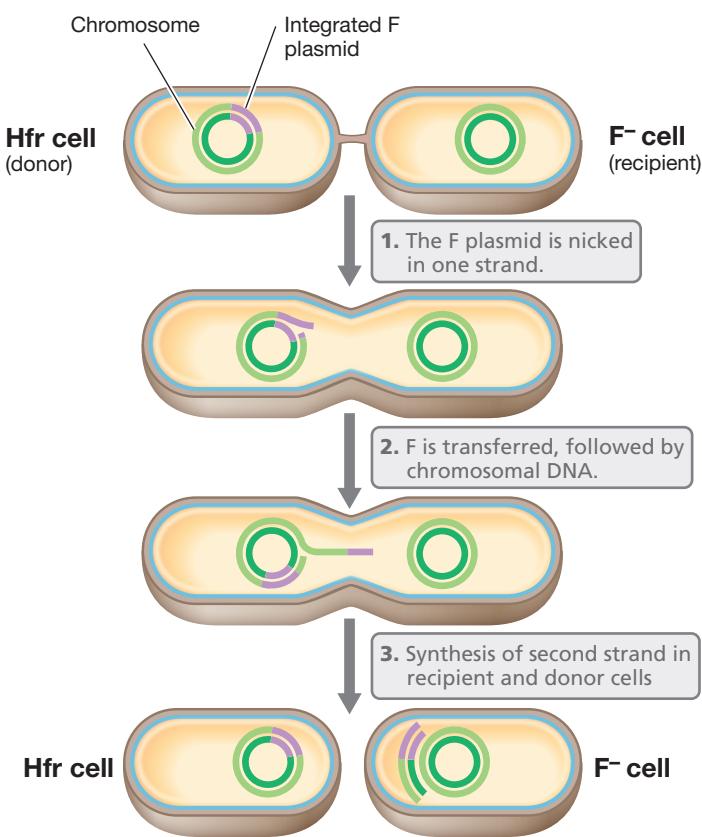

Figure 10.21 Transfer of chromosomal DNA by conjugation. Transfer of the integrated F plasmid from an Hfr strain results in the cotransfer of chromosomal DNA because this is linked to the plasmid. The steps in transfer are similar to those in Figure 10.18a. However, the recipient remains F⁻ and receives a linear fragment of donor chromosome attached to part of the F plasmid. For donor DNA to survive, it must be recombined into the recipient chromosome after transfer (not shown).

integrated F plasmid is transferred (Figure 10.21). However, after transfer, the Hfr strain remains Hfr because it retains a copy of the integrated F plasmid. Because a partial chromosome cannot replicate, for incoming donor DNA to survive, it must recombine with the recipient chromosome. Following recombination, the recipient cell may express a new phenotype due to the incorporation of donor genes. Although Hfr strains transmit chromosomal genes at high frequency, they generally do not convert F⁻ cells to F⁺ or Hfr because the entire F plasmid is rarely transferred. Instead, an Hfr × F⁻ cross yields the original Hfr and an F⁻ cell that now has a new genotype. As in transformation and transduction, genetic recombination between Hfr genes and F⁻ genes involves homologous recombination in the recipient cell.

Because several distinct insertion sequences are present on the chromosome, a number of distinct Hfr strains are possible. A given Hfr strain always donates genes in the same order, beginning at the same position. However, Hfr strains that differ in the chromosomal integration site of the F plasmid transfer genes in different orders (Figure 10.22). At some insertion sites, the F plasmid is integrated with its origin pointing in one direction, whereas at other sites the origin points in the opposite direction. The orientation of the F plasmid determines which chromosomal genes enter the recipient first and illustrates how genes acquired from horizontal transfer and recombined into the chromosome can be transferred

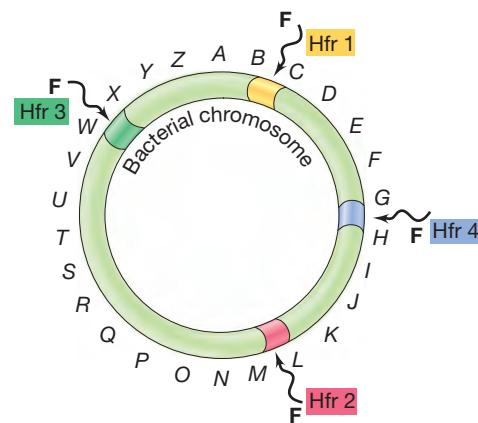

Figure 10.22 Formation of different Hfr strains. Different Hfr strains donate genes in different orders and from different origins. (a) F plasmids can be inserted into various insertion sequences on the bacterial chromosome, forming different Hfr strains. (b) Order of gene transfer for different Hfr strains.

to new recipient cells (Figure 10.22). By using various Hfr strains in mating experiments, it was possible to determine the arrangement and orientation of most of the genes in the *E. coli* chromosome (Section 4.3) long before it was sequenced.

Transfer of Chromosomal Genes to the F Plasmid

Occasionally, integrated F plasmids may be excised from the chromosome. During excision, chromosomal genes may sometimes be incorporated into the liberated F plasmid. This can happen because both the F plasmid and the chromosome contain multiple identical insertion sequences where recombination can occur (Figure 10.20). F plasmids containing chromosomal genes are called *F'* plasmids. When F' plasmids promote conjugation, they transfer the chromosomal genes they carry at high frequency to the recipients. F'-mediated transfer resembles specialized transduction (Section 10.7) in that only a restricted group of chromosomal genes is transferred by any given F' plasmid. Transferring a known F' into a recipient allows one to establish diploids (two copies of each gene) for a limited region of the chromosome. Such partial diploids (merodiploids) are important for complementation tests (Section 10.5).

MINIQUIZ

- In conjugation involving the F plasmid of *Escherichia coli*, how is the host chromosome mobilized?
- Why does an Hfr × F⁻ mating not yield two Hfr cells?
- At which sites in the chromosome can the F plasmid integrate?

III • Gene Transfer in Archaea and Other Genetic Events

Although far less studied than the genetics of *Bacteria*, the genetics of *Archaea* are beginning to emerge along with archaeal versions of the genetic tools necessary for more detailed analyses. In addition, other genetic events in *Bacteria* are important general concepts but do not deal with horizontal gene flow itself. We cover all of these topics here.

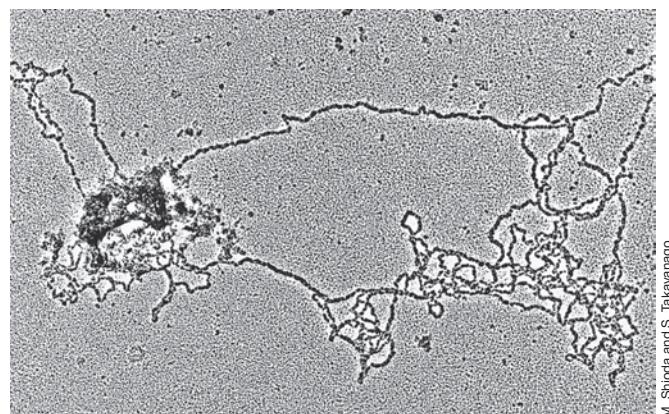

10.10 Horizontal Gene Transfer in Archaea

Although *Archaea* contain a single circular chromosome like most *Bacteria* (Figure 10.23) and genome analysis indicates that horizontal transfer of archaeal DNA also occurs in nature, the development of laboratory-based gene transfer systems lags far behind that for *Bacteria*. Practical problems here include the fact that most well-studied *Archaea* are extremophiles, capable of growth only under extreme conditions of high salt or high temperature (Chapter 16). The temperatures necessary to culture some hyperthermophiles, for example, will melt agar, and alternative materials are required to form solid media and obtain colonies.

Another problem is that most common antibiotics do not affect *Archaea*. For example, penicillins do not affect *Archaea* because their cell walls lack peptidoglycan. The choice of selectable markers for genetic crosses is therefore often limited. However, novobiocin (a DNA gyrase inhibitor) and mevinolin (an inhibitor of isoprenoid biosynthesis) are used to inhibit growth of extreme halophiles, and puromycin and neomycin (both protein synthesis inhibitors) inhibit methanogens. Auxotrophic strains of a few *Archaea* have also been isolated for genetic selection purposes.

Examples of Archaeal Genetics

No single species of *Archaea* has become a model organism for archaeal genetics, although more genetic work has been done on select species of extreme halophiles (*Halobacterium*, *Haloferax*, [Section 16.1](#)) than on any other *Archaea*. Instead, individual mechanisms for gene transfer have been found scattered among a

M. Shioya and S. Takayanagi

Figure 10.23 An archaeal chromosome, as shown in the electron microscope. The circular chromosome is from the hyperthermophile *Sulfolobus*, a member of the *Archaea*.

range of *Archaea*. In addition, several plasmids have been isolated from *Archaea* and some have been used to construct cloning vectors, allowing genetic analysis through cloning and sequencing rather than traditional genetic crosses. Transposon mutagenesis (Section 10.11) has been well developed in certain methanogen species including *Methanococcus* and *Methanosarcina*, and other tools such as shuttle vectors and other *in vitro* methods of genetic analysis have been developed for study of the highly unusual biochemistry of the methanogens ([Sections 13.20 and 16.2](#)).

Transformation works reasonably well in several *Archaea* although details and conditions vary from organism to organism. One approach requires removal of divalent metal ions, which in turn results in the disassembly of the glycoprotein cell wall layer surrounding many archaeal cells and hence allows access by transforming DNA. However, *Archaea* with rigid cell walls have proven difficult to transform, although electroporation sometimes works. One exception is in *Methanosarcina* species, organisms with a thick cell wall, for which high-efficiency transformation systems have been developed that employ DNA-loaded lipid preparations (liposomes) to deliver DNA into the cell.

Although viruses that infect *Archaea* are plentiful, transduction is extremely rare. Only one archaeal virus, which infects the thermophilic methanogen *Methanothermobacter thermautotrophicus*, has been shown to transduce the genes of its host. Unfortunately the low burst size (about six phages liberated per cell) makes using this system for gene transfer impractical.

Conjugation in Archaea

Two types of conjugation have been detected in *Archaea*. Some strains of *Sulfolobus solfataricus* ([Section 16.10](#)) contain plasmids that promote conjugation between two cells in a manner similar to that seen in *Bacteria*. In this process, cell pairing is independent of pili formation and DNA transfer is unidirectional. However, most of the genes encoding these functions seem to have little similarity to those in gram-negative *Bacteria*. The exception is a gene similar to *traG* from the F plasmid, whose protein product participates in stabilizing mating pairs. It thus seems likely that the actual mechanism of conjugation in *Archaea* is quite different from that in *Bacteria*.

Some halobacteria, in contrast, perform a novel form of conjugation. No fertility plasmids are required, and DNA transfer is bidirectional. Cytoplasmic bridges form between the mating cells and probably facilitate intercell DNA transfer. Neither type of conjugation has been developed to the point of being used for routine gene transfer or genetic analysis. However, these genetic resources will likely be useful for developing more routine genetic transfer systems for these organisms in the future.

MINIQUIZ

- Why is it usually more difficult to select recombinants with *Archaea* than with *Bacteria*?
- Why do penicillins not kill species of *Archaea*?

10.11 Mobile DNA: Transposable Elements

As we have seen, molecules of DNA may move from one cell to another, but to a geneticist, “mobile DNA” has a specialized meaning. Mobile DNA refers to discrete segments of DNA that move as units from one location to another *within* other DNA molecules.

Although the DNA of certain viruses can be inserted into and excised from the genome of the host cell, most mobile DNA consists of **transposable elements**. These are stretches of DNA that can move from one site to another. However, transposable elements are always found inserted into another DNA molecule such as a plasmid, a chromosome, or a viral genome. Transposable elements do not possess their own origin of replication. Instead, they are replicated when the host DNA molecule into which they are inserted is replicated.

Transposable elements move by a process called *transposition* that is important both in genome rearrangement and in genetic analysis. The frequency of transposition is extremely variable, and ranges from 1 in 10^3 to 1 in 10^7 per transposable element per cell generation, depending on both the transposable element and the organism. Transposable elements are abundant and widespread in nature and can be found in the genomes of all three domains of life as well as in many viruses and plasmids, which suggests that the elements offer a selective advantage by accelerating genome rearrangement.

The two major types of transposable elements in *Bacteria* are *insertion sequences* (IS) and *transposons*. Both elements have two important features in common: They carry genes encoding *transposase*, the enzyme necessary for transposition, and they have short inverted terminal repeats at their ends that are also needed for transposition (the ends of transposable elements are not free but are continuous with the host DNA molecule into which the transposable element has inserted). **Figure 10.24** shows genetic maps of the insertion element IS2 and of the transposon Tn5.

Insertion Sequences and Transposons

Insertion sequences are the simplest type of transposable element. They are short DNA segments, about 1000 nucleotides long, and typically contain inverted repeats of 10–50 base pairs. Each different IS has a specific number of base pairs in its terminal repeats, and the only protein encoded is the transposase. Several

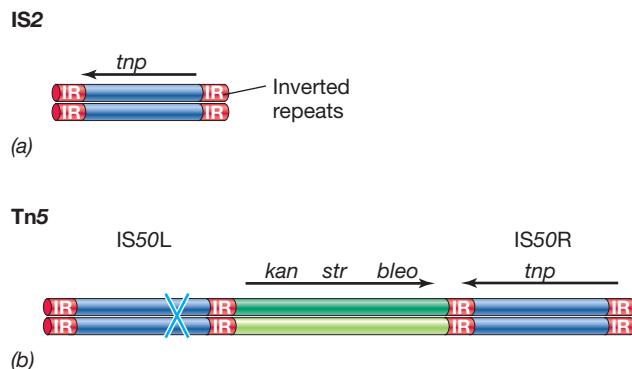

Figure 10.24 Maps of the transposable elements IS2 and Tn5. The arrows above the maps show the direction of transcription of any genes on the elements. The gene encoding the transposase is *trp*. (a) IS2 is an insertion sequence of 1327 bp with inverted repeats of 41 bp at its ends. (b) Tn5 is a composite transposon of 5.7 kbp containing the insertion sequences IS50L and IS50R at its left and right ends, respectively. IS50L is not capable of independent transposition because there is a nonsense mutation, marked by a blue cross, in its transposase gene. The genes *kan*, *str*, and *bleo* confer resistance to the antibiotics kanamycin (and neomycin), streptomycin, and bleomycin.

hundred distinct IS elements have been characterized. IS elements are found in the chromosomes and plasmids of both *Bacteria* and *Archaea*, as well as in certain bacteriophages. Individual strains of the same bacterial species vary in the number and location of the IS elements they harbor. For instance, the genome of one strain of *Escherichia coli* has five copies of IS2 and five copies of IS3. Many plasmids, such as the F plasmid, also carry IS elements. Indeed, integration of the F plasmid into the *E. coli* chromosome (Figure 10.19) is due to recombination between identical IS elements on the F plasmid and the chromosome (Section 10.9).

Transposons are larger than IS elements, but have the same two essential components: inverted repeats at both ends and a gene that encodes transposase (Figure 10.24b). The transposase recognizes the inverted repeats and moves the segment of DNA flanked by them from one site to another. Consequently, any DNA that lies between the two inverted repeats is moved and is, in effect, part of the transposon. Genes included inside transposons vary widely. Some of these genes, such as antibiotic resistance genes, confer important new properties on the organism harboring the transposon. Because antibiotic resistance is both important and easy to detect, most highly investigated transposons have antibiotic resistance genes as selectable markers. Examples include transposon Tn5, which encodes kanamycin resistance (Figure 10.24b) and Tn10, which encodes tetracycline resistance.

Because any genes lying between the inverted repeats become part of a transposon, it is possible to get hybrid transposons that display complex behavior. For example, conjugative transposons contain *tra* genes and can move between bacterial species by conjugation as well as transpose from place to place within a single bacterial genome. Even more complex is bacteriophage Mu, which is both a virus and a transposon (see Section 9.4). In this case a complete virus genome is contained within a transposon. Other composite genetic elements consist of a segment of DNA lying between two identical IS elements. This whole structure can move as a unit and is called a *composite transposon*. The behavior of composite transposons indicates that novel transposons likely arise periodically in cells that contain IS elements located close to one another.

Mechanisms of Transposition

Both the inverted repeats (located at the ends of transposable elements) and transposase are essential for transposition. The transposase recognizes, cuts, and ligates the DNA during transposition. When a

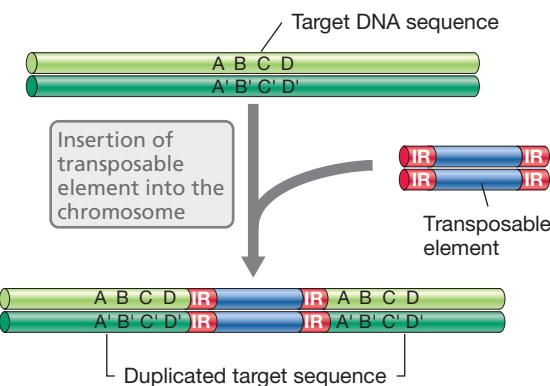

Figure 10.25 Transposition. Insertion of a transposable element generates a duplication of the target sequence. Note the presence of inverted repeats (IR) at the ends of the transposable element.

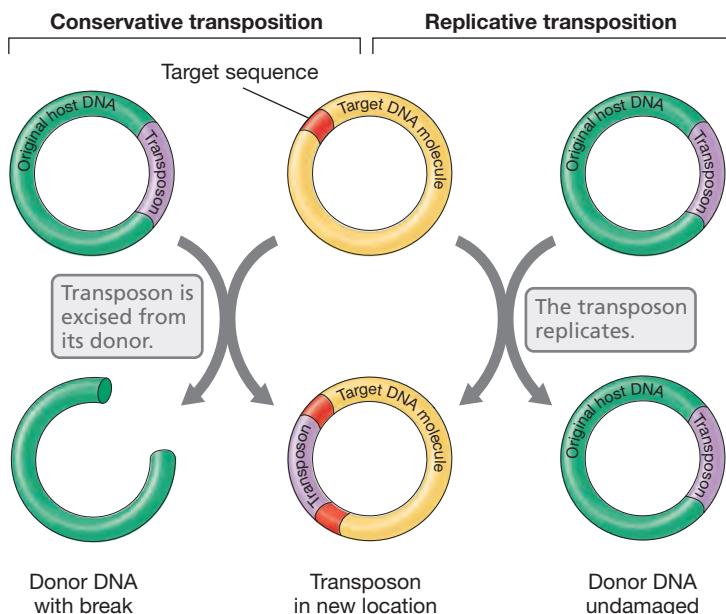

Figure 10.26 Two mechanisms of transposition. Donor DNA (carrying the transposon) is shown in green, and recipient DNA carrying the target sequence is shown in yellow. In both conservative and replicative transposition the transposase inserts the transposon (purple) into the target site (red) on the recipient DNA. During this process, the target site is duplicated. In conservative transposition, the donor DNA is left with a double-stranded break at the previous location of the transposon. In contrast, after replicative transposition, both donor and recipient DNA possess a copy of the transposon.

transposable element is inserted into target DNA, a short sequence in the target DNA at the site of integration is duplicated during the insertion process (Figure 10.25). The duplication arises because single-stranded DNA breaks are made by the transposase. The transposable element is then attached to the single-stranded ends that have been generated. Finally, enzymes of the host cell repair the single-strand portions, which results in the duplication.

Two mechanisms of transposition are known: *conservative* and *replicative* (Figure 10.26). In conservative transposition, as occurs with the transposon Tn5, the transposon is excised from one location and is reinserted at a second location. The copy number of a conservative transposon therefore remains at one. By contrast, during replicative transposition, a new copy of the transposon is produced and is inserted at the second location. Thus, after a replicative transposition event, one copy of the transposon remains at the original site, while a second copy is incorporated at the new site.

Mutagenesis with Transposons

When a transposon inserts itself within a gene, a mutation occurs in that particular gene (Figure 10.27). Mutations due to transposon insertion do occur naturally. However, deliberate use of transpo-

sions is a convenient way to create bacterial mutants in the laboratory. Typically, transposons carrying antibiotic resistance genes are used. The transposon is introduced into the target cell on a phage or plasmid that cannot replicate in that particular host. Consequently, antibiotic-resistant colonies will mostly be due to insertion of the transposon into the bacterial genome.

Because bacterial genomes contain relatively little noncoding DNA, most transposon insertions will occur in genes that encode proteins. This technique can be used to determine the function of a novel gene (Figure 10.27). If a transposon inserts into a gene encoding a product of interest such as a new antibiotic synthetase, the transposon mutant will no longer produce the antibiotic. Further analyses can be performed to reveal which gene the transposon has disrupted.

Two transposons widely used for mutagenesis of *Escherichia coli* and related bacteria are Tn5 (Figure 10.24b), which confers neomycin and kanamycin resistance, and Tn10, which confers tetracycline resistance. Many *Bacteria*, a few *Archaea*, and the yeast *Saccharomyces cerevisiae* have all been mutagenized using engineered transposons. More recently, transposons have even been used to isolate mutations in animals, including mice.

MINIQUIZ

- Which features do insertion sequences and transposons have in common?
- What is the significance of the terminal inverted repeats of transposons?
- How can transposons be used in bacterial genetics?

10.12 Preserving Genome Integrity: CRISPR Interference

Bacteria and *Archaea* not only produce restriction endonucleases (Sections 8.6 and 11.1) that function to destroy incoming foreign DNA, they also have an RNA-based defense program to destroy invading DNA from viral infection and sometimes conjugation. This type of prokaryotic “immune system” helps preserve genome stability and is called the CRISPR system, which stands for clustered regularly interspaced short palindromic repeats.

The CRISPR region on the bacterial chromosome is essentially a memory bank of incoming nucleic acid sequences used for surveillance against foreign DNA. It consists of many different segments of foreign DNA called *spacers* alternating with identical repeated sequences (Figure 10.28). The spacer sequences correspond to pieces of foreign DNA that have previously invaded the cell. Once the spacers are recombined into the CRISPR region, the system provides resistance to any incoming DNA (and sometimes RNA) that contains the same or very closely related sequences to

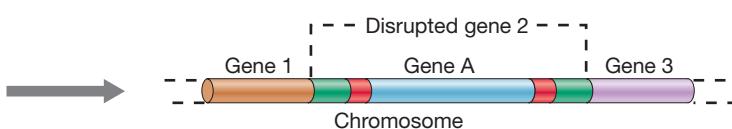

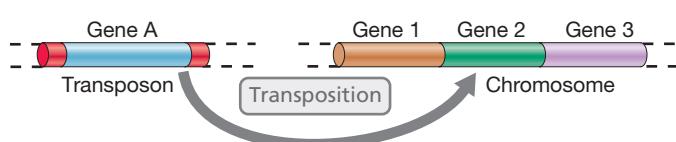

Figure 10.27 Transposon mutagenesis. The transposon moves into the middle of gene 2. Gene 2 is now disrupted by the transposon and is inactivated. Gene A from the transposon is now expressed from the chromosome.

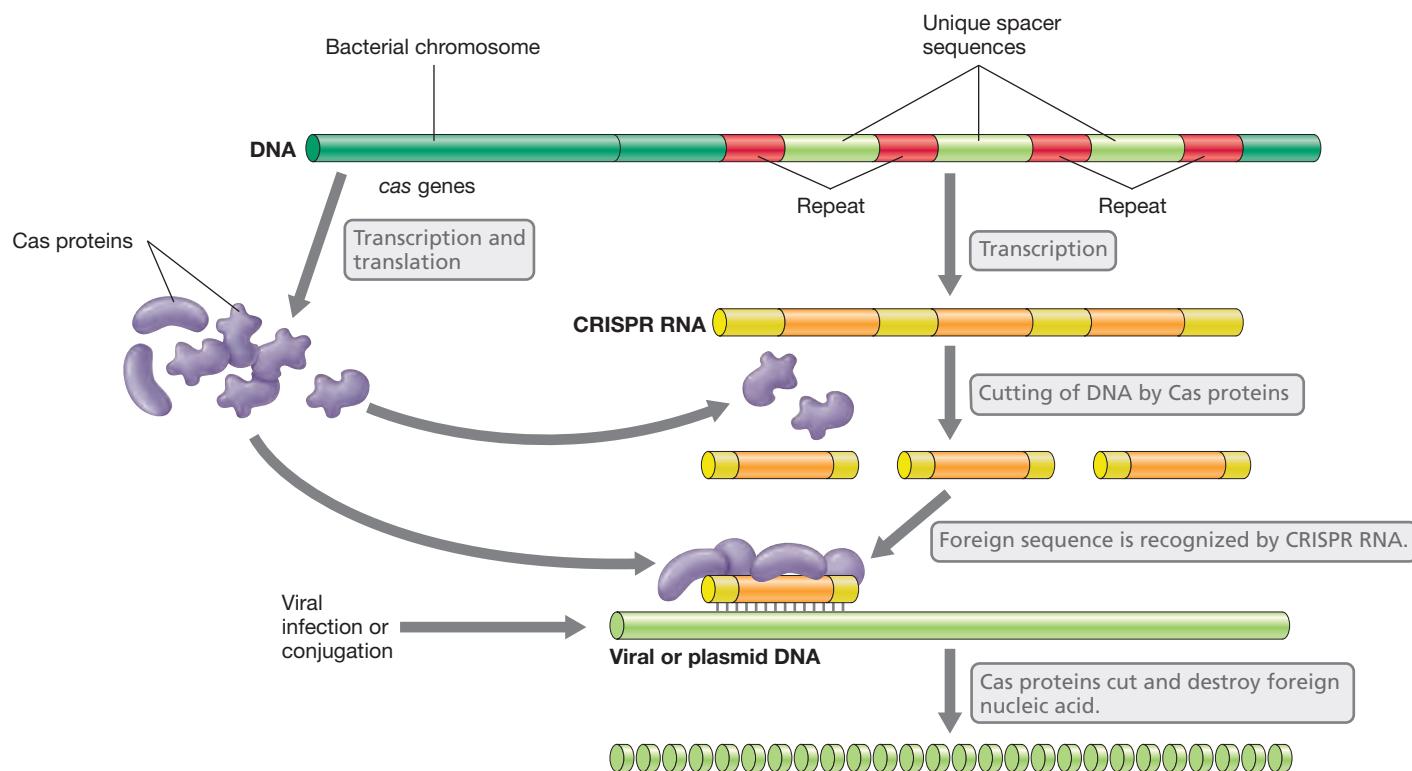

Figure 10.28 Operation of the CRISPR system. The CRISPR region on the bacterial chromosome is transcribed into a long RNA molecule that is then processed into segments by some of the Cas proteins. Each spacer segment corresponds to previous encounters with incoming foreign nucleic acid. If one of these short CRISPR RNA molecules (corresponding to a spacer) recognizes and base-pairs with incoming nucleic acid from transduction or conjugation, other Cas proteins destroy the foreign nucleic acid.

individual spacer regions. Proteins of the CRISPR system carry out essential functions of this RNA-based “immunity.”

The proteins of the CRISPR system (CRISPR-associated proteins, or Cas proteins) perform two roles. Some participate in obtaining and storing segments of foreign DNA as spacers by recognizing specific nucleotide sequences associated with the spacers. Others use the stored sequence information to recognize intruding DNA and destroy it. The Cas proteins themselves are encoded by genes that lie upstream of the CRISPR DNA sequences (Figure 10.28).

The CRISPR region is transcribed as a whole into a long RNA molecule that is then cleaved in the middle of each of the repeated sequences by the nuclease activity of Cas proteins. This converts the long RNA molecule into spacer segments of small RNAs called *CRISPR RNAs* (*crRNAs*). If one of these crRNAs base-pairs with invading nucleic acid, then the foreign DNA or RNA is destroyed by the nuclease activity of other Cas proteins.

The CRISPR system is widely distributed in both *Archaea* and *Bacteria*. Approximately 90% of the sequenced genomes of

Archaea and 70% of those of *Bacteria* possess the CRISPR system. The utility of the system was first demonstrated in the dairy industry where starter cultures used for milk fermentation are susceptible to rampant bacteriophage infection. However, a strain of *Streptococcus thermophilus* was found to be resistant to virulent bacteriophage. The difference between this *S. thermophilus* strain and those susceptible to viral infection was its spacers within the CRISPR region. While it is unknown why some viruses are not targeted by the CRISPR system, laboratory experiments have shown that bacteriophages can overcome recognition by the Cas proteins and crRNAs by modifying their genome through mutation.

MINIQUIZ

- Why is the CRISPR system considered a prokaryotic “immune system”?
- What do the spacers within the CRISPR region correspond to?

BIG IDEAS

10.1 • Mutation is a heritable change in DNA sequence and may lead to a change in phenotype. Selectable mutations are those that give the mutant a growth advantage under certain environmental conditions and are especially useful in genetic research. If selection is not possible, mutants must be identified by screening.

10.2 • Mutations, either spontaneous or induced, are in the base sequence of the nucleic acid in a genome. A point mutation is due to a single base-pair change. In a nonsense mutation, the codon becomes a stop codon and an incomplete polypeptide is made. Deletions and insertions cause more

dramatic changes in the DNA, including frameshift mutations that often result in complete loss of gene function.

10.3 • Different types of mutations occur at different frequencies. For a typical bacterium, mutation rates of 10^{-6} to 10^{-7} per kilobase pair are generally seen. Although RNA and DNA polymerases make errors at about the same rate, RNA genomes typically accumulate mutations at much higher frequencies than DNA genomes.

10.4 • Mutagens are chemical, physical, or biological agents that increase the mutation rate. Mutagens can alter DNA in many different ways. However, alterations in DNA are not mutations unless they are inherited. Some DNA damage can lead to cell death if not repaired, and both error-prone and high-fidelity DNA repair systems exist.

10.5 • Homologous recombination occurs when closely related DNA sequences from two distinct genetic elements are combined together in a single element. Recombination is an important evolutionary process, and cells have specific mechanisms for ensuring that recombination takes place.

10.6 • Certain prokaryotes exhibit competence, a state in which cells are able to take up free DNA released by other bacteria. Incorporation of donor DNA into a recipient cell requires the activity of single-strand binding protein, RecA protein, and several other enzymes. Only competent cells are transformable.

10.7 • Transduction is the transfer of host genes from one bacterium to another by a bacterial virus. In generalized transduction, defective virus particles randomly incorporate fragments of the cell's chromosomal DNA, but the transducing efficiency is low. In specialized transduction, the DNA of a temperate virus excises incorrectly and takes adjacent host genes along with it; the transducing efficiency here may be very high.

10.8 • Conjugation is a mechanism of DNA transfer in prokaryotes that requires cell-to-cell contact. Conjugation is controlled by genes carried by certain plasmids (such as the F plasmid) and requires transfer of the plasmid from a donor cell to a recipient cell. Plasmid DNA transfer requires replication using the rolling circle mechanism.

10.9 • The donor cell chromosome can be mobilized for transfer to a recipient cell. This requires an F plasmid to integrate into the chromosome to form the Hfr phenotype. Because transfer of the host chromosome is rarely complete, recipient cells rarely become F⁺. F' plasmids are previously integrated F plasmids that have excised and captured some chromosomal genes.

10.10 • Archaeal research lags behind bacterial research in the development of systems for gene transfer. Many antibiotics are ineffective against *Archaea*, making it difficult to select recombinants effectively. The unusual growth conditions needed by many *Archaea* also make genetic experimentation difficult. Nevertheless, the genetic transfer systems of *Bacteria*—transformation, transduction, and conjugation—are all known in *Archaea*.

10.11 • Transposons and insertion sequences are genetic elements that can move from one location on a host DNA molecule to another by transposition. Transposition can be either replicative or conservative. Transposons often carry genes encoding antibiotic resistance and can be used as biological mutagens.

10.12 • The clustered regularly interspaced short palindromic repeat (CRISPR) system is an RNA-based mechanism of protecting the prokaryotic genome from invading DNA resulting from infection and conjugation. If small RNA molecules resulting from the spacer regions of the CRISPR region bind to incoming complementary DNA, Cas proteins destroy the nucleic acid duplex.

REVIEW OF KEY TERMS

Auxotroph an organism that has developed a nutritional requirement, often as a result of mutation

Conjugation the transfer of genes from one prokaryotic cell to another by a mechanism requiring cell-to-cell contact

Frameshift mutation a mutation in which insertion or deletion of nucleotides changes the groups of three bases in which the genetic code is read within an mRNA, usually resulting in a faulty product

Genotype the complete genetic makeup of an organism; the complete description of a cell's genetic information

Heteroduplex a DNA double helix composed of single strands from two different DNA molecules

Hfr cell a cell with the F plasmid integrated into the chromosome

Induced mutation a mutation caused by external agents such as mutagenic chemicals or radiation

Insertion sequence (IS) the simplest type of transposable element, which carries only genes that participate in transposition

Misense mutation a mutation in which a single codon is altered so that one amino acid in a protein is replaced with a different amino acid

Mutagen an agent that causes mutation

Mutant an organism whose genome carries a mutation

Mutation a heritable change in the base sequence of the genome of an organism

Mutator strain a mutant strain in which the rate of mutation is increased

Nonsense mutation a mutation in which the codon for an amino acid is changed to a stop codon

Phenotype the observable characteristics of an organism

Point mutation a mutation that involves a single base pair

Recombination a resorting or rearrangement of DNA fragments resulting in a new sequence combination

Reversion an alteration in DNA that reverses the effects of a prior mutation

Rolling circle replication a mechanism of replicating double-stranded circular DNA that starts by nicking and unrolling one strand and using the other

(still circular) strand as a template for DNA synthesis

Screening a procedure that permits the identification of organisms by phenotype or genotype, but does not inhibit or enhance the growth of particular phenotypes or genotypes

Selection placing organisms under conditions that favor or inhibit the growth of those with a particular phenotype or genotype

Silent mutation a change in DNA sequence that has no effect on the phenotype

SOS repair a DNA repair system activated by DNA damage

Spontaneous mutation a mutation that occurs "naturally" without the help of mutagenic chemicals or radiation

Transduction the transfer of host cell genes from one cell to another by a virus

Transformation the transfer of bacterial genes involving free DNA

Transition a mutation in which a pyrimidine base is replaced by another pyrimidine or a purine is replaced by another purine

Transposable element a genetic element able to move (transpose) from one site to another on host DNA molecules

Transposon a type of transposable element that carries genes in addition to those required for transposition

Transversion a mutation in which a pyrimidine base is replaced by a purine or vice versa

Wild-type strain a bacterial strain isolated from nature or one used as a parent in a genetics investigation

REVIEW QUESTIONS

- Write a one-sentence definition of the term "genotype." Do the same for "phenotype." Does the phenotype of an organism automatically change when a change in genotype occurs? Why or why not? Can phenotype change without a change in genotype? In both cases, give examples to support your answer. (Section 10.1)
- Explain why an *Escherichia coli* strain that is His⁻ is an auxotroph and one that is Lac⁻ is not. (*Hint:* Think about how *E. coli* metabolizes histidine and lactose and what each compound is used for.) (Section 10.1)
- What are silent mutations? From your knowledge of the genetic code, why do you think most silent mutations affect the third position in a codon? (Section 10.2)
- What is the average rate of mutation in a cell? Can this rate change? (Section 10.3)
- Give an example of one biological, one chemical, and one physical mutagen and describe the mechanism by which each causes a mutation. (Section 10.4)
- What are heteroduplex regions of DNA and what process leads to their formation? (Section 10.5)
- Explain why recipient cells do not successfully take up plasmids during natural transformation. (Section 10.6)
- Explain how a generalized transducing particle differs from a specialized transducing particle. (Section 10.7)
- What is a sex pilus and which cell type, F⁻ or F⁺, would produce this structure? (Section 10.8)
- What does an F⁺ cell need to do before it can transfer chromosomal genes? (Section 10.9)
- Explain why performing genetic selection is difficult when studying *Archaea*. Give examples of some selective agents that work well with *Archaea*. (Section 10.10)
- What are the major differences between insertion sequences and transposons? (Section 10.11)
- Explain why incoming DNA recognized by a short RNA molecule expressed from the CRISPR region cannot be completely foreign to the cell. (Section 10.12)

APPLICATION QUESTIONS

- A constitutive mutant is a strain that continuously makes a protein that is inducible in the wild type. Describe two ways in which a change in a DNA molecule could lead to the emergence of a constitutive mutant. How could these two types of constitutive mutants be distinguished genetically?
- Although a large number of mutagenic chemicals are known, none is known that induces mutations in only a single gene (gene-specific mutagenesis). From what you know about mutagens, explain why it is unlikely that a gene-specific chemical mutagen will be found. How then is site-specific mutagenesis accomplished?
- Why is it difficult in a single experiment to transfer a large number of genes to a recipient cell using transformation or transduction?
- Transposable elements cause mutations when inserted within a gene. These elements disrupt the continuity of a gene. Introns also disrupt the continuity of a gene, yet the gene is still functional. Explain why the presence of an intron in a gene does not inactivate that gene but insertion of a transposable element does.

From Pathogen to Tumor Assassin

Not only are cutting-edge advances in biotechnology providing critical information regarding the basic biology of life, they are also the cornerstones to improving naturally occurring products. Molecular techniques have been used to engineer the production of biofuels, drought-resistant crops, and hormones such as insulin. But what about human diseases such as cancer; is there hope here, too?

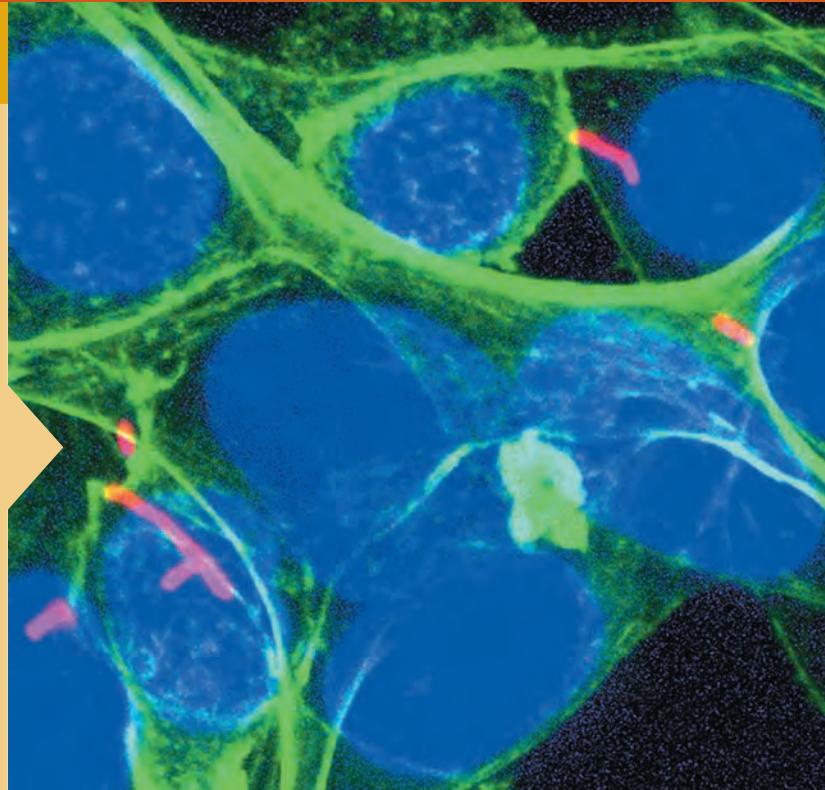

Pancreatic cancer is one of the leading causes of cancer deaths. Current radiation and chemotherapy treatments are ineffective, with dismal patient survival rates. While anticancer drugs are available, they only increase survival time for patients with advanced stages of the disease. Alternative treatments are desperately needed, and biotechnologists are coming to the rescue.

Listeria monocytogenes is a pathogen that causes listeriosis, a serious foodborne illness. *L. monocytogenes* possesses an intracellular lifestyle that allows it to evade the human immune system. However, scientists have discovered that a weakly pathogenic recombinant strain can be cleared by the immune system of healthy cells but not tumor cells. This led to an exciting idea—could this strain of *L. monocytogenes* be used to deliver anticancer agents such as therapeutic radionuclides to tumor cells only?

Radionuclides can physically destroy cancer cells, but delivering these molecules specifically to tumor cells has been problematic. Using an ingenious scheme, scientists coupled the radionuclide ^{188}Re to the weakly pathogenic strain of *L. monocytogenes*.¹ This “tumor-killing” strain of *Listeria* (pink in photo) was not only able to infect and multiply in pancreatic tumor cells of mice (blue), but also reduced the incidence of metastases without harming normal pancreatic cells.

This research illustrates how microbiology and biotechnology can team up to tame a virulent bacterium and convert it into a therapeutic superhero!

¹Quispe-Tintaya, W., et al. 2013. Nontoxic radioactive *Listeria* is a highly effective therapy against metastatic pancreatic cancer. *Proc. Natl. Acad. Sci.* 110: 8668–8673.

- I **Methods for Manipulating DNA** 316
- II **Gene Cloning** 326
- III **Products from Genetically Engineered Microorganisms** 333

In this chapter we discuss the basic techniques of genetic engineering, in particular those used to clone, alter, and express genes efficiently in host organisms. Performing genetics *in vivo* (in living organisms) has many limitations that can be overcome by manipulating DNA *in vitro* (in a test tube). These molecular

techniques are the foundation of biotechnology. Toward the end of the chapter, we will give some examples of how genetically modified organisms can be used for industrial, medical, and agricultural applications.

I • Methods for Manipulating DNA

Genetic engineering refers to the use of *in vitro* techniques to alter genes in the laboratory. Such altered genes may be reinserted into the original source organism or into some other host organism. Genetic engineering requires that DNA be isolated in specific fragments and purified for further manipulation. We begin by considering some of the basic tools of the genetic engineer including restriction enzymes, the separation of nucleic acids by electrophoresis, nucleic acid hybridization, amplification of DNA, and molecular cloning.

11.1 Restriction Enzymes and Nucleic Acid Separation

All cells contain enzymes that can chemically modify DNA. One major class of such enzymes is the *restriction endonucleases*, or **restriction enzymes** for short. Restriction enzymes recognize specific base sequences (recognition sequences) within DNA and cut the phosphodiester backbone, resulting in double-stranded breaks. Although restriction enzymes are widespread among both *Bacteria* and *Archaea*, they are very rare in eukaryotes. Restriction enzymes undoubtedly protect prokaryotes from hostile foreign DNA, such as virus genomes. However, restriction enzymes are also used for *in vitro* DNA manipulation and are a major tool of genetic engineering.

Mechanism of Restriction Enzymes

Restriction endonucleases are divided into three major classes. Type I and III restriction enzymes bind to the DNA at their recognition sequences but cut the DNA at some distance away. In contrast, the type II restriction enzymes cleave the DNA within their recognition sequences, making this class of enzymes much more useful for the specific manipulation of DNA.

Most of the DNA sequences recognized by type II restriction enzymes are short inverted repeats of 4 to 8 base pairs (bp). **Figure 11.1** shows two 6-bp sequences recognized and cleaved by two different type II restriction enzymes from *Escherichia coli*; arrows indicate the cleavage sites. Note that the two strands of the recognition sequences have the same sequence if one is read from the left and the other from the right (that is, both are read 5' → 3'). Such inverted repeat sequences are called *palindromes*. The endonuclease activity of *EcoRI* (this acronym stands for *Escherichia coli*, strain RY13, restriction enzyme I) makes staggered cuts, leaving short, single-stranded overhangs known as “sticky” ends at the ends of the two fragments. Other restriction enzymes such as *EcoRV* cut both strands of the DNA directly opposite each other, resulting in blunt ends (Figure 11.1a). As explained below, fragments with sticky ends are beneficial for molecular cloning of DNA (see Figure 11.7).

Consider again the enzymes *EcoRI* and *EcoRV*, which recognize a specific 6-bp sequence (Figure 11.1). Any specific 6-base sequence should appear in a strand of DNA about once every 4096 nucleotides on average ($4096 = 4^6$; there are 4 possible bases at each of 6 positions). This assumes that all base pairs may occur at any given position with equal probability and that the DNA consists of 50% GC. Thus, several *EcoRI* and *EcoRV* cut sites should be present in any lengthy DNA molecule. Several thousand restriction enzymes with different specificities are known, many of which are commercially available. **Table 11.1** lists a few of these enzymes and their recognition sequences.

Modification: Protection from Restriction

The natural role of restriction enzymes is to protect the cell from invasion by foreign DNA, especially viral DNA. If foreign DNA

^aNomenclature: The first letter of the three-letter abbreviation of a restriction endonuclease designates the genus from which the enzyme originates; the second two letters, the species. The roman numeral designates the order of discovery of enzymes in that particular organism, and any additional letters are strain designations.

^bArrows indicate the sites of enzymatic attack. Asterisks indicate the site of methylation (modification). G, guanine; C, cytosine; A, adenine; T, thymine. Only the 5' – 3' sequence is shown.

^cSee Figure 11.1a.

enters the cell, the restriction enzymes will destroy it (Section 8.6). However, a cell must protect its own DNA from inadvertent destruction by its own restriction enzymes. Such protection is conferred by **modification enzymes**. Each restriction enzyme is partnered with a corresponding modification enzyme that shares the same recognition sequence. The modification enzymes chemically modify specific nucleotides in the restriction recognition sequences of the cell's own DNA. These modified sequences can no longer be cut by the corresponding restriction enzymes. Typically, modification consists of methylating specific bases within the recognition sequence, which prevents the restriction endonuclease from binding. For example, the sequences recognized by the *Eco*RI and *Eco*RV restriction enzymes (Figure 11.1a) can be modified by methylation of the two most interior adenines (Figure 11.1b). The enzymes that perform this modification are called *methylases*. If even a single strand is modified, the recognition sequence is no longer a substrate for the corresponding restriction enzyme.

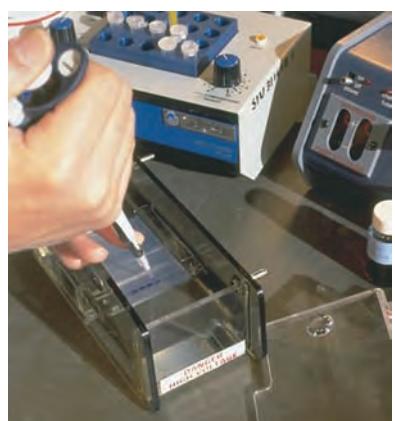

Gel Electrophoresis: Separation of DNA Molecules

In vitro manipulation of nucleic acid often requires separation of molecules based on size. For example, many restriction enzymes cut DNA molecules into segments that range in length from a few hundred to a few thousand base pairs. After the DNA is cleaved, the fragments generated can be separated from each other by **gel electrophoresis** and analyzed. Gel electrophoresis is also used to verify that amplification of a nucleic acid was successful (Section 11.3).

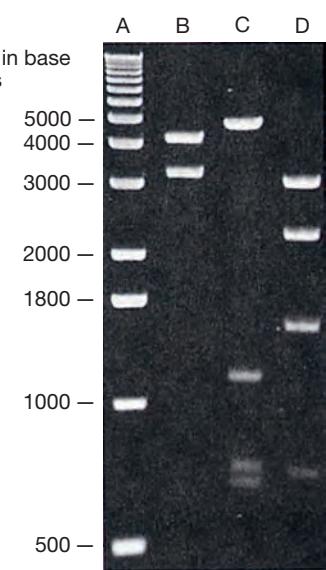

Electrophoresis is a procedure that separates charged molecules by migration in an electrical field. The rate of migration is determined by the charge on the molecule and by its size and shape. In gel electrophoresis (Figure 11.2a) the molecules are separated in a

porous gel. Gels made of *agarose*, a polysaccharide, are used for separating DNA fragments. When an electrical current is applied, nucleic acids move through the gel toward the positive electrode due to their negatively charged phosphate groups. The presence of the gel meshwork hinders the progress of the DNA, and small or compact molecules migrate more rapidly than large molecules. The higher the concentration of agarose in the gel, the greater is the resistance to movement for larger molecules. Consequently, gels of different concentrations are used to separate molecules of different size ranges.

After the gel has been run for sufficient time to separate the DNA molecules, the gel can be stained with a compound that binds to DNA, such as *ethidium bromide*, and the DNA will then

(b)

Figure 11.2 Agarose gel electrophoresis of DNA. (a) DNA samples are loaded into wells in a submerged agarose gel. (b) A photograph of a stained agarose gel. The DNA was loaded into wells toward the top of the gel (negative pole) as shown, and the positive electrode is at the bottom. The standard sample in lane A (DNA ladder) has fragments of known size that may be used to determine the sizes of the fragments in the other lanes. Bands stain less intensely at the bottom of the gel because the fragments are smaller, and thus there is less DNA to stain.

fluoresce under ultraviolet light (Figure 11.2b). To determine the size of the DNA of interest, the migration can be compared to a standard sample consisting of DNA fragments of known sizes, called a *DNA ladder*. After electrophoresis, DNA fragments can be purified from gels and used for a variety of purposes.

MINIQUIZ

- Why are restriction enzymes useful to the molecular biologist?
- What is the basis for separating DNA molecules by electrophoresis?

11.2 Nucleic Acid Hybridization

When DNA is denatured (that is, the two strands are separated), the single strands can form hybrid double-stranded molecules with other single-stranded DNA (or RNA) molecules by complementary (or almost complementary) base pairing (► Section 4.2). This is called *nucleic acid hybridization*, or **hybridization** for short, and is used in detecting, characterizing, and identifying segments of DNA and RNA.

Segments of single-stranded nucleic acids whose identity is already known and that are used in hybridization are called **nucleic acid probes** or, simply, *probes*. To allow detection, probes can be made radioactive or labeled with chemicals that are colored or yield fluorescent products (► Section 18.4). By varying the hybridization conditions, it is possible to adjust the “stringency” of the hybridization such that complementary base pairing must be nearly exact; this helps to avoid nonspecific pairing between nucleic acid sequences that are only partly complementary.

Southern and Northern Blots

Hybridization can be very useful for finding related sequences in different genomes or other genetic elements and to determine if a gene is expressed into an RNA transcript. In *Southern blotting*, probes of known sequence are hybridized to target DNA fragments that have been separated by gel electrophoresis (Section 11.1). The hybridization procedure in which DNA is the target sequence in the gel, and RNA or DNA is the probe, is called a **Southern blot**. By contrast, a **Northern blot** uses RNA as the target sequence and DNA or RNA as the probe to detect gene expression.

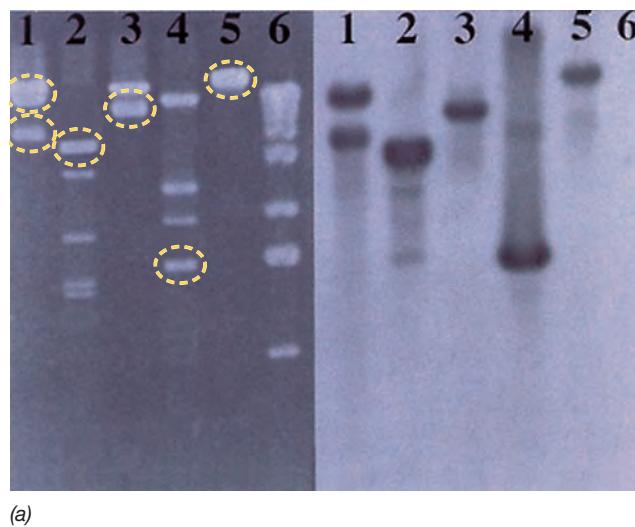

In a Southern blot the DNA fragments in the gel are first denatured to yield single strands and then transferred to a synthetic membrane. Although RNA is single-stranded, denaturant is added to the gel to prevent the formation of secondary structures (► Section 4.7). The membrane is then exposed to a labeled probe. If the probe is complementary to any of the fragments, hybrids form, and the probe attaches to the membrane at the locations of the complementary fragments. Hybridization can be detected by monitoring the labeled probe that has bound to the membrane. Figure 11.3a shows how a Southern blot can be used to identify fragments of DNA containing sequences that hybridize to the probe.

The procedure for Northern blots is analogous except that molecules of RNA instead of DNA are separated on a gel and transferred to a synthetic membrane where they are probed. Northern blotting is often used to identify messenger RNA (mRNA) derived from specific genes. The intensity of a Northern blot gives a rough estimate

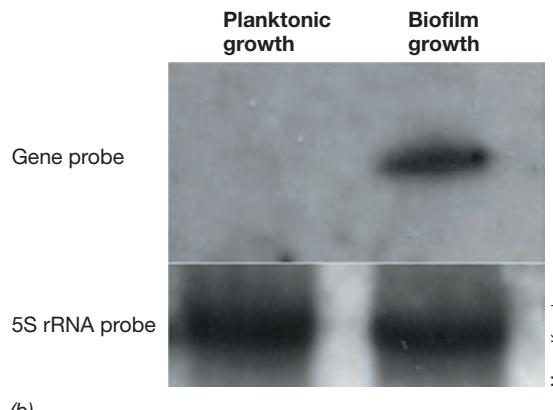

of mRNA abundance from the target gene and may therefore be used to monitor transcription (Figure 11.3b).

Other Hybridization Methods

Hybridization is often used to detect the presence of specific genes in genomes that have not yet been sequenced, as well as the movement of genetic elements such as a transposon (► Section 10.11). To find the specific genome location of a gene of interest, total genomic DNA can be cloned (Section 11.4). Hybridization on the resulting colonies using a nucleic acid probe can detect recombinant DNA in colonies, as shown in Figure 11.8a. This procedure uses *replica plating* to produce a duplicate of the master plate on a

Figure 11.3 Nucleic acid hybridization. (a) Southern blotting. (Left panel) Purified molecules of DNA from several different plasmids were treated with restriction enzymes and then subjected to agarose gel electrophoresis. (Right panel) Blot of the DNA gel shown to the left. After blotting, DNA in the gel was hybridized to a radioactive probe. The positions of the bands were visualized by X-ray autoradiography. Note that only some of the DNA fragments (circled in yellow) have sequences complementary to the labeled probe. Lane 6 contained DNA used as a size marker and none of the bands hybridized to the probe. (b) Northern blotting. (Top panel) Hybridization and detection of a radioactive gene-specific probe to a blot of total RNA. The probe only bound to RNA from biofilm-grown cells, indicating that the target gene is not expressed during planktonic (suspended) growth. (Bottom panel) Hybridization and detection of a radioactive probe corresponding to the 5S rRNA to the same blot. The signal intensity indicates that equal amounts of RNA from each sample were loaded into the gel.

Figure 11.4 Fluorescence spectral image of 28 differently labeled strains of *Escherichia coli*. Cells were labeled with combinations of fluorophore-conjugated oligonucleotides that are complementary to *E. coli* 16S rRNA.

membrane filter. The cells on the filter are lysed in place to release their DNA, and the filter is treated to separate the DNA into single strands and fix them to the filter. This filter is then exposed to a labeled nucleic acid probe to allow hybridization, and unbound probe is washed away. The filter is then overlaid with X-ray film if a radioactive probe was used. After development, the X-ray film is examined for spots. Colonies corresponding to these spots are then chosen and studied further.

Hybridization is also the basis of fluorescence *in situ* hybridization (FISH) (Section 18.4, Figure 11.4). Using this technique, a range of different fluorescent signals can be covalently linked to *oligonucleotide* (short single-stranded DNA or RNA molecules) probes to target specific DNA sequences. Such probes can be used to identify particular species or strains of bacteria by hybridizing to characteristic sequences in the genes for their 16S ribosomal RNA or to ribosomal RNA directly. This approach allows the identification of pathogens in clinical samples or bacteria of interest in environmental samples. Figure 11.4 demonstrates the simultaneous use of eight different oligonucleotide probes in combinations to distinguish between 28 different strains of *Escherichia coli* whose 16S rRNA sequences varied slightly from strain to strain. The variations in color give a visual indication of the specificity and power of nucleic acid probes.

MINIQUIZ

- What are some applications of nucleic acid hybridization in molecular biology?
- What is the difference between a Southern blot and a Northern blot?

11.3 Polymerase Chain Reaction (PCR)

The **polymerase chain reaction (PCR)** is essentially DNA replication *in vitro*. The PCR can copy segments of DNA by up to a billionfold in the test tube, a process called *amplification*. This yields large amounts of specific genes or other DNA segments

that may be used for a range of applications in molecular biology. PCR uses the enzyme DNA polymerase, which naturally copies DNA molecules (Section 4.4). Artificially synthesized oligonucleotide primers (Section 11.5) are used to initiate DNA synthesis, but are made of DNA (rather than RNA like the primers used by cells). PCR does not actually copy whole DNA molecules but amplifies stretches of up to a few thousand base pairs (the *target*) from within a larger DNA molecule (the *template*).

The steps in PCR amplification of DNA are as follows (Figure 11.5):

1. Template DNA is denatured by heating.
2. Two artificial DNA oligonucleotide primers flanking the target DNA on each strand are added in excess. This ensures that

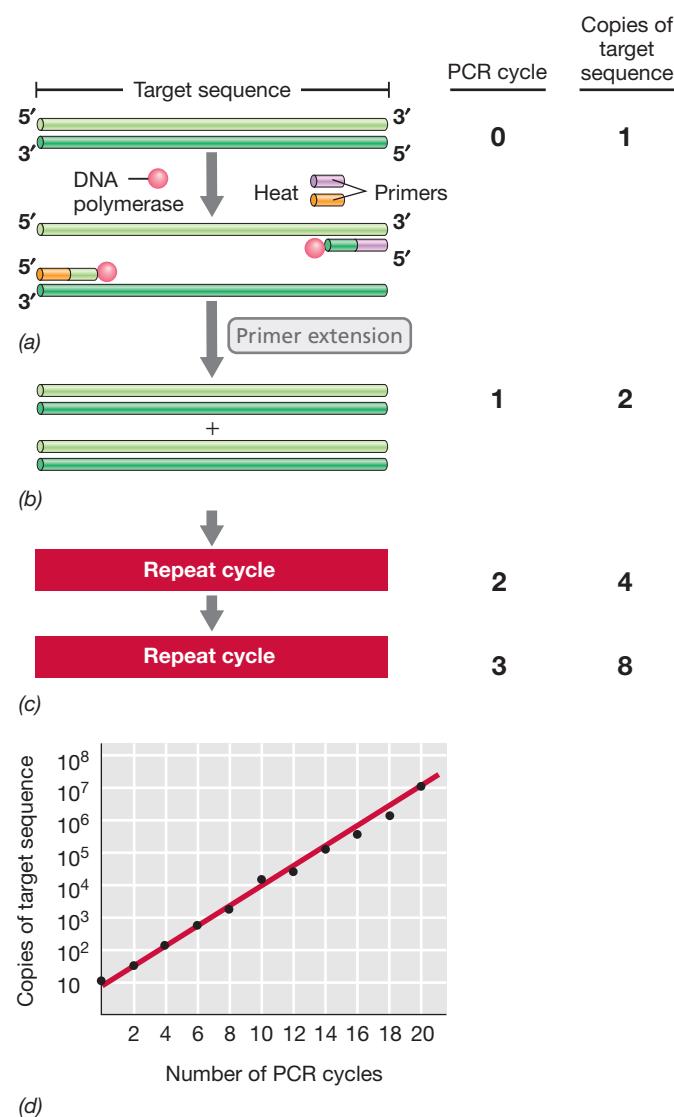

Figure 11.5 The polymerase chain reaction (PCR). The PCR amplifies specific DNA sequences. (a) Target DNA is heated to separate the strands, and a large excess of two oligonucleotide primers, one complementary to each strand, is added along with DNA polymerase. (b) Following primer annealing, primer extension yields a copy of the original double-stranded DNA. (c) Two additional PCR cycles yield four and eight copies, respectively, of the original DNA sequence. (d) Effect of running 20 PCR cycles on a DNA preparation originally containing ten copies of a target gene. Note that the plot is semilogarithmic.

most template strands anneal to a primer, and not to each other, as the mixture cools (Figure 11.5a).

3. DNA polymerase then extends the primers using the original DNA as the template (Figure 11.5b).
4. After an appropriate incubation period, the mixture is heated again to separate the strands, but now the target gene is present in twice the original amount. The mixture is then cooled to allow the primers to hybridize with complementary regions of newly synthesized DNA, and the whole process is repeated (Figure 11.5c).

PCR is a powerful tool and has revolutionized all of biology. It is easy to perform, extremely sensitive, specific, and highly efficient. During each round of amplification the amount of product doubles, leading to an exponential increase in the DNA. In practice, 20–30 cycles are usually run, yielding a 10^6 -fold to 10^9 -fold increase in the target sequence (Figure 11.5d). In just a few hours, a large amount of amplified DNA can be produced using a few molecules of initial target DNA in an automated PCR machine called a *thermocycler*. Using specific primers of 15 or so nucleotides and high annealing temperatures, PCR is so specific that there is almost no “false priming” and therefore the amplified DNA is virtually homogeneous.

PCR and Polymerases

Because high temperatures are used to denature the double-stranded copies of DNA in vitro, a thermostable DNA polymerase isolated from the thermophilic hot spring bacterium *Thermus aquaticus* (Section 15.20) is used. DNA polymerase from *T. aquaticus*, called *Taq polymerase*, is stable to 95°C and thus is unaffected by the denaturation step employed in the PCR. DNA polymerase from *Pyrococcus furiosus*, a hyperthermophile with a growth temperature optimum of 100°C (Section 16.4) is called *Pfu polymerase* and is even more thermostable than *Taq* polymerase. Moreover, unlike *Taq* polymerase, *Pfu* polymerase has proofreading activity (Section 4.6), making it especially useful when high accuracy is crucial. Thus, the error rate for *Taq* polymerase under standard conditions is 8.0×10^{-6} (per base duplicated), whereas for *Pfu* polymerase it is only 1.3×10^{-6} . To supply the commercial demand for thermostable DNA polymerases, the genes encoding these enzymes have been cloned into *Escherichia coli*, allowing the enzymes to be produced in large quantities.

PCR Applications

PCR is extremely valuable for obtaining DNA for gene cloning or for sequencing purposes because the gene or genes of interest can easily be amplified if flanking sequences are known. PCR is also used routinely in comparative or phylogenetic studies to amplify genes from various sources. In these cases the primers are made commercially to regions of the gene that are conserved in sequence across a wide variety of organisms. Because 16S rRNA, a molecule used for phylogenetic analyses, has both highly conserved and highly variable regions (Section 12.5), primers specific for the 16S rRNA gene from various taxonomic groups can be synthesized and used to survey different habitats for specific groups of organisms. This technique

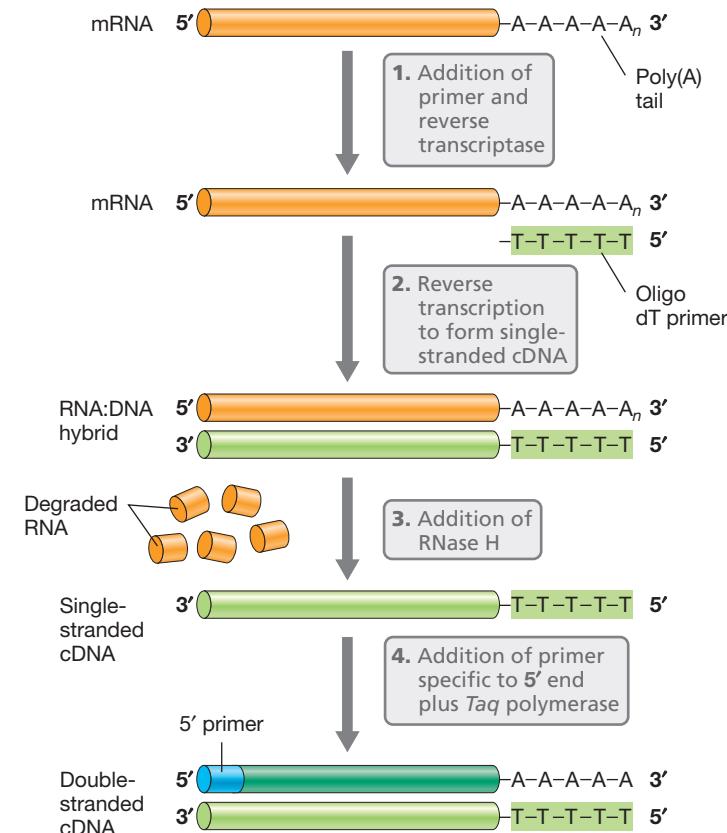

Figure 11.6 Reverse transcription PCR. Steps in the synthesis of cDNA from a eukaryotic mRNA. Reverse transcriptase synthesizes a hybrid molecule containing both RNA and DNA using the mRNA as a template and oligo-T primer as a substrate. Next, the enzyme RNaseH hydrolyzes the RNA portion of the hybrid molecule yielding a single-stranded molecule of complementary DNA (cDNA). Following the addition of a primer complementary to the 5' end of the cDNA, *Taq* polymerase produces a double-stranded cDNA.

is widely used in microbial ecology and has revealed the enormous diversity of the microbial world, much of it as yet cultured (Section 18.5).

Because it is so sensitive, PCR can be used to amplify very small quantities of DNA. For example, PCR has been used to amplify and clone DNA from sources as varied as mummified human remains and fossilized plants and animals. The ability of PCR to amplify and analyze DNA from cell mixtures has also made it a common tool of diagnostic microbiology (Section 27.10). PCR has also been used in forensics to identify humans from very small samples of their DNA.

Variations in the standard PCR procedure have been developed depending on the molecular objective. **Reverse transcription** PCR (RT-PCR) can be used to make DNA from an mRNA template (Figure 11.6). This procedure can be used to detect if a gene is expressed or to produce an intron-free eukaryotic gene for expression in bacteria as described for the hormones insulin and somatotropin in Section 11.11. RT-PCR uses the retroviral enzyme *reverse transcriptase* to convert RNA into *complementary DNA* (cDNA) (Section 9.11). To quantify the amount of initial target DNA or RNA in a sample, a procedure called *quantitative PCR* (*qPCR*) can also be used. This technique uses fluorescent

probes to monitor the amplification process (☞ Figures 27.18 and 27.19).

Figure 11.6 illustrates how reverse transcriptase makes a single strand of cDNA using RNA as a template. When making DNA using RNA as a template, a primer complementary to the 3' end of the target transcript is used by the enzyme reverse transcriptase to initiate RNA synthesis. If the template is eukaryotic mRNA, a primer complementary to the poly(A) tail (☞ Section 4.9) of the mRNA can be used. The activity of reverse transcriptase results in a hybrid nucleic acid molecule containing both DNA and RNA. RNaseH, a ribonuclease specific for the hybrid molecule, hydrolyzes the RNA, leaving the cDNA as template for standard PCR using an additional primer complementary to the 5' end. Modifications to this procedure can be made if the 5' end of the mRNA is not known.

MINIQUIZ

- Why is a primer needed at each end of the DNA segment being amplified by PCR?
- From which organisms are thermostable DNA polymerases obtained?
- How does RT-PCR differ from traditional PCR?

11.4 Essentials of Molecular Cloning

In **molecular cloning** a fragment of DNA is isolated and replicated. The basic strategy of molecular cloning is to isolate the desired gene (or other segment of DNA) from its original location and move it to a small, simple, and manipulable genetic element, such as a plasmid or virus, which is called a **vector** (Figure 11.7). Molecular cloning results in **recombinant DNA**, a DNA molecule that contains DNA from two or more sources. When the recombinant vector replicates, the cloned DNA that it contains is also replicated. Once cloned, the gene of interest can be manipulated in various ways and may eventually be inserted back into a living cell. This approach provides the foundation for much of genetic engineering and has greatly helped the detailed analysis of genomes.

The first objective of gene cloning is to isolate copies of specific genes in pure form. Consider the problem. For a genetically “simple” organism such as *Escherichia coli*, an average gene is encoded by 1–2 kbp of DNA out of a genome of over 4600 kbp (☞ Section 4.3). An average *E. coli* gene is thus less than 0.05% of the total DNA in the cell. In human DNA the problem is even greater because the coding regions of average genes are not much larger than in *E. coli* but genes are typically split into pieces and the genome is almost 1000 times larger! Nonetheless, our knowledge of DNA chemistry and enzymology allows us to routinely break, rejoin, and replicate DNA molecules *in vitro*. Restriction enzymes, DNA ligase, the polymerase chain reaction (PCR), and synthetic DNA are the key tools for molecular cloning.

Steps in Gene Cloning: A Summary

The following list outlines the sequence of events in gene cloning:

1. **Isolation and fragmentation of the source DNA.** The source DNA can be total genomic DNA from an organism of interest,

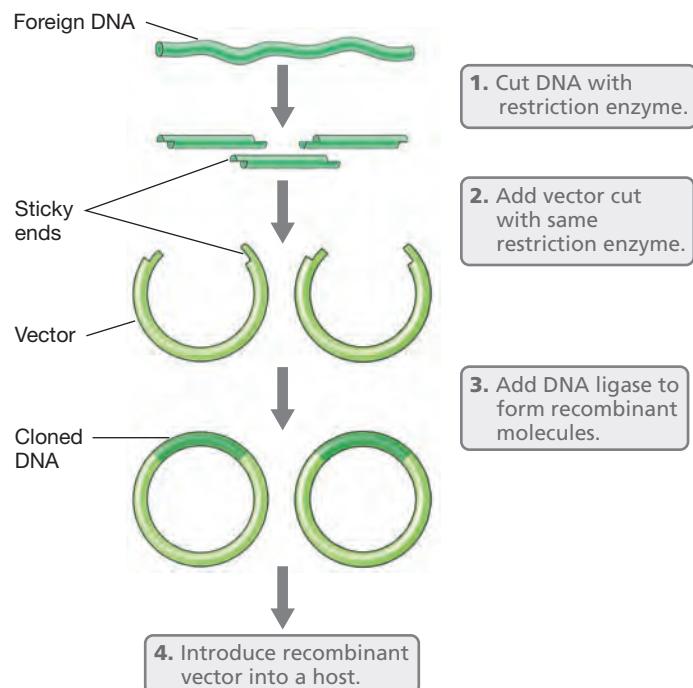

Figure 11.7 Major steps in gene cloning. The vector can be a plasmid or a viral genome. By cutting the foreign DNA and the vector DNA with the same restriction enzyme, complementary sticky ends are generated that allow foreign DNA to be inserted into the vector.

DNA synthesized from an RNA template by reverse transcriptase (Section 11.3), a gene or genes amplified by the polymerase chain reaction (Section 11.3), or even completely synthetic DNA made *in vitro* (Section 11.5). If genomic DNA is the source, it is first cut with restriction enzymes (Section 11.1) to give a mixture of fragments of manageable size (Figure 11.7).

2. Inserting the DNA fragment into a cloning vector. Cloning vectors are small, independently replicating genetic elements used to carry and replicate cloned DNA segments. Most vectors are plasmids or viruses. Cloning vectors are typically designed to allow insertion of foreign DNA at a restriction site that cuts the vector without affecting its replication (Figure 11.7). If the source DNA and the vector are both cut with the *same* restriction enzyme that yields sticky ends, joining the two molecules is greatly assisted by annealing of the complementary ends. Blunt ends generated by some restriction enzymes can be joined by direct ligation or by using synthetic DNA linkers or adapters. In either case, the strands are joined by **DNA ligase**, an enzyme that covalently links both strands of the vector and the inserted DNA. If the source DNA is PCR-generated, DNA ligase is used to join the amplified DNA to specialized vectors (see Figure 11.15).

3. Introduction of the cloned DNA into a host organism. Recombinant DNA molecules made *in vitro* are introduced into suitable host organisms where they can replicate. Transformation (☞ Section 10.6) is often used to get recombinant DNA into cells. In practice this often yields a mixture of recombinant constructs. Some cells contain the desired cloned gene, whereas other cells may contain other cloned genes from the

same source DNA. Such a mixture is known as a **genomic library** because many different clones can be purified from the mixture, each containing different cloned DNA segments from the source organism. Making a genomic library by cloning random fragments of a genome is called **shotgun cloning** and is widely used in genomic analyses as described in Section 11.15 for *genome mining*.

Finding the Right Clone

Genetic engineering often begins by cloning a gene of interest. But first it is necessary to identify the host colony containing the correct clone. One can isolate host cells containing a plasmid vector by selecting for a marker such as antibiotic resistance, so that only these cells form colonies. When using a viral vector, one simply looks for viral plaques (☞ Section 8.4). These colonies or plaques can be screened for recombinant vectors by looking for the inactivation of a vector gene due to insertion of foreign DNA (Section 11.7). When cloning a single DNA fragment generated by PCR or purified by some other means, simple selections or screenings are usually sufficient.

A genomic library may contain thousands or tens of thousands of clones, and often only one or a few may contain the genes of interest. Hence, identifying cells carrying cloned DNA is only the first step. The biggest challenge remains finding the clone carrying the gene of interest. One must examine colonies of bacteria or plaques from viral-infected cells growing on agar plates and detect those few that contain the gene of interest. This can be done by DNA sequencing or by restriction digests performed on plasmids extracted from a large number of colonies. Another approach is to use hybridization as described in Section 11.2 and as depicted in **Figure 11.8a**.

Detecting Proteins Expressed in the Cloning Host

If the foreign gene is expressed in the cloning host, the encoded protein can be screened for. For this to work, the host itself must not produce the protein being studied. Selection of cells containing cloned genes is relatively simple provided that the encoded protein can be assayed conveniently.

Antibodies can be used to detect a protein of interest. Antibodies are proteins of the immune system that bind in a highly specific way to a target molecule, the antigen (☞ Section 24.4). In this case the protein encoded by the cloned gene is the antigen. Because the antibody combines specifically with the antigen, observing the binding of the antibody can identify colonies that contain the antigen. Because very little of the antigen is present in each colony, only a small amount of antibody is bound, and so a highly sensitive procedure for detecting bound antibody must be used. In practice, radioisotopes, fluorescent chemicals, or enzymes are used. Techniques for detecting antigens are discussed in Chapter 27.

The procedure using antibody detection is outlined in **Figure 11.8b**. *Replica plating* is used to duplicate the master plate onto a synthetic membrane filter, and all further manipulations are done with this filter. The duplicate colonies are lysed to release the antigen of interest. The antibody is then added and it binds the antigen. Unbound antibody is washed off and a radioactive reagent is added that binds specifically to the antibody. A sheet of X-ray

film is placed over the filter and exposed, and radioactive colonies appear as spots on the X-ray film after it is developed (Figure 11.8b). The location of such spots corresponds to the location of a colony on the master plate that produces the protein. This colony is picked from the master plate and subcultured.

A major limitation of this procedure is that a specific antibody must be made in an experimental animal against the antigen in question. To be successful, however, the injected protein must be pure; otherwise, antibodies against multiple antigens will be formed, leading to false-positive reactions. As one might expect, such reactions make selection of the right clones very difficult.

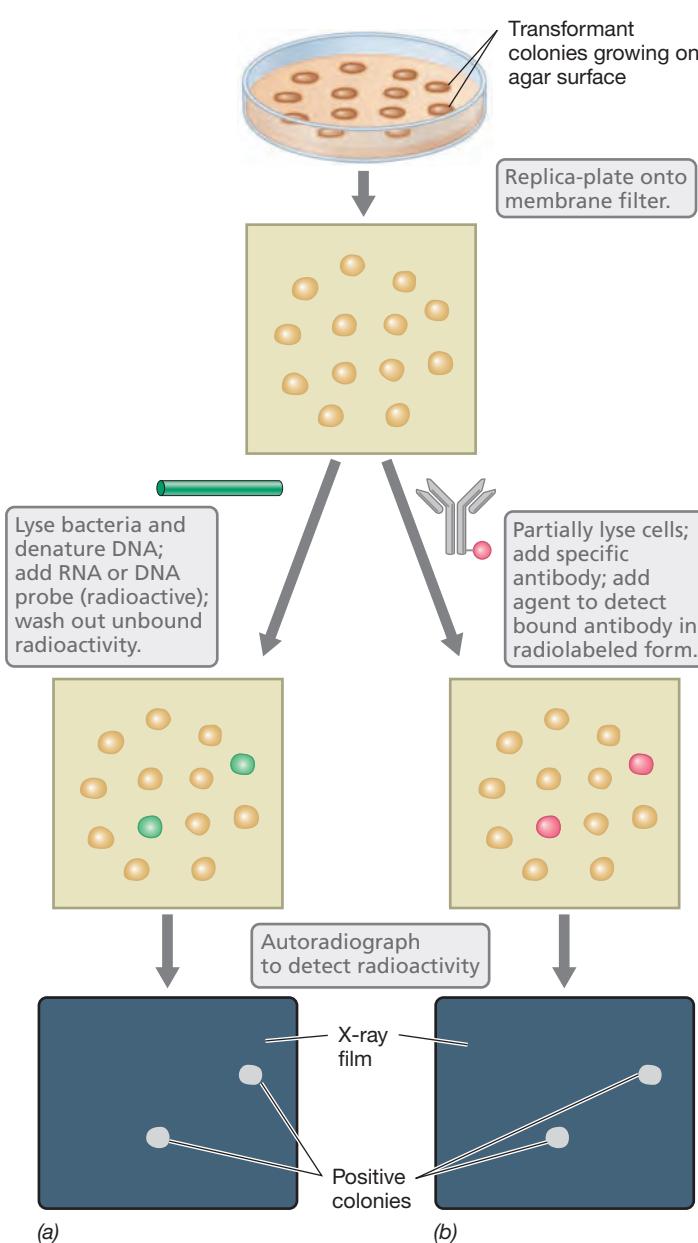

Figure 11.8 Finding the right clone. (a) Method for detecting recombinant clones by colony hybridization with a radioactive nucleic acid probe. Formation of a DNA duplex binds the DNA probe to a particular spot on the membrane. (b) Method for detecting production of protein by using a specific antibody containing a radioactive or fluorescent label.

- How may cloned genes be identified?

11.5 Molecular Methods for Mutagenesis

As we have seen, conventional mutagens introduce mutations *at random* in the intact organism (Section 10.4). In contrast, *in vitro* mutagenesis, better known as **site-directed mutagenesis**, uses synthetic DNA plus DNA cloning techniques to introduce mutations into genes *at precisely determined sites*. In addition to changing one or just a few bases, mutations may also be engineered by inserting large segments of DNA at precisely determined locations.

Synthesizing DNA

Segments of DNA may be artificially synthesized and used as primers or probes for polymerase chain reaction, hybridization, or to provide altered versions of parts of genes or regulatory regions. Oligonucleotides of 12–40 bases are commercially available and oligonucleotides of over 100 bases in length can be made if necessary. It is also possible to synthesize entire genes if they encode small proteins (less than 600 bp) such as the subunits of insulin (Section 11.11).

DNA is synthesized *in vitro* in an automated solid-phase procedure in which the first nucleotide in the chain is fastened to an insoluble support, such as tiny porous glass beads. Several steps are needed for the addition of each nucleotide, and the required chemistry is complex. After each step is completed, the reaction mixture is flushed out of the solid support and the series of reactions repeated for the addition of the next nucleotide. Once the oligonucleotide is the desired length, it is cleaved from the solid-phase support by a specific reagent and purified to eliminate by-products and contaminants.

Site-Directed Mutagenesis

Site-directed mutagenesis is a powerful tool, as it allows for a change to any base pair in a specific gene and thus has many

uses in genetics. By altering gene sequences to produce amino acid sequence changes, site-directed mutagenesis is used to manipulate protein characteristics such as enzyme activity or protein-binding affinity (Section 11.12). The basic procedure is to synthesize a short DNA oligonucleotide primer containing the desired base change (mutation) and to allow this to base-pair with single-stranded DNA containing the target gene. Pairing will be complete except for the region of mismatch. Then the synthetic oligonucleotide is extended using DNA polymerase, thus copying the rest of the gene, and the double-stranded molecule is inserted into a host cell by transformation. Mutants are often selected by positive selection, such as antibiotic resistance; in this case, the mutated DNA would also carry a nearby antibiotic resistance marker.

One procedure for site-directed mutagenesis is illustrated in Figure 11.9. The process starts with cloning the target gene into a plasmid vector. The double-stranded vector is then denatured to yield single-stranded DNA and allow for the mutagenized oligonucleotide to bind by base-pairing with the target gene. After extension by DNA polymerase, the DNA molecule contains one strand with the mismatch. After transformation into host cells, vector DNA replication, and cell division, both daughter molecules will be fully base paired but one daughter molecule will carry the mutation and the other will be wild type. Progeny bacteria are then screened for those with the mutation.

Site-directed mutagenesis may also be carried out using PCR. In this case, the short DNA oligonucleotide with the required mutation is used as a PCR primer. The mutation-carrying primer is designed to anneal to the target with the mismatch in the middle and must have enough matching nucleotides on both sides for binding to be stable during the PCR reaction. The mutant primer is then paired with a normal primer, and when the PCR reaction amplifies the target DNA, it incorporates the mutation(s) into the final amplified product.

Applications of Site-Directed Mutagenesis

Site-directed mutagenesis can be used to investigate the activity of proteins with known amino acid substitutions. For example,

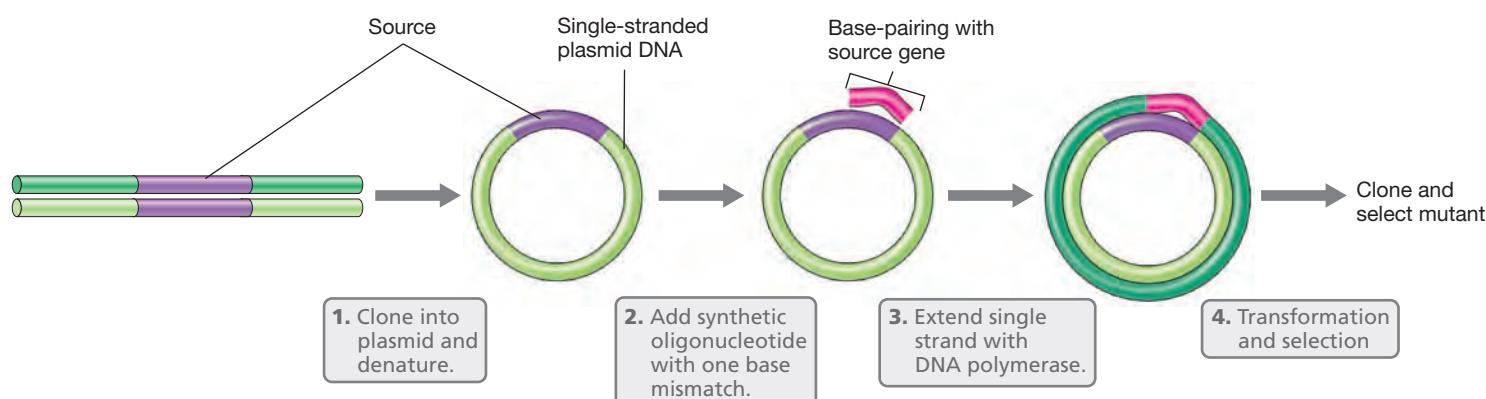

Figure 11.9 Site-directed mutagenesis using synthetic DNA. Short synthetic oligonucleotides may be used to generate mutations. Cloning the source DNA into a plasmid followed by denaturation yields the single-stranded DNA needed for site-directed mutagenesis to work.

suppose one was studying the active site of an enzyme. Site-directed mutagenesis could be used to change a specific amino acid in the active site, and the modified enzyme would then be assayed and compared to the wild-type enzyme. In such experiments, the vector encoding the mutant enzyme is inserted into a mutant host strain unable to make the original enzyme. Consequently, the activity measured is due to the mutant version of the enzyme alone.

Using site-directed mutagenesis, enzymologists can link virtually any aspect of an enzyme's activity, such as catalysis, resistance, or susceptibility to chemical or physical agents, or interactions with other proteins, to specific amino acids in the protein. In a genetic engineering example, site-directed mutagenesis has allowed scientists to alter the receptor-binding affinity of the bovine growth hormone somatotropin so that it only stimulates growth and not milk production in humans (Section 11.12).

Cassette Mutagenesis and Gene Disruption

To make more than a few base-pair changes or replace sections of a gene of interest, synthetic fragments called **DNA cassettes** (or cartridges) can be used to mutate DNA in a process known as **cassette mutagenesis**. These cassettes can be synthesized using the polymerase chain reaction or by direct DNA synthesis. The cassette can then replace sections of the DNA of interest using restriction sites. However, if sites for the appropriate restriction enzyme are not present at the required location, they can be inserted by site-directed mutagenesis as shown in Figure 11.9. Cassettes used to replace sections of genes are typically the same size as the wild-type DNA fragments they replace.

Another type of cassette mutagenesis is called **gene disruption**. In this technique, cassettes are inserted into the middle of a gene, thus disrupting the coding sequence. Cassettes used for making insertion mutations can be almost any size and can even carry an entire gene. To facilitate selection, cassettes that encode antibiotic resistance are commonly used. The process of gene disruption is illustrated in Figure 11.10. In this case, a DNA cassette carrying a gene conferring kanamycin resistance (the Kan cassette) is inserted at a restriction site in a cloned gene. The vector carrying the disrupted gene is then linearized by cutting with a different restriction enzyme to prevent replication. Finally, the linear DNA is transformed into the host, and kanamycin resistance is selected. The linear plasmid cannot replicate, and so resistant cells arise mostly by homologous recombination (Section 10.5) between the mutated gene on the plasmid and the wild-type gene on the chromosome.

Note that when a cassette is inserted, the cells not only gain antibiotic resistance but also *lose the function of the gene* into which the cassette is inserted. Such mutations are called **knockout mutations**. These are similar to insertion mutations made by transposons (Section 10.11), but here the experimenter chooses which gene will be mutated. Knockout mutations in haploid organisms (such as prokaryotes) yield viable cells only if the disrupted gene is nonessential. Indeed, the generation of gene knockouts is frequently used to investigate whether a given gene is essential.

- Why is a solid support used during chemical synthesis of DNA?
- How can site-directed mutagenesis be useful to enzymologists?
- What are knockout mutations?

11.6 Gene Fusions and Reporter Genes

DNA manipulation has revolutionized the study of gene regulation. A coding sequence from one source (the *reporter*) may be fused to a regulatory region from another source to form a hybrid gene. Such gene fusions are often used in studying gene regulation (Section 7.1), especially where assaying the levels of the natural gene product is difficult, expensive, or time consuming. Fusions may also be used to increase expression of a desired gene product.

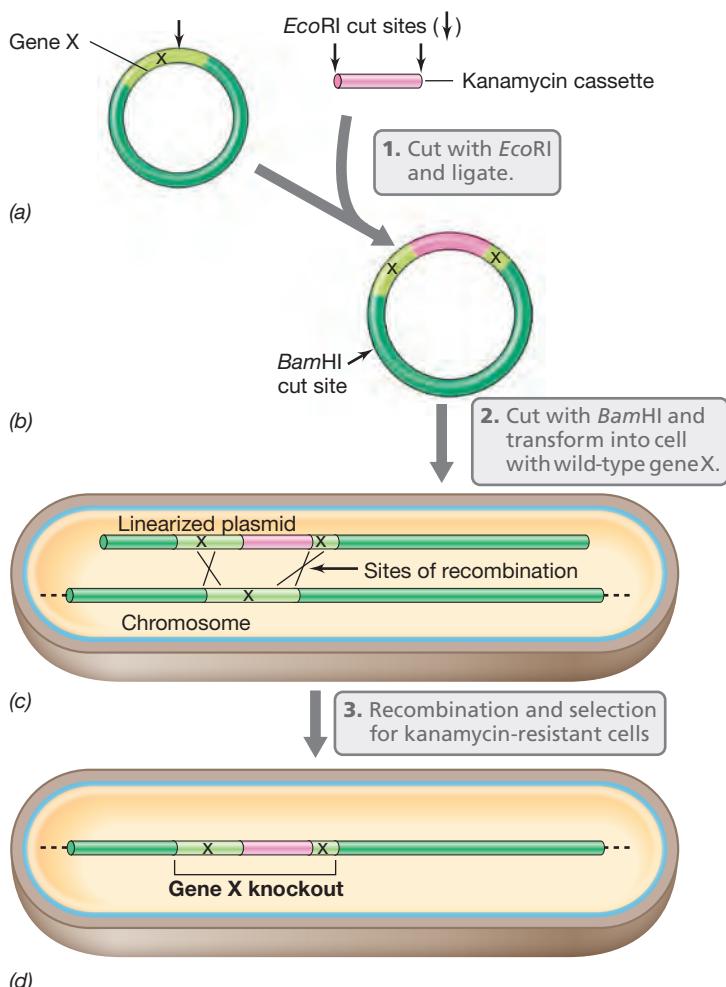

Figure 11.10 Gene disruption by cassette mutagenesis. (a) A cloned wild-type copy of gene X, carried on a plasmid, is cut with EcoRI and mixed with the kanamycin cassette. (b) The cut plasmid and the cassette are ligated, creating a plasmid with the kanamycin cassette as an insertion mutation within gene X. This new plasmid is cut with BamHI and transformed into a cell. (c) The transformed cell contains the linearized plasmid with a disrupted gene X and its own chromosome with a wild-type copy of the gene. (d) In some cells, homologous recombination occurs between the wild-type and mutant forms of gene X. Cells that can grow in the presence of kanamycin have only a single, disrupted copy of gene X.

Reporter Genes

The key property of a **reporter gene** is that it encodes a protein that is easy to detect and assay. Reporter genes are used for a variety of purposes. They may be used to report the presence or absence of a particular genetic element (such as a plasmid) or DNA inserted within a vector. They can also be fused to other genes or to the promoter of other genes so that gene expression can be studied.

The first gene to be used widely as a reporter was the *Escherichia coli* gene *lacZ*, which encodes the enzyme β -galactosidase, required for lactose catabolism (Section 7.3). Cells expressing β -galactosidase can be detected easily by the color of their colonies on indicator plates that contain the artificial substrate Xgal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside); Xgal is cleaved by β -galactosidase to yield a blue color (see Figure 11.14). The **green fluorescent protein (GFP)** is widely used as a reporter (Figure 11.11). Although the gene for GFP was originally cloned from the jellyfish *Aequorea victoria*, GFP may be expressed in most cells as it is stable and causes little or no disruption of host cell metabolism. If expression of a cloned gene is linked to the expression of GFP, the latter signals (reports) that the cloned gene has also been expressed (Figure 11.11).

Gene Fusions

It is possible to engineer constructs that consist of segments from two different genes. Such constructs are called **gene fusions**. If the promoter that controls a coding sequence is removed, the coding sequence can be fused to a different regulatory region to place the gene under the control of a different promoter. Alternatively, the promoter region can be fused to a gene whose product is easy to assay. There are two different types of gene fusions. In **operon fusions**, a coding sequence that retains its own translational start site and signals is fused to the transcriptional signals of another gene. In **protein fusions**, genes that encode two different proteins

Jason A. Kahn and Pamela A. Silver

Figure 11.11 Green fluorescent protein (GFP). GFP can be used as a tag for protein localization in vivo. In this example, the gene encoding Pho2, a DNA-binding protein from the yeast *Saccharomyces cerevisiae*, was fused to the gene encoding GFP and photographed by fluorescence microscopy. The recombinant gene was transformed into budding yeast cells. These expressed the fluorescent fusion protein localized in the nucleus.

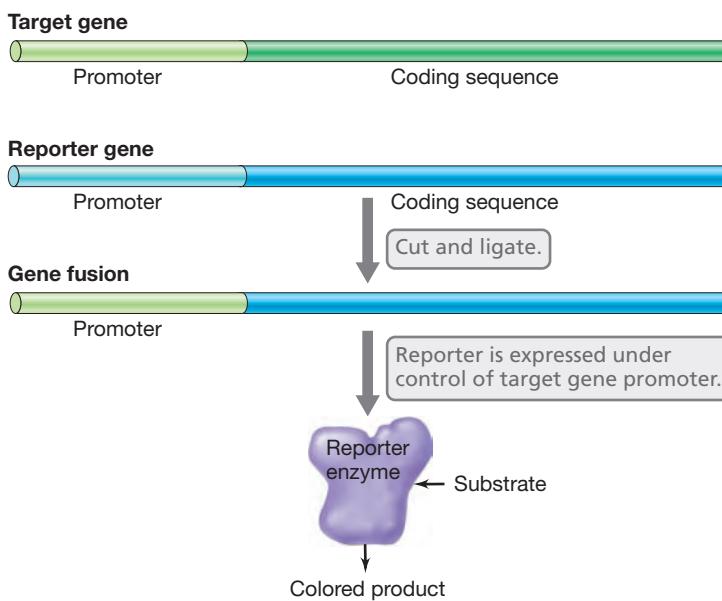

Figure 11.12 Construction and use of gene fusions. The promoter of the target gene is fused to the reporter coding sequence. Consequently, the reporter gene is expressed under those conditions where the target gene would normally be expressed. The reporter shown here is an enzyme (such as β -galactosidase) that converts a substrate to a colored product that is easy to detect. This approach greatly facilitates the investigation of regulatory mechanisms.

are fused together so that they share the same transcriptional and translational start and stop signals. Following translation, protein fusions yield a single hybrid polypeptide.

Gene fusions are often used in studying gene regulation, especially if measuring the levels of the natural gene product is difficult, expensive, or time consuming. The regulatory region of the gene of interest is fused to the coding sequence for a reporter gene, such as that for β -galactosidase or GFP. The reporter is then made under the conditions that would trigger expression of the target gene (Figure 11.12). The expression of the reporter is assayed under a variety of conditions to determine how the gene of interest is regulated (Section 7.1). *Transcriptional control* is assayed by fusing the transcriptional start signals of the gene of interest to a reporter gene, whereas *translational control* is assayed by fusing translational start signals of a gene of interest to a reporter gene under the control of a known promoter.

Gene fusions may also be used to test for the effects of regulatory genes. Mutations that affect regulatory genes are introduced into cells carrying gene fusions, and expression is measured and compared to cells lacking the regulatory mutations. This allows the rapid screening of multiple regulatory genes that are suspected of controlling the target gene. Besides using fusions to monitor for the presence or expression of a gene, proteins that are easily purified can also be fused to proteins of interest to aid in purification (Section 11.11).

MINIQUIZ

- What is a reporter gene?
- Why are gene fusions useful in studying gene regulation?

II • Gene Cloning

A major step in genetic engineering is the manipulation of DNA for cloning purposes. Cloning allows the genetic engineer to isolate genes of interest away from their host genomes and insert them into carrier molecules where they can be more easily manipulated or otherwise studied.

11.7 Plasmids as Cloning Vectors

The replication of plasmids in their host cell proceeds independently of chromosomal control. In addition to encoding genes required for their own replication, most plasmids are natural vectors because they often encode other genes that confer important properties on their hosts (☞ Section 4.3). As discussed below, certain plasmids have other very useful properties as *cloning vectors*.

Although conjugative plasmids are transferred by cell-to-cell contact in nature (☞ Section 10.8), most plasmid cloning vectors have been genetically modified to abolish conjugative transfer. This prevents unwanted movement of the vector into other organisms. However, vector transfer in the laboratory can be accomplished by chemically mediated transformation or electroporation (☞ Section 10.6). Depending on the host–plasmid system, replication of the plasmid may be under tight control, in which case only a few copies are made, or under relaxed control, in which case a large number of copies are made. Obtaining a high copy number is often important in gene cloning, and by proper selection of the host–plasmid system and manipulation of cellular macromolecule synthesis, plasmid copy numbers of several thousand per cell can be obtained.

An Example of a Cloning Vector: The Plasmid pUC19

While the first plasmid cloning vectors used were natural isolates, vectors currently used in molecular biology have been genetically engineered to show specific properties. For example, widely used cloning vectors are derivatives of the plasmid pUC19 (Figure 11.13). This plasmid was derived in several steps from a ColE1 toxin-encoding plasmid (☞ Section 4.3) by removing the colicin genes and inserting genes for ampicillin resistance and for a blue–white color-screening system (see below). A short segment of artificial DNA containing cut sites for many restriction enzymes, called a *multiple cloning site* (MCS), was also inserted into the *lacZ* gene in pUC19; *lacZ* encodes the lactose-degrading enzyme β -galactosidase (☞ Section 7.3). The presence of the short MCS does not inactivate *lacZ*, and cut sites for restriction enzymes present in the MCS are absent from the rest of the vector. Consequently, treatment with each of these restriction enzymes opens the vector at a unique location but does not cut the vector into multiple pieces.

Plasmid pUC19 displays a number of other characteristics that make it ideal as a cloning vehicle:

1. It is relatively small, only 2686 base pairs, which makes the DNA easier to isolate and manipulate.
2. It is stably maintained in its host (*E. coli*) in relatively high copy number, about 50 copies per cell.

3. It can be amplified to a very high number (1000–3000 copies per cell, about 40% of the cellular DNA) if necessary by inhibiting protein synthesis with the antibiotic chloramphenicol.
4. It is easy to isolate in the supercoiled form.
5. Moderate amounts of foreign DNA can be inserted, although inserts of more than 10 kilobase pairs lead to plasmid instability.
6. The complete base sequence of the plasmid is known, allowing identification of all restriction enzyme cut sites.
7. The MCS contains single cut sites for over a dozen restriction enzymes, thus increasing the versatility of the vector.
8. It has a gene conferring ampicillin resistance. This permits ready selection of host cells containing the plasmid because such hosts gain resistance to the antibiotic.
9. It can be inserted into cells easily by transformation.
10. Insertion of foreign DNA into the MCS can be detected by blue–white screening (see below) because of *lacZ*.

Cloning Genes into Plasmid Vectors

The use of plasmid vectors such as pUC19 in gene cloning is shown in Figure 11.14. A suitable restriction enzyme with a cut site within the MCS is chosen. Both the vector and the foreign DNA to be cloned are cut with this enzyme. The vector is linearized, and segments of the foreign DNA are inserted into the open cut site and ligated into position with the enzyme DNA ligase. This

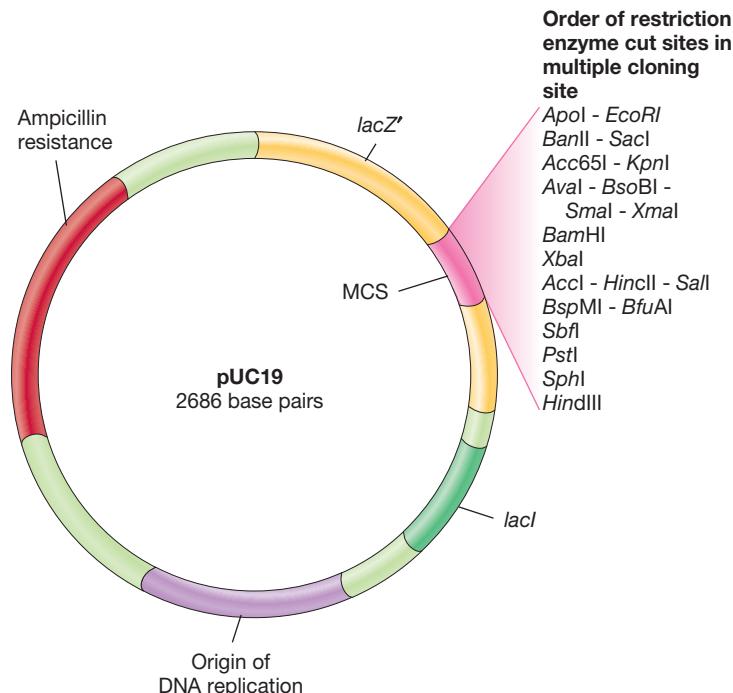

Figure 11.13 Cloning vector plasmid pUC19. Essential features include an ampicillin resistance marker and the multiple cloning site (MCS) with multiple restriction enzyme cut sites. Insertion of cloned DNA within the MCS inactivates the truncated *lacZ'* gene that encodes part of β -galactosidase and allows for easy identification of transformants by blue–white screening.

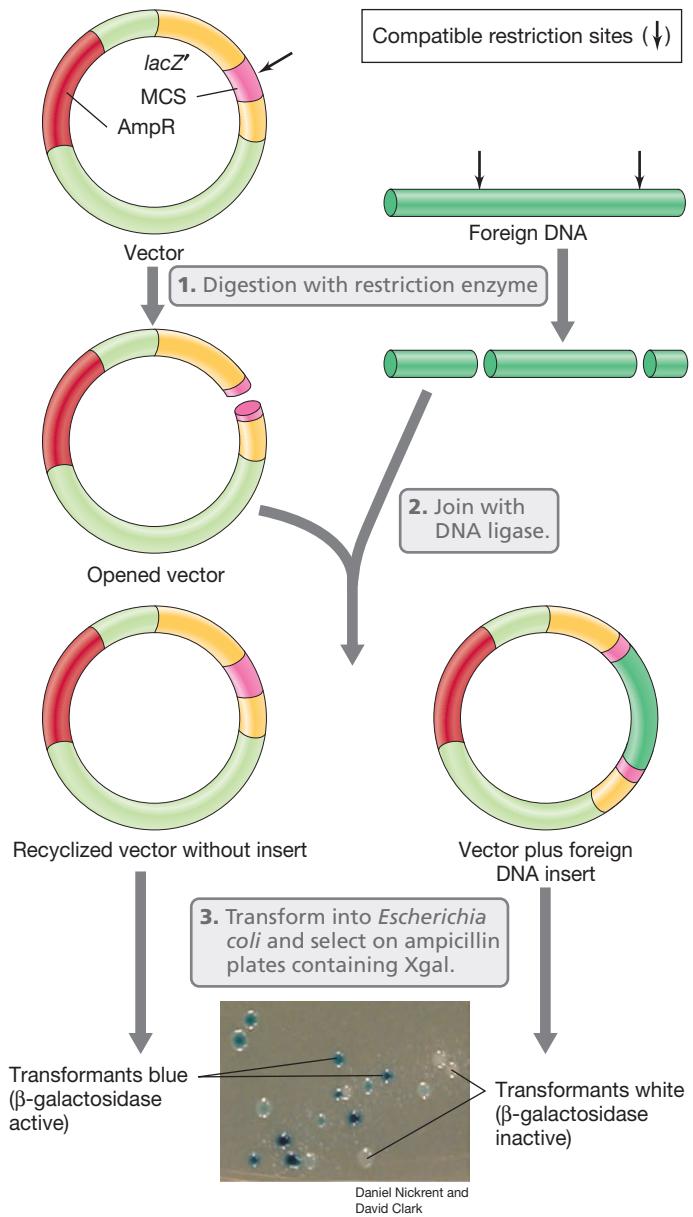

Figure 11.14 Cloning into the plasmid vector pUC19. The cloning vector and foreign DNA are cut with compatible restriction enzymes at positions indicated by the arrows. Insertion of DNA inactivates β -galactosidase, allowing blue-white screening for the presence of the insert. The photo on the bottom shows colonies of *Escherichia coli* on an Xgal plate. The enzyme β -galactosidase can cleave the normally colorless Xgal to form a blue product. AmpR, gene encoding ampicillin resistance.

disrupts the *lacZ* gene, a phenomenon called *insertional inactivation*, and is used to detect the presence of foreign DNA within the vector or recombinant vector. When the colorless reagent Xgal is added to the medium, β -galactosidase cleaves it, generating a blue product. Thus, cells containing the vector *without* cloned DNA form blue colonies, whereas cells containing the vector *with* an insert of cloned DNA do not form β -galactosidase and are therefore white.

After DNA ligation, the resulting plasmids are transformed into cells of *E. coli*. The colonies are selected on media containing both ampicillin, to select for the presence of the plasmid,

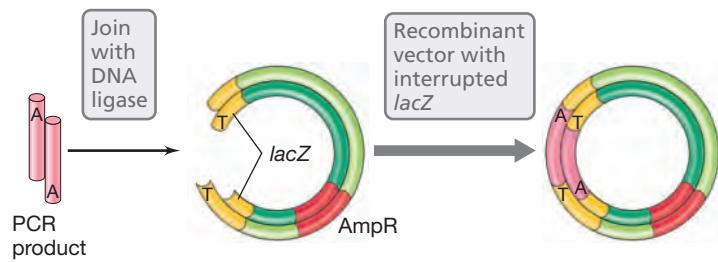

Figure 11.15 PCR vector. The linearized cloning vector contains overhanging thymine residues that base-pair with the adenine residues present on the 3' ends of *Taq*-polymerase-generated PCR. Ligation of the two pieces of DNA yields a circular plasmid containing an interrupted *lacZ*. AmpR, gene encoding ampicillin resistance.

and Xgal, to test for β -galactosidase activity. Those colonies that are *blue* contain the plasmid without any inserted foreign DNA (i.e., the plasmid merely recycled without picking up foreign DNA), whereas those colonies that are *white* contain plasmid with inserted foreign DNA and are picked for further analyses (see Figure 11.20b for a related example of the blue–white selection system).

Other Plasmid Vectors

Many subsequent plasmid vectors have been developed that include features similar to those of pUC19 listed above but also show other desirable features. For example, some vectors have been developed specifically for cloning DNA products synthesized by *Taq* polymerase in a polymerase chain reaction (PCR) (Section 11.3). The enzymatic activity of *Taq* polymerase adds a template-independent adenine residue to the 3' ends of its products. Commercial linearized vectors are available that contain overhanging thymidine residues that allow for base-pairing with the PCR product and subsequent ligation using DNA ligase (Figure 11.15).

Other vectors have been designed to directly select for recombinant vectors through cell viability rather than by screening. For example, a vector with an MCS containing a toxin gene can be designed. Without insertion of foreign DNA into the MCS that interrupts the toxin gene, the vector encodes a protein that is lethal to the host cell. Therefore, only cells containing a recombinant plasmid in which the toxin gene has been inactivated can grow.

Cloning using plasmid vectors is versatile and widely used in genetic engineering, particularly when the fragment to be cloned is fairly small. Also, plasmids are often used as cloning vectors if expression of the cloned gene is desired, since regulatory genes can be engineered into the plasmid to obtain expression of the cloned genes under specific conditions (Section 11.9).

MINIQUIZ

- Explain why it is necessary in cloning to use a restriction enzyme that cuts the vector in only one location.
- What is a multiple cloning site?
- What is insertional inactivation?

11.8 Hosts for Cloning Vectors

To produce large amounts of cloned DNA, an ideal host should grow rapidly in an inexpensive culture medium. Ideally, the host should be nonpathogenic, be easy to transform with engineered DNA, be genetically stable in culture, and have the appropriate enzymes to allow replication of the vector. It is also helpful if considerable background information on the host and a wealth of tools for its genetic manipulation exist.

The most useful hosts for cloning are microorganisms that are easily grown and for which we have much information. These include the bacteria *Escherichia coli* and *Bacillus subtilis*, and the yeast *Saccharomyces cerevisiae* (Figure 11.16). Complete genome sequences are available for all of these organisms, and they are widely used as cloning hosts. However, in some cases other hosts and specialized vectors may be necessary to get the DNA properly cloned and expressed.

Prokaryotic Hosts

Although most molecular cloning has been done in *E. coli* (Figure 11.16), this host has a few disadvantages. *E. coli* is an excellent choice for initial cloning work, but it is problematic as an expression host because it is found in the human intestine and some wild-type strains are potentially harmful (see Section 31.12). However, several modified *E. coli* strains have been developed specifically for cloning purposes, and thus *E. coli* remains the organism of choice for most molecular cloning. A major problem with using any bacterial host, including *E. coli*, is the lack of systems to correctly modify eukaryotic proteins; this problem may be solved by using eukaryotic host cells, as discussed below.

Another problem with using *E. coli* is that, like all gram-negative bacteria, it has an outer membrane that hinders protein secretion. This issue may be resolved by using the gram-positive organism *B. subtilis* as a cloning host (Figure 11.16). Although the technology for cloning in *B. subtilis* is less advanced than

for *E. coli*, several plasmids and phages suitable for cloning have been developed, and transformation is a well-developed procedure in *B. subtilis*. The main disadvantage of using *B. subtilis* as a cloning host is plasmid instability. It is often difficult to maintain plasmid replication over many subcultures of the organism. Also, foreign DNA is not as well maintained in *B. subtilis* as in *E. coli*; thus the cloned DNA is often unexpectedly lost.

Often host organisms for cloning must have specific genotypes to be effective. For instance, if the cloning vector uses the *lacZ* gene for screening, then the host must either naturally lack *lacZ* or carry a mutation that has disabled this gene. These types of considerations and others, such as the ease of selection of transformants, must be taken into account when choosing a cloning host.

Eukaryotic Hosts

Cloning in eukaryotic microorganisms has focused on the yeast *S. cerevisiae* (Figure 11.16). Plasmid vectors as well as artificial chromosomes (Section 11.10) have been developed for yeast. One important advantage of eukaryotic cells as hosts for cloning vectors is that they already possess the complex RNA and post-translational processing systems required for the production of eukaryotic proteins. Thus these systems do not have to be engineered into the vector or host cells as would be required if cloned eukaryotic DNA was to be expressed in a prokaryotic host.

For many applications, gene cloning in mammalian cells has been done. Cultured mammalian cells can be handled in some ways like microbial cultures, and are widely used in research on human genetics, cancer, infectious disease, and physiology. A disadvantage of using mammalian cells is that they are expensive and difficult to produce under large-scale conditions. Insect cell lines are simpler to grow, and vectors have been developed from an insect DNA virus, the baculovirus. For some applications, in particular for plant agriculture, the cloning host can be a culture line of plant cell tissue or even an entire plant. Indeed, genetic engineering has many applications in plant agriculture that will be discussed in Section 11.13. Regardless of eukaryotic host type, it is necessary to get the vector DNA into the host cells. Techniques to transfer DNA into eukaryotic cells are not discussed here, but they include transfection (see Figure 11.28), microinjection, and electroporation.

MINIQUIZ

- Why does molecular cloning require a host?
- When would it be beneficial to use a eukaryotic host for molecular cloning?

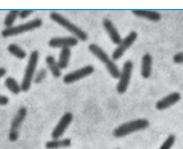

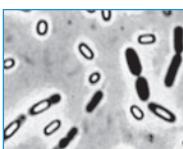

Bacteria			Eukaryote
<i>Escherichia coli</i>	<i>Bacillus subtilis</i>	<i>Saccharomyces cerevisiae</i>	
			
Well-developed genetics Many strains available Best-known bacterium	Easily transformed Nonpathogenic Naturally secretes proteins Endospore formation simplifies culture	Well-developed genetics Nonpathogenic Can process mRNA and proteins Easy to grow	
Advantages			Disadvantages
Potentially pathogenic Periplasm traps proteins	Genetically unstable Genetics less developed than in <i>E. coli</i>	Plasmids unstable Will not replicate most bacterial plasmids	

Figure 11.16 Hosts for molecular cloning. A summary of the advantages and disadvantages of some common cloning hosts.

11.9 Shuttle Vectors and Expression Vectors

Cloned genes are used for a variety of purposes. To facilitate some of the most common uses, specialized vectors have been engineered for moving cloned genes between organisms of different species or to optimize expression of cloned genes in a given host; these are called *shuttle vectors* and *expression vectors*, respectively.

Shuttle Vectors

Vectors that can replicate and are stably maintained in two (or more) unrelated host organisms are called **shuttle vectors**. Genes carried by a shuttle vector can thus be moved between unrelated organisms. Shuttle vectors have been developed that replicate in both *Escherichia coli* and *Bacillus subtilis*, *E. coli* and yeast, and *E. coli* and mammalian cells, as well as in many other pairs of organisms. The importance of a shuttle vector is that it allows for DNA to be easily cloned in a genetically manipulable organism and yields a recombinant vector that can replicate in a second host without any vector modifications.

Many shuttle vectors have been designed to move genes between *E. coli* and yeast. Bacterial plasmid vectors were the starting point and were modified to function in yeast as well. Because bacterial origins of replication do not function in eukaryotes, it is necessary to provide a yeast replication origin. One bonus is that DNA sequences of replication origins are similar in different eukaryotes, so the yeast origin functions in higher organisms as well. When eukaryotic cells divide, the duplicated chromosomes are pulled apart by microtubules (“spindle fibers”) attached to their centromeres (☞ Section 2.20). Consequently, shuttle vectors for eukaryotes must contain a segment of DNA from the centromere in order to be properly distributed at cell division (Figure 11.17). Luckily, the yeast centromere recognition sequence, the CEN sequence, is relatively short and easy to insert into shuttle vectors.

Another requirement is a convenient marker to select for the plasmid in yeast. Unfortunately, yeast is not susceptible to most antibiotics that are effective against bacteria. In practice, yeast host strains are used that are defective in making a particular amino acid or purine or pyrimidine base. A functional copy of the

biosynthetic gene that is defective in the host is inserted into the shuttle vector. For example, if the *URA3* gene, needed for synthesis of uracil, is used, the yeast will not grow in the absence of uracil unless it gains a copy of the shuttle vector.

Expression Vectors

Organisms have complex regulatory systems, and cloned genes are often expressed poorly or not at all in a foreign host cell. This problem is tackled by using **expression vectors** that are designed to allow the experimenter to control the expression (transcription and translation) of cloned genes. Generally, the objective is to obtain high levels of expression, especially in biotechnological applications. However, when dealing with potentially toxic gene products, a low but strictly controlled level may be appropriate.

Expression vectors contain regulatory sequences that allow manipulation of gene expression. Usually the control is transcriptional because for high levels of expression it is essential to produce high levels of mRNA. In practice, high levels of transcription require strong promoters that bind RNA polymerase efficiently (☞ Section 4.7). However, the native promoter of a cloned gene may work poorly in the new host. For example, promoters from eukaryotes or even from other bacteria function poorly or not at all in *E. coli*. Indeed, even some *E. coli* promoters function at low levels in *E. coli* because their sequences match the promoter consensus poorly and bind RNA polymerase inefficiently (☞ Section 4.7).

For this reason, expression vectors must contain a promoter that functions efficiently in the host and one that is correctly positioned to control transcription of the cloned gene. Promoters from *E. coli* that are used in expression vectors include *lac* (the *lac* operon promoter), *trp* (the *trp* operon promoter), and *tac* and *trc* (synthetic hybrids of the *trp* and *lac* promoters). These are all “strong” promoters in *E. coli*, and in addition they can be specifically regulated.

Regulation of Transcription from Expression Vectors

Although producing very high levels of mRNA and having this translated into large amounts of protein is often desirable, massive overproduction of foreign proteins can damage the host cell. Therefore, it is important to regulate the expression of cloned genes. Often, in order to avoid damaging the host cells, the culture containing the expression vector is grown without expression of the foreign gene. Then, once a large population of healthy cells is obtained, expression of the cloned gene(s) is triggered by a *genetic switch*.

Regulating transcription by a repressor protein (☞ Section 7.3) is a useful way to control a cloned gene. A strong repressor can completely block the synthesis of the proteins under its control by binding to the operator. When gene expression is required, the inducer is added. The repressor binds the inducer and is released from the DNA, thus allowing transcription of the regulated genes. The expression vector is designed such that the cloned gene is inserted just downstream from the chosen promoter and operator region. A strong ribosome-binding site is often included between the promoter and the cloned gene to allow for efficient translation. The overall result is control of the cloned gene by the chosen promoter together with efficient transcription and translation.

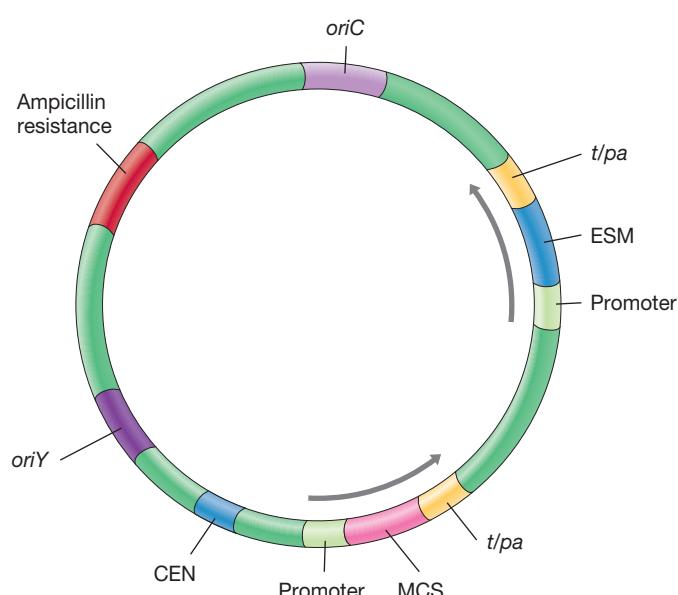

Figure 11.17 Genetic map of a shuttle vector used in yeast. The vector contains components that allow it to shuttle between *Escherichia coli* and yeast and be selected in each organism: *oriC*, origin of replication in *E. coli*; *oriY*, origin of replication in yeast; MCS, multiple cloning site; ESM, eukaryotic selectable marker; CEN, yeast centromere sequence; promoter; *t/pa*, transcription termination/polyadenylation signals. Arrows indicate the direction of transcription.

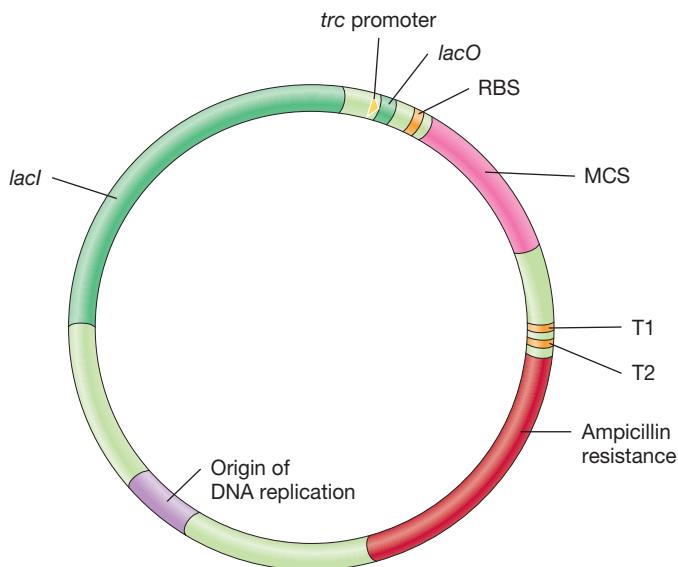

Figure 11.18 Genetic map of the expression vector pSE420. This vector was developed by Life Technologies Corp., a biotechnology company. The MCS (multiple cloning site) contains many different restriction enzyme recognition sequences to facilitate cloning. This region, plus the inserted cloned gene, are transcribed by the *trc* promoter, which is immediately upstream of the *lac* operator (*lacO*). Immediately upstream of the MCS is a sequence that encodes a ribosome-binding site (RBS) on the resulting mRNA. Downstream of the MCS are two transcription terminators (T1 and T2). The plasmid also contains the *lacI* gene, which encodes the *lac* repressor, and a gene conferring resistance to the antibiotic ampicillin. These two genes are under the control of their own promoters, which are not shown.

Figure 11.18 shows an expression vector controlled by *trc* (*trp* promoter and *lac* operator). This plasmid also contains a copy of the *lacI* gene that encodes the *lac* repressor. The level of repressor in a cell containing this plasmid is sufficient to prevent transcription from the *trc* promoter until inducer is added. Addition of lactose or related *lac* inducers triggers transcription of the cloned DNA. In addition to a strong and easily regulated promoter, most expression vectors contain an effective transcription terminator (Section 4.7). This prevents transcription from the strong cloning promoter continuing on into other genes on the vector, which would interfere with vector stability. The expression vector shown in Figure 11.18 has strong transcription terminators in order to halt transcription immediately downstream from the cloned gene.

Regulating Expression with Bacteriophage

T7 Control Elements

In some cases the transcriptional control system may not be a normal part of the host at all. An example of this is the use of the bacteriophage T7 promoter and T7 RNA polymerase to regulate gene expression. When T7 infects *E. coli*, it encodes its own RNA polymerase that recognizes only T7 promoters (Section 9.4). In T7 expression vectors, cloned genes are placed under control of the T7 promoter. To achieve this, the gene for T7 RNA polymerase must also be present in the cell under the control of an easily regulated system, such as *lac* (Figure 11.19). This is usually done by integrating the gene for

T7 RNA polymerase with a *lac* promoter into the chromosome of a specialized host strain.

The BL21 series of *E. coli* host strains are especially designed to work with the pET series of T7 expression vectors. The cloned genes are expressed shortly after T7 RNA polymerase transcription has been switched on by a *lac* inducer, such as IPTG. Because it recognizes only T7 promoters, the T7 RNA polymerase transcribes only the cloned genes. The T7 RNA polymerase is so highly active that it uses most of the RNA precursors, thereby limiting transcription to the cloned genes. Consequently, host genes that require host RNA polymerase are for the most part not transcribed and thus the cells stop growing; translation in such cells then yields primarily the protein of interest. The T7 control system is thus very effective for generating large amounts of a particular protein.

Translation of the Cloned Gene

Expression vectors must also be designed to ensure that the mRNA produced is efficiently translated. To synthesize protein from an mRNA molecule, it is essential for the ribosomes to bind at the correct site and begin reading in the correct frame. In bacteria this is accomplished by having a ribosome-binding site (RBS, Section 4.11) and a nearby start codon on the mRNA. Bacterial RBSs are not found in eukaryotic genes and must be engineered into the vector if high levels of expression of the eukaryotic gene are to be obtained. The vector in Figure 11.18 shows such a site.

Other adjustments to a cloned gene may be necessary to ensure high-efficiency translation. For example, codon usage can be an obstacle (Section 6.3 and Table 6.3). Codon usage is related to the concentration of the appropriate tRNA in the cell. Because of the redundancy of the genetic code, more than one tRNA exists for most amino acids (Section 4.11). Therefore, if a cloned

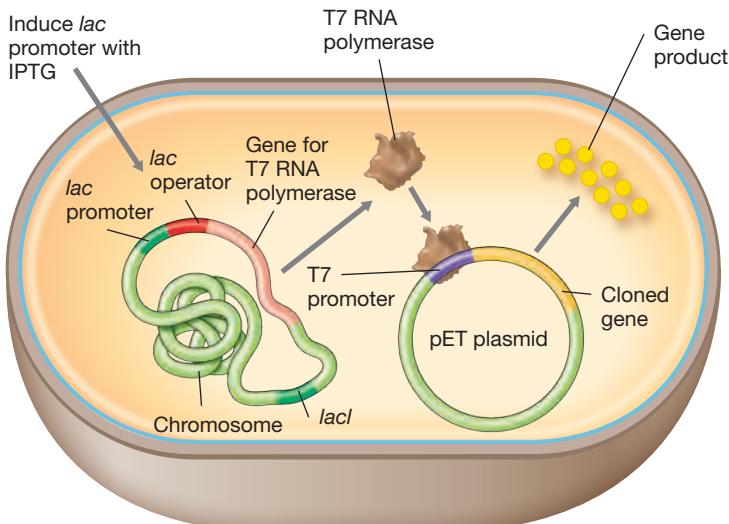

Figure 11.19 The T7 expression system. The gene for T7 RNA polymerase is in a gene fusion under control of the *lac* promoter and is inserted into the chromosome of a special host strain of *Escherichia coli*. Addition of IPTG induces the *lac* promoter, causing expression of T7 RNA polymerase. This transcribes the cloned gene, which is under control of the T7 promoter and is carried by the pET plasmid.

gene has a codon usage pattern distinct from that of its expression host, it will probably be translated inefficiently in that host. Site-directed mutagenesis (Section 11.5) can then be used to change selected codons in the gene, making it more amenable to the codon usage pattern of the host.

Finally, if the cloned gene contains introns, as eukaryotic genes typically do (☞ Section 4.9), the correct protein product will not be made if the expression host is a prokaryote. This problem can also be corrected by using synthetic DNA. However, the usual method to create an intron-free gene is to obtain the mRNA (from which the introns have already been removed) and use reverse transcriptase to generate a complementary DNA (cDNA) copy (see Figures 11.6 and 11.23).

MINIQUIZ

- Describe the components needed for an efficient shuttle vector.
- Describe some of the components of an expression vector that improve expression of the cloned gene.

11.10 Other Cloning Vectors

Typical plasmid vectors used for molecular cloning are limited in the amount of DNA that can be inserted, with 10 kilobase pairs (kbp) being the maximum. For applications that require cloning large genomic regions such as operons and eukaryotic genes, vectors based on bacteriophages, cosmids, and artificial chromosomes have been developed. While not discussed in detail here, derivatives of viruses are commonly used as vectors in multicellular eukaryotes. In particular, retroviruses can be used to introduce genes into mammalian cells because these viruses replicate via a DNA form that is directly integrated into the host chromosome (☞ Section 9.11).

Cloning with Bacteriophage Lambda

Bacteriophage lambda (☞ Section 8.8) is a useful cloning vector because its biology is well understood, it can hold larger amounts of DNA than most plasmids, and DNA can be efficiently packaged into phage particles *in vitro*. Also recall that during the lytic phase of phage development, the *Escherichia coli* host cell is reprogrammed to replicate large amounts of lambda DNA (☞ Section 10.7).

Phage lambda has a large number of genes; however, a third of the lambda genome is not essential for infectivity and can be replaced with foreign DNA. This allows relatively large DNA fragments, up to about 20 kbp, to be cloned into lambda. This is twice the cloning capacity of typical small plasmid vectors. To facilitate the use of lambda as a molecular cloning vector, many of its restriction enzyme sites have been altered and a multiple cloning site (MCS) containing the gene for β -galactosidase has been added to select for recombinant vectors.

Figure 11.20a illustrates cloning with lambda vectors. The initial process is similar to cloning DNA into plasmid vectors in that restriction enzymes and DNA ligase are used. Once the DNA of interest has been inserted into the lambda DNA, the vector is *packaged* by adding extracts from lambda-lysed cells that contain the head and tail proteins and allowing the formation of mature

phage virions to occur spontaneously. These virions can be used to infect suitable host cells, and such infection is much more efficient than transformation. Individual clones are then isolated by plating on an *E. coli* host strain and picking plaques. Recombinant phage can be selected by screening for interruption of the β -galactosidase gene using a color indicator agar (Section 11.7). Plaques containing phage that do not produce β -galactosidase can be readily detected as colorless plaques among a background of colored plaques (Figure 11.20b). Nucleic acid hybridization procedures (Section 11.2) and DNA sequencing can be used to determine if recombinant lambda DNA contains the desired foreign DNA sequence.

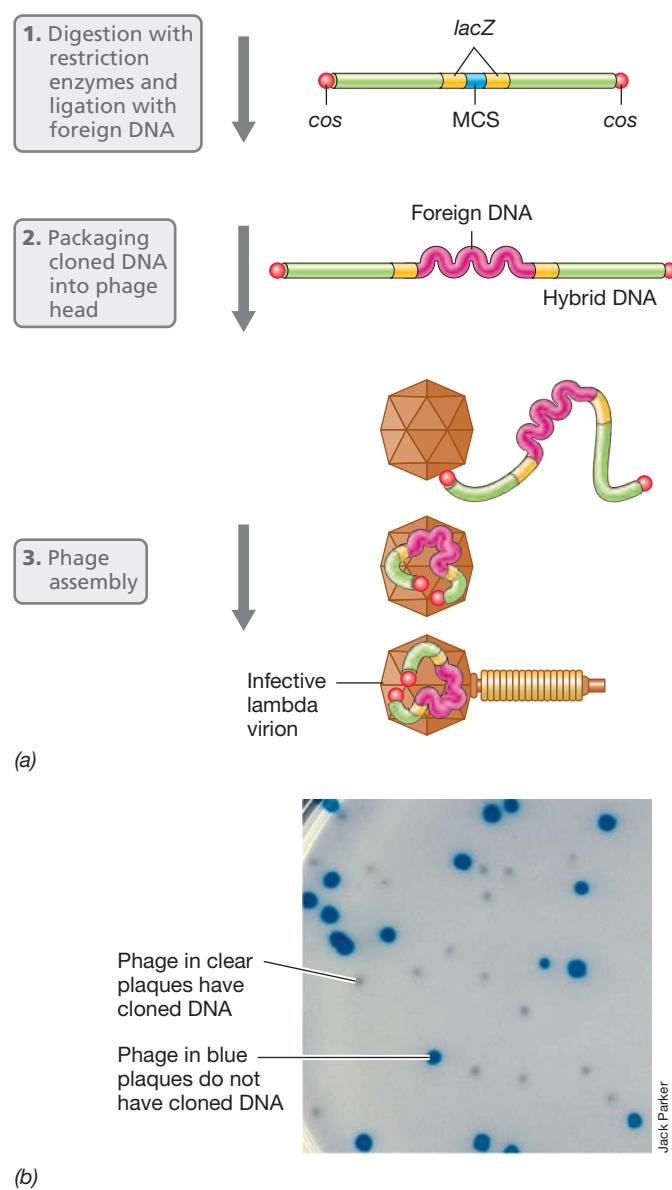

Figure 11.20 Bacteriophage lambda as a cloning vector. (a) Insertion of foreign DNA into lambda DNA modified to contain an MCS within a *lacZ* gene and subsequent packaging of a recombinant infective lambda virion. The maximum size of inserted DNA is about 20 kbp. (b) Portion of an Xgal-containing agar plate showing white plaques formed by lambda phage containing cloned DNA and blue plaques formed by phage lacking cloned DNA. Jack Parker

Cosmid Vectors

Cosmid vectors employ specific lambda genes and are packaged into lambda virions. *Cosmids* are plasmid vectors containing the *cos* site from the lambda genome, which yields cohesive ends when cut (➡ Section 8.8). The *cos* site is required for packaging DNA into lambda virions. Cosmids are constructed from plasmids by ligating the lambda *cos* region to the plasmid DNA; foreign DNA is then ligated into the vector. The modified plasmid, plus cloned DNA, can then be packaged into lambda virions *in vitro* as described previously and the phage particles used to transduce *E. coli*.

One major advantage of cosmids is that they can be used to clone large fragments of DNA, with inserts as large as 50 kbp possible. With big inserts, fewer clones are needed to cover a whole genome. Using cosmids also avoids the necessity of having to transform *E. coli*, which is especially inefficient with larger plasmids. Cosmids also permit storage of the DNA in phage virions instead of as plasmids. Virions are more stable than plasmids, so the recombinant DNA can be kept for long periods of time.

Artificial Chromosomes

Vectors that hold about 2–10 kbp of cloned DNA are adequate for making gene libraries for sequencing prokaryotic genomes. Bacteriophage lambda vectors, which hold 20 kbp or more, are also widely used in genomics projects. However, as the size of the genome increases, so does the number of clones needed to obtain a complete sequence. Therefore, for making libraries of DNA from eukaryotic microorganisms or from higher eukaryotes such as humans, it is useful to have vectors that can carry very large segments of DNA. This allows the size of the initial library to be manageable. Such vectors have been developed and are called **artificial chromosomes**.

The naturally occurring F plasmid of *E. coli* is composed of 99.2 kbp of DNA (➡ Section 10.8) and derivatives called F' plasmids are known that may carry large amounts of chromosomal DNA (➡ Section 10.9). Because of these desirable properties, the F plasmid has been used to engineer cloning vectors called **bacterial artificial chromosomes (BACs)**. Figure 11.21 shows the structure of a 6.7-kbp BAC that contains only a few genes from F necessary for replication and to keep the copy number very low. The plasmid also contains the *cat* gene, which confers chloramphenicol resistance on the host, and a multiple cloning site that includes several restriction sites for cloning DNA. Foreign DNA

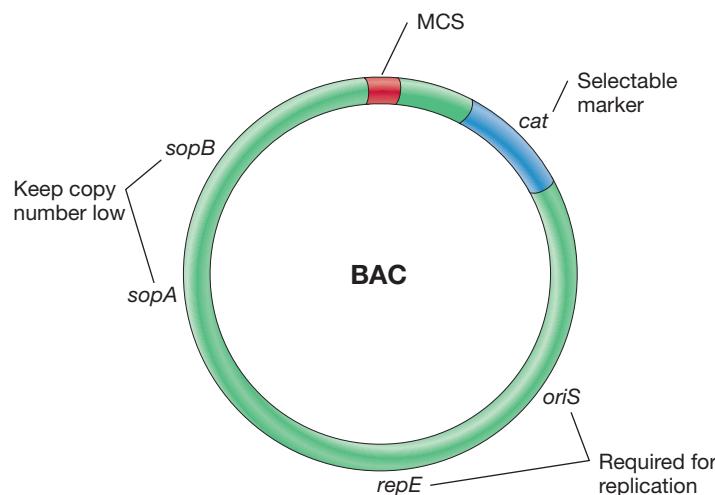

Figure 11.21 Genetic map of a bacterial artificial chromosome. The BAC shown is 6.7 kbp. The cloning region has several unique restriction enzyme sites. This BAC contains only a small fraction of the 99.2-kbp F plasmid.

of more than 300 kbp can be inserted and stably maintained in a BAC vector such as this.

Yeast artificial chromosomes (YACs) (Figure 11.22) are vectors that replicate in yeast like normal chromosomes, but have sites where very large fragments of DNA can be inserted. To function like normal eukaryotic chromosomes, YACs must have (1) an origin of DNA replication, (2) telomeres for replicating DNA at the ends of the chromosome, and (3) a centromere for segregation during mitosis. They must also contain a cloning site and a gene for selection following transformation into the host, which is typically the yeast *Saccharomyces cerevisiae*. Figure 11.22 shows a YAC vector into which foreign DNA has been cloned. Remarkably, YAC vectors are themselves only about 10 kbp in size but can have 200–800 kbp of cloned DNA inserted.

MINIQUIZ

- Why is the ability to package recombinant DNA in phage particles in a test tube useful?
- What do the acronyms BAC and YAC stand for?
- The yeast artificial chromosome behaves like a chromosome in a yeast cell. What makes this possible?

Figure 11.22 A yeast artificial chromosome containing foreign DNA. The foreign DNA was cloned into the vector at a *NotI* restriction site. The telomeres are labeled TEL and the centromere CEN. The origin of replication is labeled ARS (for autonomous replication sequence). The *URA3* gene is used for selection. The host into which the clone is transformed has a mutation in *URA3* and requires uracil for growth (*Ura*⁻). Host cells containing this YAC become *Ura*⁺. The diagram is not to scale; vector DNA is only 10 kbp whereas cloned DNA can be up to 800 kbp.

III • Products from Genetically Engineered Microorganisms

Genetic engineering has been used to transform microorganisms into tiny factories for the production of valuable products such as fuels, chemicals, drugs, and human hormones, such as insulin. Up to this point we have discussed the techniques used for manipulating, cloning, and expressing DNA. We now consider how these techniques can be directly applied to **biotechnology**, including some of the major challenges that exist with expressing eukaryotic genes in bacteria and purifying the subsequent protein products. We also discuss the genetic engineering of modified plants, animals, vaccines, and metabolic pathways.

11.11 Expressing Mammalian Genes in Bacteria

Some common problems of expression vectors were mentioned in Section 11.9, and there are other obstacles to cloning a mammalian gene in bacteria. The problems include the realities that (1) the eukaryotic genes must be placed under control of a bacterial promoter (Section 11.9); (2) any introns (☞ Section 4.9) must be removed; (3) codon bias (☞ Section 4.11) may require edits to gene sequences; and (4) many mammalian proteins require modification after translation to yield the active form, and bacteria cannot perform most such modifications. Here we consider solutions to these challenges.

Cloning the Gene via mRNA

The usual way to obtain an intron-free eukaryotic gene is to clone its messenger RNA (mRNA). Because introns are removed during the processing of mRNA, the mature mRNA carries an uninterrupted coding sequence (☞ Section 4.9 and Figure 4.29). Tissues expressing the gene of interest often contain large amounts of the corresponding mRNA, although other mRNAs are also present. In certain situations, however, a single mRNA dominates in a tissue type, and extraction of bulk mRNA from that tissue provides a useful starting point for gene cloning.

In a typical mammalian cell, about 80–85% of the RNA is ribosomal RNA, 10–15% is transfer RNA, and only 1–5% is mRNA. However, eukaryotic mRNA is unique because of the poly(A) tails found at the 3' end (☞ Section 4.9), and this makes it easy to isolate, even though it is of low abundance. If a cell extract is passed over a chromatographic column containing strands of poly(T) linked to a cellulose support, most of the mRNA separates from other RNAs by sticking to the support by the specific pairing of A and T bases. The RNA is then released from the column by a low-salt buffer, which gives a preparation greatly enriched in mRNA.

Once mRNA has been isolated, the genetic information is converted into complementary DNA (cDNA) by RT-PCR as illustrated in Figure 11.6. This double-stranded cDNA contains the coding sequence but lacks introns (Figure 11.23), and thus it can be inserted into a plasmid or other vector for cloning. However, because the cDNA contains only the DNA sequences encoding the protein, it lacks a promoter and other upstream regulatory sequences necessary for expression. Special expression vectors

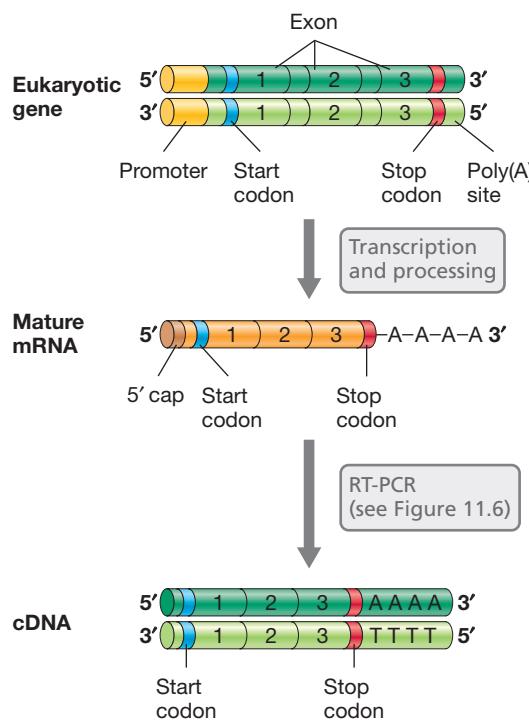

Figure 11.23 Complementary DNA (cDNA). Steps illustrating the synthesis of an intron-lacking cDNA corresponding to a eukaryotic gene using reverse transcription PCR (RT-PCR).

with bacterial promoters and ribosome-binding sites are used to obtain high-level expression of genes cloned in this way (☞ Section 11.9).

Finding the Gene via the Protein

Knowing the sequence of an mRNA allows for the production of cDNA for cloning. In some cases, however, only the amino acid sequence of a desired protein is known. This amino acid sequence can be used to design and synthesize an oligonucleotide probe that encodes it. This process is illustrated in Figure 11.24. Unfortunately, degeneracy of the genetic code complicates this approach. Most amino acids are encoded by more than one codon (☞ Table 4.5), and codon usage varies from organism to organism. Thus, the best region of a gene to synthesize as a probe is one that encodes part of the protein rich in amino acids specified by only a single codon (for example, methionine, AUG; tryptophan, UGG) or at most two codons (for example, phenylalanine, UUU, UUC; tyrosine, UAU, UAC; histidine, CAU, CAC). This strategy increases the chances that the probe will be nearly complementary to the mRNA or gene of interest. If the complete amino acid sequence of the protein is unknown, partial sequence data may be sufficient.

For very small proteins it may be feasible to artificially synthesize the entire gene (Section 11.5). Many mammalian proteins (including high-value peptide hormones) are made by protease cleavage of larger precursors. Thus, to produce a short peptide

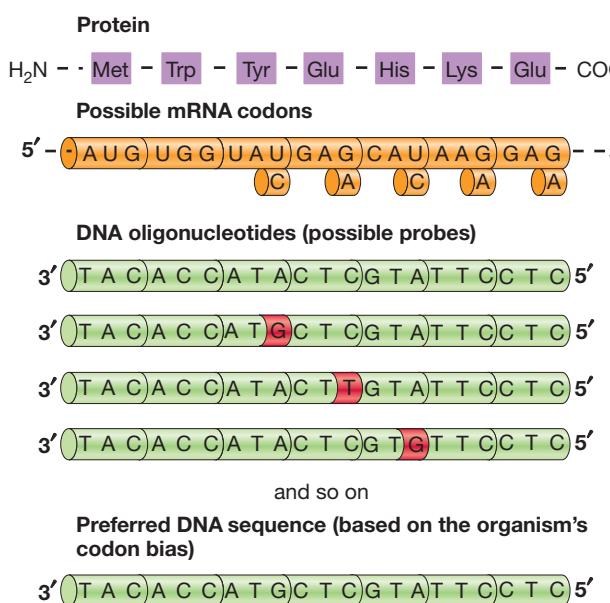

Figure 11.24 Deducing the best sequence of an oligonucleotide probe from the amino acid sequence of a protein. Because many amino acids are encoded by multiple codons, many nucleic acid probes are possible for a given polypeptide sequence. If codon usage by the target organism is known, a preferred sequence can be selected. Complete accuracy is not essential because a small amount of mismatch can be tolerated, especially with long probes.

hormone such as insulin, it may be more efficient to construct an artificial gene that encodes just the final hormone rather than the larger precursor protein from which it is derived naturally. Chemical synthesis also allows synthesis of modified genes that may encode useful new proteins. The synthetic approach was first used in a major way for production of the human hormone insulin in bacteria. Moreover, constructed genes are free of introns and thus the mRNA does not need processing. Also, promoters and other regulatory sequences can easily be built into the gene upstream of the coding sequences, and codon bias (Sections 4.11 and 6.3) can be accounted for.

With these techniques, many human and viral proteins have been expressed at high yield under the control of bacterial regulatory systems. These include insulin, somatostatin, viral capsid proteins, and interferon.

Protein Folding and Stability

The synthesis of a protein in a new host may spawn additional problems. For example, some proteins are susceptible to degradation by intracellular proteases and may be destroyed before they can be isolated. Moreover, some eukaryotic proteins are toxic to prokaryotic hosts, and the host cell may be killed before a sufficient amount of the product is synthesized. Further engineering of either the host or the vector may eliminate these problems.

Sometimes when foreign proteins are massively overproduced, they form inclusion bodies inside the host. Inclusion bodies consist of aggregated insoluble protein that is often misfolded or partly denatured, and they are often toxic to the host cell. Although inclusion bodies are relatively easy to purify because of

their size, the protein they contain is often difficult to solubilize and may be inactive. One possible solution to this problem is to use a host that overproduces molecular chaperones that aid in folding (Section 4.14).

Fusion Proteins for Improved Purification

Protein purification can often be made much simpler if the target protein is made as a *fusion protein* along with a carrier protein encoded by the vector. To do this, the two genes are fused to yield a single coding sequence. A short segment that is recognized and cleaved by a commercially available protease is included between them. After transcription and translation, a single protein is made. This is purified by methods designed for the carrier protein. The fusion protein is then cleaved by the protease to release the target protein from the carrier protein. Fusion proteins simplify purification of the target protein because the carrier protein can be chosen to have ideal properties for purification.

Several fusion vectors are available to generate fusion proteins. Figure 11.25 shows an example of a fusion vector that is also an expression vector. In this example, the carrier protein is the *Escherichia coli* maltose-binding protein, and the fusion protein is easily purified by methods based on its affinity for maltose. Once purified, the two portions of the fusion protein are separated by a specific protease. In some cases the target protein is released from the carrier protein by specific chemical treatment, rather than by protease cleavage.

Fusion systems are also used for other purposes. One advantage of making a fusion protein is that the carrier protein can be

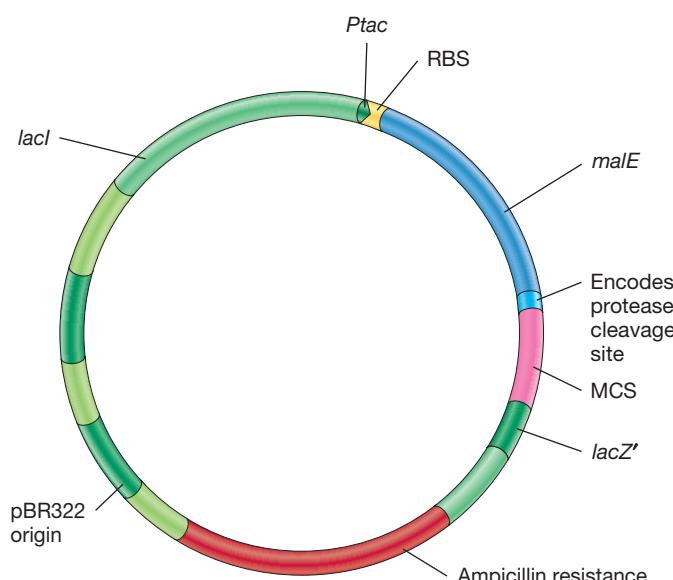

Figure 11.25 An expression vector for fusions. The gene to be cloned is inserted into the multiple cloning site (MCS) so it is in frame with the *malE* gene, which encodes maltose-binding protein. The insertion inactivates the gene for the alpha fragment of *lacZ*, which encodes β-galactosidase. The fused gene is under control of the hybrid *tac* promoter (*Ptac*) and an *Escherichia coli* ribosome-binding site (RBS). The plasmid also contains the *lacI* gene, which encodes the *lac* repressor. Therefore, an inducer must be added to turn on the *tac* promoter. The plasmid contains a gene conferring ampicillin resistance on its host. This vector was developed by New England Biolabs.

chosen to contain the bacterial *signal sequence*, a peptide rich in hydrophobic amino acids that enables transport of the protein across the cytoplasmic membrane (Section 4.14). This makes possible a bacterial expression system that not only makes mammalian proteins, but also secretes them. When the right strains and vectors are employed, the desired protein can constitute as much as 40% of the protein molecules in a cell.

MINIQUIZ

- What major advantage does cloning mammalian genes from mRNA or using synthetic genes have over PCR amplification and cloning of the native gene?
- How is a fusion protein made?

11.12 Somatotropin and Other Mammalian Proteins

One of the most economically profitable areas of biotechnology has been the production of human proteins. Many mammalian proteins have high pharmaceutical value but are typically present in very low amounts in normal tissue, and it is therefore extremely costly to purify them. Even if the protein can be produced in cell culture, this is much more expensive and difficult than growing microbial cultures that produce the protein in high yield. Therefore, the biotechnology industry has developed genetically engineered microorganisms to produce many different mammalian proteins.

Somatotropin

Although insulin was the first human protein to be produced by bacteria, the procedure had several unusual complications because insulin consists of two short polypeptides held together by disulfide bonds. A more typical example is *somatotropin* (growth hormone), and we focus on this here.

Somatotropin consists of a single polypeptide encoded by a single gene, and a shortage of somatotropin in the body results in hereditary dwarfism. Because the human somatotropin gene was successfully cloned and expressed in bacteria, children showing stunted growth can be treated with *recombinant human somatotropin*. However, dwarfism may also be caused by lack of the somatotropin receptor, and in such cases, administration of somatotropin has no effect.

The somatotropin gene was cloned as complementary DNA (cDNA) from mRNA as described in Section 11.11 (Figure 11.26). The cDNA was then expressed in a bacterial expression vector. The main problem with producing relatively short polypeptide hormones such as somatotropin is their susceptibility to protease digestion. This problem can be countered by using bacterial host strains defective for several proteases.

Recombinant bovine somatotropin (rBST) is used in the dairy industry (Figure 11.26). Injection of rBST into cows does not make them grow larger but instead stimulates milk production. The reason for this is that somatotropin has two binding sites. One binds to the somatotropin receptor and stimulates growth; the other binds to the prolactin receptor and promotes milk production. When human somatotropin is used to remedy

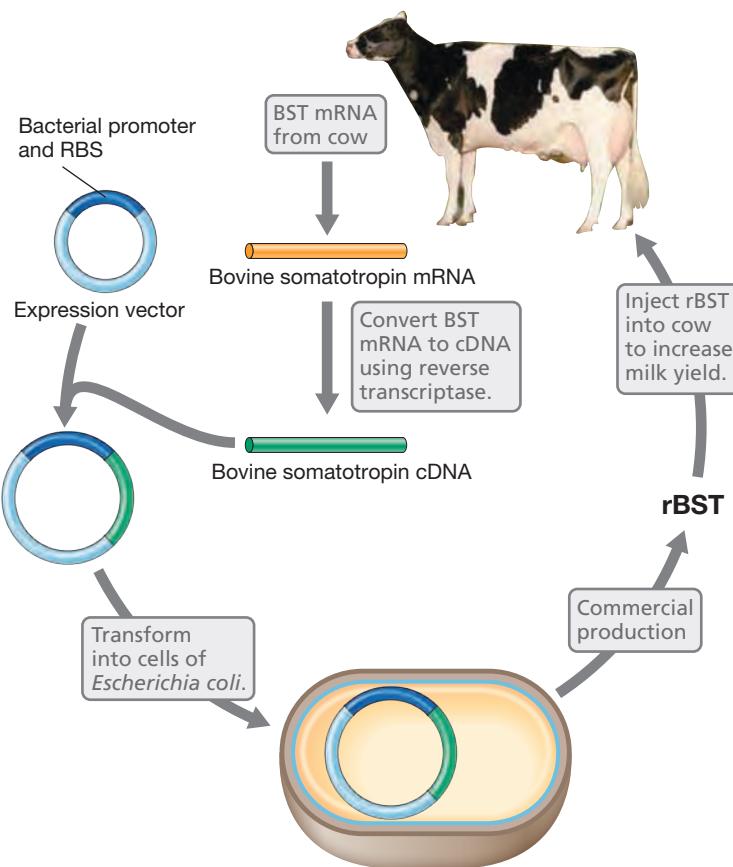

Figure 11.26 Cloning and expression of bovine somatotropin. The mRNA for bovine somatotropin (BST) is obtained from an animal. The mRNA is converted to cDNA by reverse transcriptase. The cDNA version of the somatotropin gene is then cloned into a bacterial expression vector that has a bacterial promoter and ribosome-binding site (RBS). The construct is transformed into cells of *Escherichia coli*, and recombinant bovine somatotropin (rBST) is produced. Milk production increases in cows treated with rBST.

human growth defects, it is desirable to avoid side effects from the hormone's prolactin activity (prolactin stimulates lactation). To alleviate this problem, site-directed mutagenesis (Section 11.5) of the human somatotropin gene was used to alter those amino acids of somatotropin that bind to the prolactin receptor. This shows that it is not only possible to make genuine human hormones, but also to alter their specificity and activity to make them better pharmaceuticals.

Other Mammalian Proteins

Many other mammalian proteins are produced by genetic engineering (Table 11.2). These include, in particular, an assortment of hormones and proteins for blood clotting and other blood processes. For example, *tissue plasminogen activator* (TPA) is a protein that dissolves blood clots in the bloodstream that may form in the final stages of the healing process. TPA is primarily used in heart patients or others suffering from poor circulation to prevent the development of clots that can be life-threatening. Heart disease is a leading cause of death in many developed countries, especially in the United States, so microbially produced TPA is in high demand.

Table 11.2 A few human medical products made by genetic engineering

Product	Function
<i>Blood proteins</i>	
Erythropoietin	Treats certain types of anemia
Factors VII, VIII, IX	Promotes blood clotting
Tissue plasminogen activator	Dissolves blood clots
Urokinase	Promotes blood clotting
<i>Human hormones</i>	
Epidermal growth factor	Wound healing
Follicle-stimulating hormone	Treatment of reproductive disorders
Insulin	Treatment of diabetes
Nerve growth factor	Treatment of degenerative neurological disorders and stroke
Relaxin	Facilitates childbirth
Somatotropin (growth hormone)	Treatment of some growth abnormalities
<i>Immune modulators</i>	
α -Interferon	Antiviral, antitumor agent
β -Interferon	Treatment of multiple sclerosis
Colony-stimulating factor	Treatment of infections and cancer
Interleukin-2	Treatment of certain cancers
Lysozyme	Anti-inflammatory
Tumor necrosis factor	Antitumor agent, potential treatment of arthritis
<i>Replacement enzymes</i>	
β -Glucocerebrosidase	Treatment of Gaucher disease, an inherited neurological disease
<i>Therapeutic enzymes</i>	
Human DNase I	Treatment of cystic fibrosis
Alginate lyase	Treatment of cystic fibrosis

In contrast to TPA, the blood clotting factors VII, VIII, and IX are critically important for the *formation* of blood clots. Hemophiliacs suffer from a deficiency of one or more clotting factors and can therefore be treated with microbially produced clotting factors. In the past hemophiliacs have been treated with clotting factor extracts from pooled human blood, some of which was contaminated with viruses such as HIV and hepatitis C, putting hemophiliacs at high risk for contracting these diseases. Recombinant clotting factors have eliminated this problem.

Some mammalian proteins made by genetic engineering are enzymes rather than hormones (Table 11.2). For instance, *human DNase I* is used to treat the buildup of DNA-containing mucus in the lungs of patients with cystic fibrosis. The mucus forms because cystic fibrosis is often accompanied by life-threatening lung infections by the bacterium *Pseudomonas aeruginosa*. The bacterial cells form biofilms (► Sections 7.9 and 19.4) within the lungs that make drug treatment difficult. DNA is released when the bacteria lyse, and this fuels mucus formation, making it harder to breathe. DNase digests the DNA and greatly decreases the viscosity of the mucus.

MINIQUIZ

- What is the advantage of using genetic engineering to make insulin?
- What are the major problems when manufacturing proteins in bacteria?
- Explain how an enzyme can be useful in treating a bacterial infection, such as that which occurs with cystic fibrosis.

11.13 Transgenic Organisms in Agriculture and Aquaculture

Genetic improvement of plants and animals by traditional selection and breeding has a long history, but recombinant DNA technology has led to revolutionary changes. On the one hand, the genetic engineering of higher organisms is not truly microbiology. On the other hand, much of the DNA manipulation is carried out using bacteria and their plasmids and genes (see herbicide- and insect-resistant plants below) long before the engineered genes are finally inserted into the plant or animal. Therefore we consider the genetic manipulation of plants and animals here with a focus on the microbiology that supported it.

Because genetically engineered plants or animals contain a gene from another organism—called a *transgene*—they are **transgenic organisms**. The public knows these as **genetically modified organisms (GMOs)**. Strictly speaking, the term *genetically modified* refers to genetically engineered organisms whether or not they contain foreign DNA. In this section we discuss how foreign genes are inserted into plant and fish genomes and how transgenic organisms may be used.

The Ti Plasmid and Transgenic Plants

While recombinant DNA can be transformed into plant cells by electroporation or transfection (see Figure 11.28), the **Ti plasmid** from the gram-negative plant pathogen *Agrobacterium tumefaciens* can be used to transfer DNA directly into the cells of certain plants. This plasmid is responsible for *A. tumefaciens* virulence and encodes genes that mobilize DNA for transfer to the plant, which as a result contracts crown gall disease (► Section 22.4). The segment of the Ti plasmid DNA that is actually transferred to the plant is called **T-DNA**. The sequences at the ends of the T-DNA are essential for transfer, and the DNA to be transferred must be included between these ends.

One common Ti-vector system that has been used for the transfer of genes to plants is a two-plasmid system called a **binary vector**, which consists of a cloning vector plus a helper plasmid. The cloning vector contains the two ends of the T-DNA flanking a multiple cloning site, two origins of replication so that it can replicate in both *Escherichia coli* (the host for cloning) and *A. tumefaciens*, and two antibiotic resistance markers, one for selection in plants and the other for selection in bacteria. The foreign DNA is inserted into the vector, which is transformed into *E. coli* and then moved to *A. tumefaciens* by conjugation (Figure 11.27).

This cloning vector lacks the genes needed to transfer T-DNA to a plant. However, when placed in an *A. tumefaciens* cell that contains a suitable helper plasmid, the T-DNA can be transferred to a plant. The “disarmed” helper plasmid, called **D-Ti**, contains

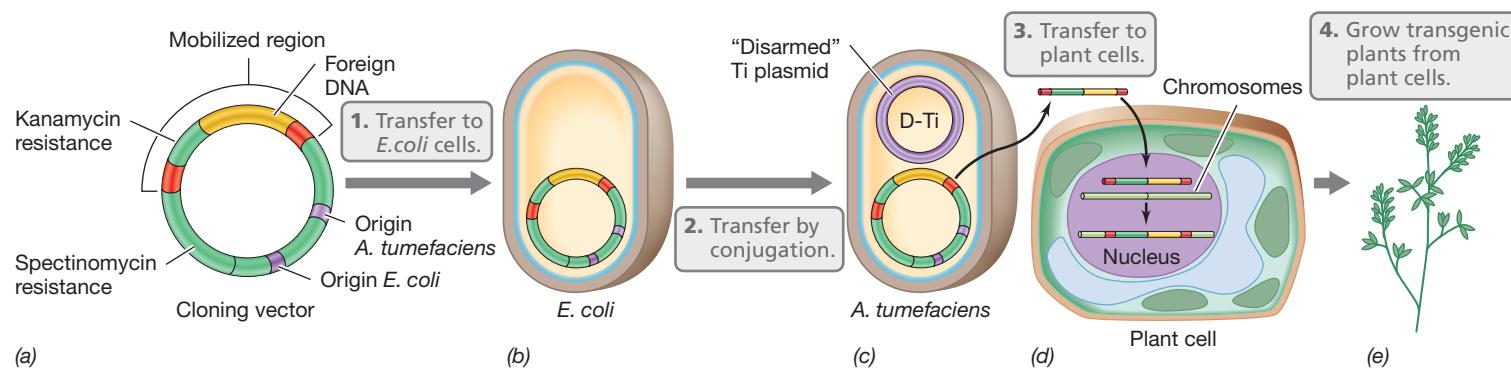

Figure 11.27 Production of transgenic plants using a binary vector system in *Agrobacterium tumefaciens*. (a) Plant cloning vector containing ends of T-DNA (red), foreign DNA, origins of replication, and resistance markers. (b) The vector is put into cells of *Escherichia coli* for cloning and then (c) transferred to *A. tumefaciens* by conjugation. The resident Ti plasmid (D-Ti) has been genetically engineered to remove key pathogenesis genes. (d) D-Ti can still mobilize the T-DNA region of the vector for transfer to plant cells grown in tissue culture. (e) From the recombinant plant cell, a whole plant can be grown. Details of Ti plasmid transfer from bacterium to plant are shown in Figure 22.21.

the virulence (*vir*) region of the Ti plasmid but lacks the T-DNA. It also lacks the genes that initiate disease but supplies all the functions needed to transfer the T-DNA from the cloning vector. The cloned DNA and the kanamycin resistance marker of the vector are mobilized by D-Ti and transferred into a plant cell where they enter the nucleus (Figure 11.27d). Following integration into a plant chromosome, the foreign DNA can be expressed and confer new properties on the plant.

A number of transgenic plants have been produced using the Ti plasmid of *A. tumefaciens*. The Ti system works well with broadleaf plants (dicots), including crops such as tomato, potato, tobacco, soybean, alfalfa, and cotton. It has also been used to produce transgenic trees, such as walnut and apple. The Ti system does not work with plants from the grass family (monocots, including the important crop plant, corn), but other methods of introducing DNA, such as transfection by microprojectile bombardment with a particle gun (Figure 11.28), have been used successfully for them.

Herbicide- and Insect-Resistant Plants

Major areas targeted for genetic improvement in plants include herbicide, insect, and microbial disease resistance, as well as improved product quality. The main genetically modified (GM) crops today are soybeans, corn, cotton, and canola. Almost all the GM soybeans and canola planted were herbicide resistant, whereas the corn and cotton were herbicide resistant or insect resistant, or both.

Herbicide resistance is genetically engineered into a crop plant to protect it from herbicides applied to kill weeds. Many herbicides inhibit a key plant enzyme or protein necessary for growth. For example, the herbicide *glyphosate* (RoundupTM) kills plants by inhibiting an enzyme necessary for making aromatic amino acids. Some bacteria contain an equivalent enzyme and are also killed by glyphosate. However, mutant bacteria were selected that were resistant to glyphosate and contained a resistant form of the enzyme. The gene encoding this resistant enzyme from *A. tumefaciens* was cloned, modified for expression in plants, and transferred into important crop plants, such as soybeans. When

sprayed with glyphosate, plants containing the bacterial gene are not killed (Figure 11.29). Thus glyphosate can be used to kill weeds that compete for water and nutrients with the growing crop plants. Herbicide-resistant soybeans are now widely planted in the United States.

Insect Resistance: Bt Toxin

Transgenic plants resistant to damage by certain insects have been produced by genetic engineering (Figure 11.30). One widely used approach is based on introducing genes encoding the toxic proteins of the gram-positive bacterium *Bacillus thuringiensis* into plants. *B. thuringiensis* produces a crystalline

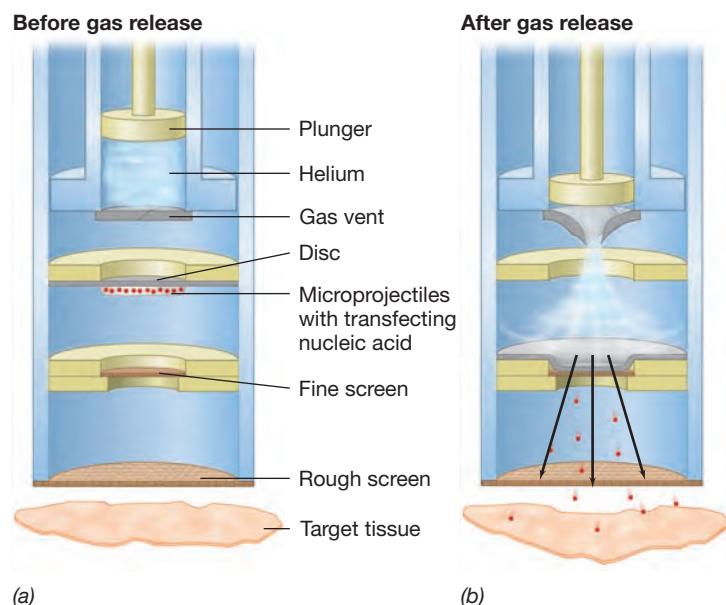

Figure 11.28 DNA gun for transfection of eukaryotic cells. The inner workings of the gun show how metal pellets coated with nucleic acids (microprojectiles) are projected at target cells. (a) Before firing and (b) after firing. A shock wave due to gas release throws the disc carrying the microprojectiles against the fine screen. The microprojectiles continue on into the target tissue.

Figure 11.29 Transgenic plants: herbicide resistance. The photograph shows a portion of a field of soybeans that has been treated with RoundupTM, a glyphosate-based herbicide manufactured by Monsanto Company (St. Louis, Missouri, USA). The plants on the right are normal soybeans; those on the left have been genetically engineered to be glyphosate resistant.

protein called *Bt toxin* (➡ Section 15.8) that is toxic to moth and butterfly larvae. Many variants of *Bt toxin* exist that are specific for different insects. Certain strains of *B. thuringiensis* produce additional proteins toxic to beetle and fly larvae and mosquitoes.

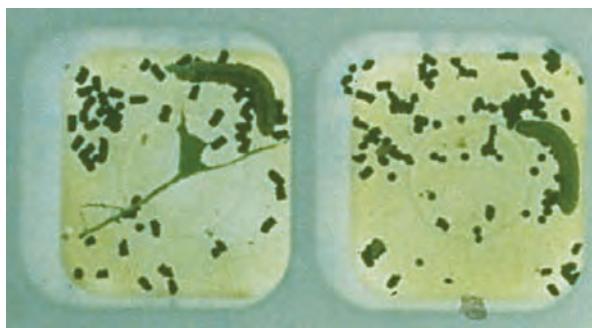

The *Bt* transgene is normally inserted directly into the plant genome. For example, a natural *Bt* toxin gene was cloned into a plasmid vector under control of a chloroplast ribosomal RNA promoter and then transfected into tobacco plant chloroplasts by microprojectile bombardment (Figure 11.28). This yielded transgenic plants that expressed *Bt* toxin at levels that were extremely toxic to larvae from a number of insect species.

Bt toxin is harmless to mammals, including humans, for several reasons. First, cooking and food processing destroy the toxin. Second, any toxin that is ingested is digested and therefore inactivated in the mammalian gastrointestinal tract. Third, *Bt* toxin works by binding to specific receptors in the insect intestine that are absent from the intestines of other groups of organisms. Binding promotes a change in conformation of the toxin, which then generates pores in the intestinal lining of the insect that disrupt the insect digestive system and kill the insect.

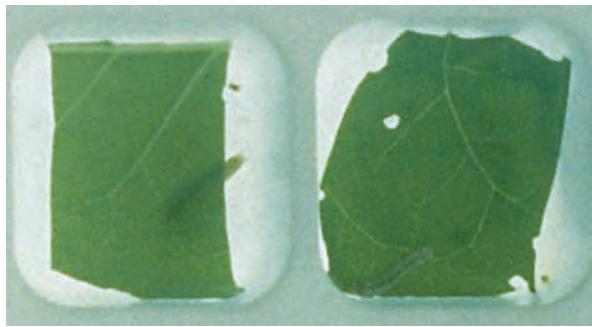

Transgenic Fish

Many foreign genes have been incorporated and expressed in laboratory research animals and in commercially important animals. The genetic engineering uses microinjection to deliver cloned genes to fertilized eggs; genetic recombination then incorporates the foreign DNA into the genomes of the eggs. More recently, farm animals and fish have been genetically modified to improve yields.

An interesting practical example of a transgenic animal is the “fast-growing salmon” (Figure 11.31). These transgenic salmon do not grow to be larger than normal salmon but simply reach market size much faster. The gene for growth hormone in natural

Figure 11.30 Transgenic plants: insect resistance. (a) The results of two different assays to determine the effect of beet armyworm larvae on tobacco leaves from normal plants. (b) The results of similar assays using tobacco leaves from transgenic plants that express *Bt* toxin in their chloroplasts.

salmon is activated by light. Consequently, salmon grow rapidly only during the summer months. In the genetically engineered salmon, the promoter for the growth hormone gene was replaced with the promoter from another fish that grows at a more or less constant rate all year round. The result was salmon that make growth hormone constantly and thus grow faster. Such salmon can be grown commercially in aquaculture operations and the transgenic fish harvested more quickly than with non-GMO farm-raised salmon.

Figure 11.31 Fast-growing transgenic salmon. The *AquAdvantage*TM Salmon (top) was engineered by Aqua Bounty Technologies (St. Johns, Newfoundland, Canada). The transgenic and the control fish are 18 months old and weigh 4.5 kg and 1.2 kg, respectively.

MINIQUIZ

- What is a transgenic plant?
- Give an example of a genetically modified plant and describe how its modification benefits agriculture.
- How have transgenic salmon been engineered to reach market size faster?

11.14 Genetically Engineered Vaccines

Vaccines are substances that elicit immunity to a particular disease when injected into an animal (Section 24.6). Typically, vaccines are suspensions of killed or modified pathogenic microorganisms or viruses (or parts isolated from them). Often the part that elicits the immune response is a surface protein, for instance, a viral coat protein. Genetic engineering can be applied in many different ways to the production of vaccines.

Recombinant Vaccines

Genetic engineering can be used in vaccine development by modifying the pathogen itself. For instance, one can delete genes from a pathogenic bacterium or virus that encode virulence factors but leave those whose products elicit an immune response. This yields a recombinant and infective (but attenuated) vaccine. Conversely, one can add genes from a pathogenic virus to another, relatively harmless virus, called a *carrier virus*. Such vaccines are called **vector vaccines** and induce immunity to the pathogenic virus. Indeed, one can even combine the two approaches. For example, a recombinant vaccine is used to protect poultry against both fowlpox (a disease that reduces weight gain and egg production) and Newcastle disease (a viral disease that is often fatal). The fowlpox virus is a typical pox virus (Section 9.6) and was first modified by deleting virulence genes but not those that elicit immunity. Then immunity-inducing genes from the Newcastle virus were inserted into the modified fowlpox virus. This resulted

in a **polyvalent vaccine**, a vaccine that immunizes against two different diseases at the same time.

Vaccinia virus (Section 9.6) is widely used to prepare recombinant vaccines for human use. Vaccinia virus itself is generally not pathogenic for humans and has been used for over 100 years as a vaccine against the related smallpox virus. However, cloning genes into vaccinia virus requires a selective marker, which is provided by the gene encoding the enzyme thymidine kinase. Vaccinia is unusual for a virus in carrying its own thymidine kinase, an enzyme that converts thymidine into thymidine triphosphate. However, this enzyme also converts the base analog 5-bromodeoxyuridine to a nucleotide that is incorporated into DNA, causing a lethal reaction. Therefore, cells that express thymidine kinase (whether from the host cell genome or from a virus genome) are killed by 5-bromodeoxyuridine.

Genes to be put into vaccinia virus are first inserted into an *Escherichia coli* plasmid that contains part of the vaccinia thymidine kinase (*tdk*) gene (Figure 11.32). The foreign DNA is inserted into the *tdk* gene, which is therefore disrupted. This recombinant plasmid is then transformed into animal cells whose own *tdk* genes have been inactivated. These cells are also infected with wild-type vaccinia virus. The two versions of the *tdk* gene—one on the plasmid and the other on the virus—then recombine. Some viruses gain a disrupted *tdk* gene plus its foreign insert (Figure 11.32). Cells infected by wild-type vaccinia virus (with an active thymidine kinase) are killed by 5-bromodeoxyuridine. By contrast, cells infected by recombinant vaccinia virus (with a disrupted *tdk* gene) grow long enough to yield a new generation of virions (Figure 11.32). The protocol thus selects for viruses whose *tdk* gene contains a cloned insert of foreign DNA.

Vaccinia virus does not actually need thymidine kinase to replicate. Consequently, recombinant vaccinia viruses can still infect human cells and express any foreign genes they carry. Vaccinia viruses can even be engineered to carry genes from multiple

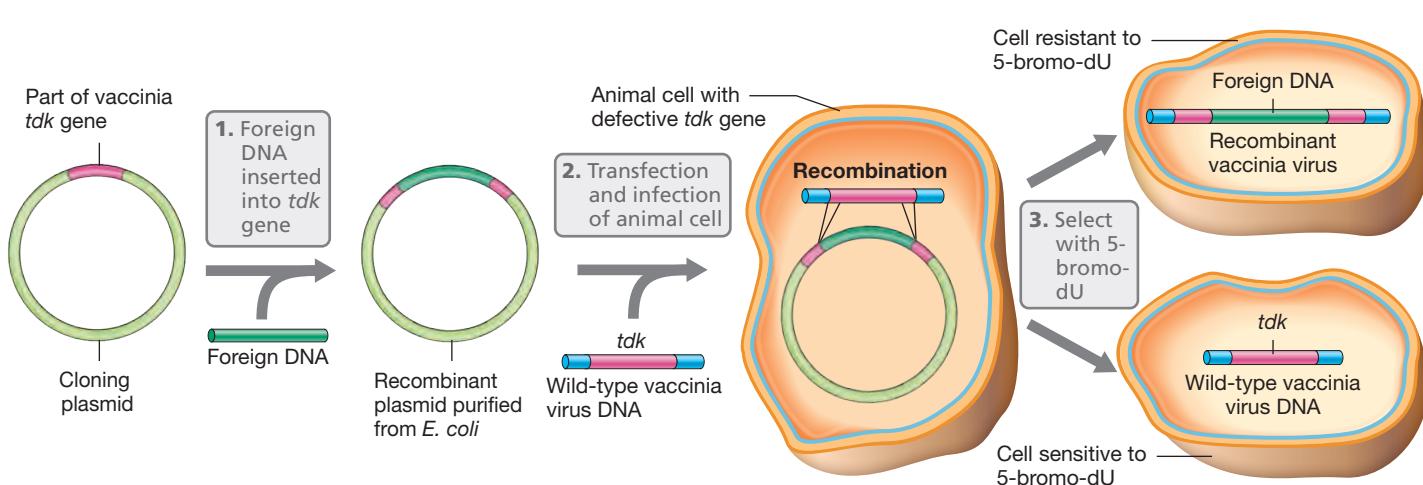

Figure 11.32 Production of recombinant vaccinia virus. Foreign DNA is inserted into a short segment of the thymidine kinase gene (*tdk*) from vaccinia virus carried on a plasmid. Following replication of this plasmid in *Escherichia coli*, both the recombinant plasmid and wild-type vaccinia virus are put into the same animal host cell to promote recombination. The animal cells are treated with 5-bromodeoxyuridine (5-bromo-dU), which kills only cells with an active thymidine kinase. Only recombinant vaccinia viruses whose *tdk* gene is inactivated by insertion of foreign DNA survive.

viruses. From an immunological standpoint, such viruses are *polyvalent vaccines*. Currently, several vaccinia vector vaccines have been developed and licensed for veterinary use, including one for rabies, while many other vaccinia vaccines are at the clinical trial stage. Vaccinia vaccines are relatively benign, yet highly immunogenic in humans, and because of this, their use will likely increase in the coming years.

Subunit Vaccines

Recombinant vaccines need not include every protein from the pathogenic organism. *Subunit vaccines* may contain only a specific protein or two from a pathogenic organism. For a pathogenic virus this is often the coat protein because coat proteins are typically highly immunogenic. The coat proteins are purified and used in high dosage to elicit a rapid and high level of immunity. Subunit vaccines are currently very popular because they can be used to produce large amounts of immunogenic proteins without the possibility that the purified products may contain the intact pathogen. Sometimes only certain portions of the viral protein are expressed rather than the entire protein, because immune cells and antibodies typically react with only small portions of the protein.

Subunit vaccines are sometimes poorly immunogenic and fail to protect in experimental tests of infection. When this occurs, it is usually because the recombinant proteins produced in bacteria are nonglycosylated, and glycosylation is necessary for the proteins to be immunologically active. Glycosylation occurs in the intact virus during the course of infection in the host animal. To solve this problem in a subunit vaccine, a eukaryotic cloning host may be necessary. For example, the first recombinant subunit vaccine approved for use in humans (against hepatitis B virus) was produced in yeast. The gene encoding a surface protein from hepatitis B virus was cloned and expressed in yeast. The protein produced was glycosylated and formed aggregates very similar to those found in patients infected with the virus. These aggregates were purified and

used to effectively vaccinate humans against infection by hepatitis B virus.

MINIQUIZ

- Explain why recombinant vaccines might be safer than some vaccines produced by traditional methods.
- What are the important differences among a recombinant live attenuated vaccine, a vector vaccine, and a subunit vaccine?

11.15 Mining Genomes

Just as the total gene content of an organism is its *genome*, the collective genomes of an environment are its *metagenome* (Sections 6.10 and 18.7). Complex environments, such as fertile soil, contain vast numbers of uncultured bacteria and other microorganisms together with the viruses that prey on them (Section 6.10). Taken together, these contain correspondingly vast numbers of novel genes. Indeed, most of the genetic information on Earth exists in microorganisms and their viruses that have not been cultured. How can genetic engineering tap this resource?

Environmental Gene Mining

Gene mining is the process of isolating potentially useful novel genes from the environment without first culturing the organisms that carry them. In gene mining, DNA (or RNA) is isolated directly from environmental samples and cloned into suitable vectors to construct a metagenomic library (Figure 11.33). The nucleic acid includes genes from viable organisms as well as DNA from dead organisms that has been released but not yet been degraded. If RNA is isolated, it must be converted to a DNA copy by reverse transcriptase (Figure 11.6). However, isolating RNA is more time consuming and limits the metagenomic library to only those genes that have been transcribed in the environment sampled.

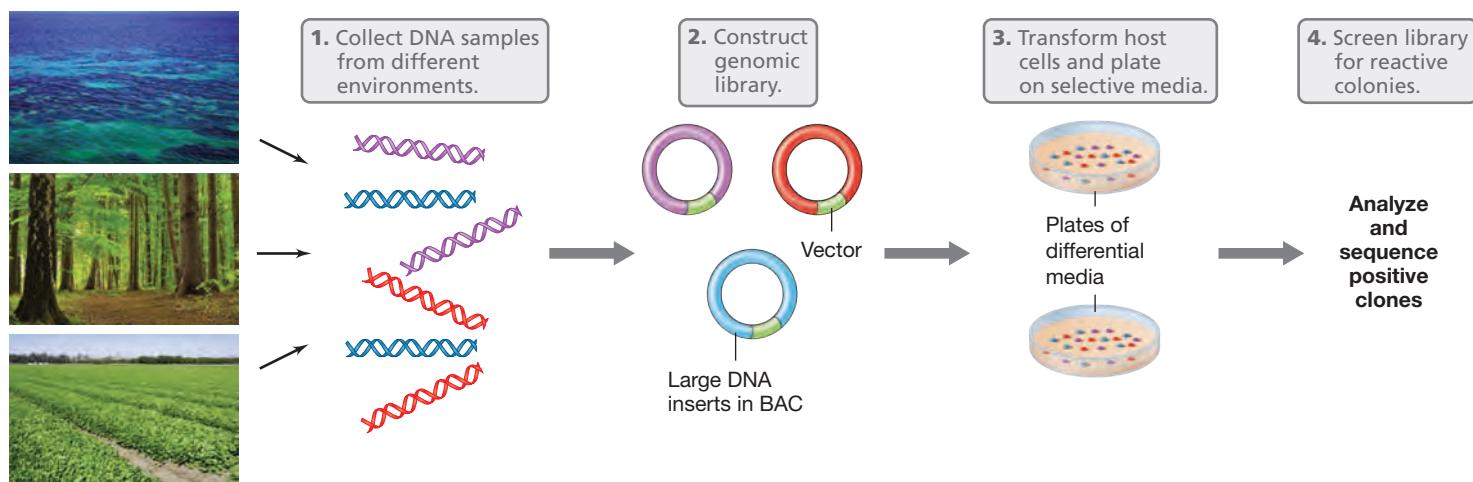

Figure 11.33 Metagenomic search for useful genes in the environment. DNA samples are obtained from different sites, such as seawater, forest soil, and agricultural soil. A clone library is constructed using bacterial artificial chromosomes (BACs) and screened for genes of interest. Possibly useful clones are analyzed further.

A metagenomic library is screened by the same techniques as any other clone library (Figure 11.8). Metagenomics has identified novel genes encoding enzymes that degrade pollutants and enzymes that make novel antibiotics. So far several lipases (see below), chitinases, esterases, and other degradative enzymes with novel substrate ranges and other properties have been isolated by this approach. Such enzymes frequently have industrial applications. Enzymes with improved resistance to industrial production conditions, such as high temperature, high or low pH, and oxidizing conditions, are especially valuable and desirable.

Retrieval of genes encoding entire metabolic pathways, such as for antibiotic synthesis, as opposed to single genes, requires vectors such as bacterial artificial chromosomes (BACs) that can carry large inserts of DNA (Section 11.10). BACs are especially useful for screening samples from rich environments, such as soil, where vast numbers of unknown genomes are present and correspondingly large numbers of genes are available to screen.

Targeted Gene Mining

Metagenomics can screen directly for enzymes with certain properties. Suppose one needed an enzyme or entire pathway capable of degrading a certain pollutant at a high temperature. The first step would be to find a hot environment polluted with the target compound. Assuming that microorganisms capable of degradation were present in the environment, a reasonable hypothesis, DNA from the environment would then be isolated and cloned. Host bacteria containing the clones would be screened for growth on the target compound. For convenience, this step is usually done in an *Escherichia coli* host, on the assumption that thermostable enzymes will still show some activity at 40°C (this is typically the case). Once suspects have been identified in the usual way, cell extracts can be tested *in vitro* at high temperatures for the enzyme of interest.

A gene mining strategy was used to isolate a thermostable lipase enzyme for commercial applications. Lipases catalyze the hydrolysis of triglycerides (fats), and because of this, they are sometimes incorporated into cosmetics and pharmaceuticals. But the industrial production of enzymes often requires them to retain activity at high temperatures. Hence, using DNA isolated from microorganisms in a hot spring, molecular biologists created a metagenomic library; the library was subsequently transformed into cells of *Escherichia coli*, and recombinant colonies expressing lipase activity were selected

using a special medium. Analysis of enzyme extracts from these lipase-producing isolates indicated enzyme activity at temperatures up to 90°C. The gene encoding this thermostable lipase was then identified by analysis of recombinant vector DNA from the lipase-producing isolates, and subsequent cloning steps to produce an expression vector for commercial production were performed.

MINIQUIZ

- Explain why metagenomic cloning gives large numbers of novel genes.
- What are the advantages and disadvantages of isolating environmental RNA as opposed to DNA?

11.16 Engineering Metabolic Pathways

Although proteins are large molecules, expressing large amounts of a single protein that is encoded by a single gene is relatively simple. By contrast, small metabolites are typically made in biochemical pathways employing several enzymes. In these cases, not only are multiple genes needed, but their expression must be regulated in a coordinated manner as well.

Pathway engineering is the process of assembling a new or improved biochemical pathway using genes from one or more organisms. Most efforts so far have modified and improved existing pathways rather than creating entirely new ones. Because genetic engineering of bacteria is simpler than that of higher organisms, most pathway engineering has been done with bacteria. Engineered microorganisms are used to make products, including alcohols, solvents, food additives, dyes, and antibiotics. They may also be used to degrade agricultural waste, pollutants, herbicides, and other toxic or undesirable materials.

An example of pathway engineering is the production of indigo by *Escherichia coli* (Figure 11.34). Indigo is an important dye used for treating wool and cotton. Blue jeans, for example, are made of cotton dyed with indigo. In ancient times indigo and related dyes were extracted from sea snails. More recently, indigo was extracted from plants, but today it is synthesized chemically. However, the demand for indigo by the textile industry has spawned new approaches for its synthesis, including a biotechnological one.

Because the structure of indigo is very similar to that of the multi-ringed hydrocarbon naphthalene, enzymes that oxygenate

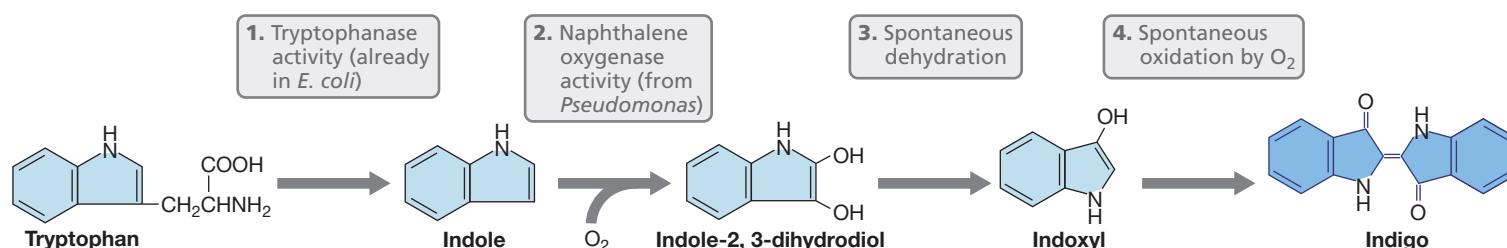

Figure 11.34 Engineered pathway for production of the dye indigo. *Escherichia coli* naturally expresses tryptophanase, which converts tryptophan into indole. Naphthalene oxygenase (originally from *Pseudomonas*) converts indole to dihydroxy-indole, which spontaneously dehydrates to indoxyl. Upon exposure to air, indoxyl dimerizes to form indigo, which is blue.

naphthalene also oxidize indole to its dihydroxy derivative; the latter oxidizes spontaneously in air to yield indigo, a bright blue pigment. Enzymes for oxygenating naphthalene are encoded by several plasmids found in *Pseudomonas* and other soil bacteria. When genes from such plasmids were cloned into *E. coli*, the cells turned blue due to production of indigo; the blue cells had incorporated the genes encoding the enzyme naphthalene oxygenase.

Although only the gene for naphthalene oxygenase was cloned during indigo pathway engineering, the indigo pathway consists of four steps, two enzymatic and two spontaneous (Figure 11.34). *E. coli* synthesizes the enzyme tryptophanase that carries out the first of these steps, the conversion of tryptophan to indole. For indigo production, tryptophan must be supplied to the recombinant *E. coli* cells. For commercial application this was accomplished by affixing the cells to a solid support in a bioreactor and trickling over the cells a tryptophan solution from waste protein sources. Recirculating the material over the cells several times, as is typically done in these types of immobilized cell industrial processes, steadily increases indigo levels until the dye can be harvested.

MINIQUIZ

- Explain why pathway engineering is more difficult than cloning and expressing a human hormone.
- How was *Escherichia coli* modified to produce indigo?

11.17 Synthetic Biology

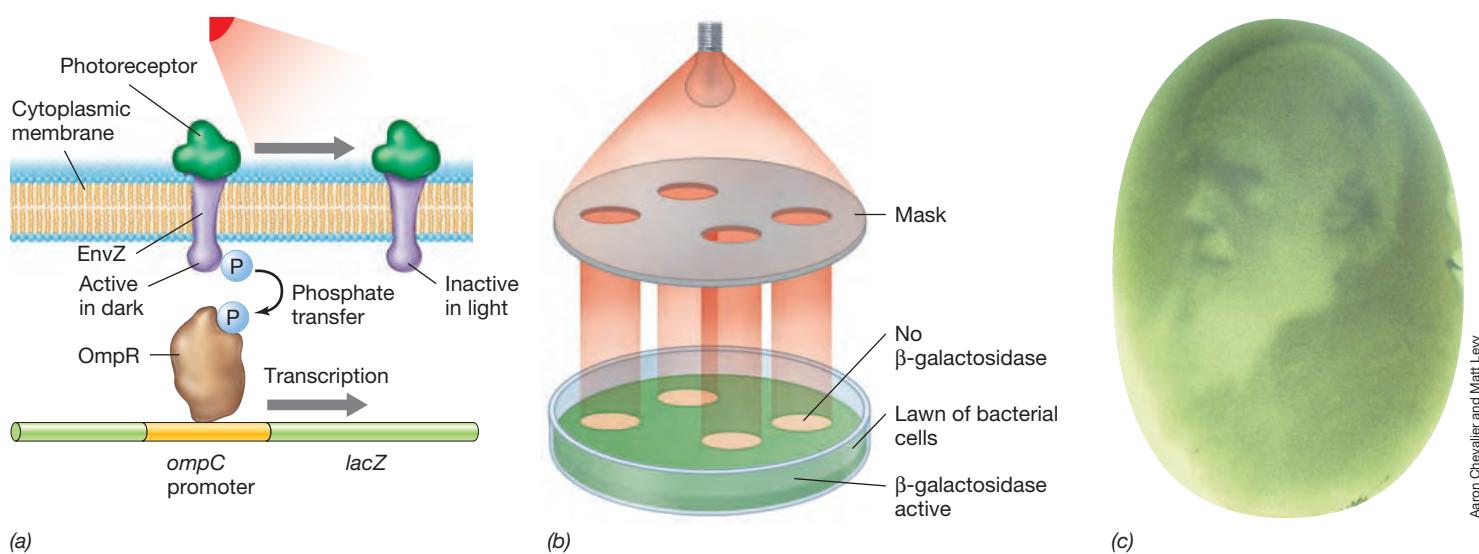

Throughout this chapter we have discussed the use of genetic engineering to modify genes and organisms. But biology today can go much farther. The term *synthetic biology* refers to the use

of genetic engineering to create novel biological systems out of available biological parts, often from several different organisms. These biological parts (promoters, enhancers, operators, ribo-switches, regulatory proteins, enzyme domains, signal receivers, etc.) have been termed *biobricks*. Synthetic biology links these biobricks together in various combinations forming modules capable of generating complex behaviors.

One example of synthetic biology is the assembly of the world's first self-replicating synthetic bacterium by synthetic biologists at the J. Craig Venter Institute in California (USA). This feat was accomplished by artificially synthesizing a 1.08-million-base-pair (Mbp) genome based on the genome sequence of the bacterium *Mycoplasma mycoides* and then displacing the native chromosome of a *Mycoplasma capricolum* cell with the newly synthesized genome. When this was done, the *M. capricolum* cell showed all of the properties of the original *M. mycoides* cell.

A fascinating example of synthetic biology on a smaller scale is the use of genetically modified *Escherichia coli* to produce photographs. The engineered bacteria are grown as a lawn on agar plates. When an image is projected onto the lawn, bacteria in the dark make a dark pigment whereas bacteria in the light do not. The result is a primitive photograph of the projected image (Figure 11.35).

Construction of the photographic *E. coli* required the synthetic biology of three genetic modules: (1) a light detector and signaling module; (2) a pathway to convert heme (already present in *E. coli*) into the photoreceptor pigment phycocyanobilin; and (3) an enzyme encoded by a gene whose transcription can be switched on and off to make the dark pigment (Figure 11.35a). The light detector is a fusion protein. The outer half is the light-detecting part of the phytochrome protein from the cyanobacterium *Synechocystis*. This requires phycocyanobilin (an accessory light-harvesting pigment of cyanobacteria, [Section 13.2](#)), which is

Aaron Chevalier and Matt Levy

Figure 11.35 Bacterial photography. (a) Light-detecting *Escherichia coli* cells were genetically engineered using components from cyanobacteria and *E. coli* itself. Red light inhibits phosphate (P) transfer to the DNA-binding protein OmpR; phosphorylated OmpR is required to activate lacZ transcription (*lacZ* encodes β-galactosidase). (b) Setup for making a bacterial photograph. The opaque portions of the mask correspond to zones where β-galactosidase is active and thus to the dark regions of the final image. (c) A bacterial photograph of a portrait of Charles Darwin.

not made by *E. coli*, hence the need to install the pathway to make phycocyanobilin.

The inner half of the light detector is the signal transmission domain of the EnvZ sensor protein from *E. coli*. EnvZ is part of a two-component regulatory system, its partner being OmpR (➡ Section 7.7). Normally, EnvZ activates the DNA-binding protein OmpR. Activated OmpR in turn activates target genes by binding to the promoter. In the present case, the hybrid protein was designed to activate OmpR in the dark but not in the light. This is because phosphorylation of OmpR is required for activation, and red light converts the sensor to a state in which phosphorylation is inhibited. Consequently the target gene is off in the light and on in the dark. When a mask is placed over the Petri plate containing a lawn of the engineered *E. coli* cells (Figure 11.35b), cells in the dark make a pigment that cells in the light do not, and in this way a “photograph” of the masked image develops (Figure 11.35c).

The pigment made by the *E. coli* cells results from the activity of the lactose-degrading enzyme β -galactosidase, naturally present in *E. coli*. The target gene, *lacZ*, encodes this enzyme. In the dark, *lacZ* is expressed and β -galactosidase is made. The enzyme

cleaves the lactose analog Xgal (Section 11.6) present in the growth medium to release galactose and a black dye. In the light, the *lacZ* gene is not expressed, no β -galactosidase is made, and so no dye is released. Contrast in the photograph is controlled by how much light cells see, which is governed by the nature of the mask that is used (Figure 11.35c).

Although the “synthetic” *M. capricolum* was not a cell in which all of its components—cytoplasm, membranes, ribosomes, and the like—were made from scratch, and cultures of *E. coli* will never replace digital photography, the knowledge gained in each case from assembling the necessary parts by synthetic biology helps build our understanding of how bioengineered components function *in vivo*. This in turn will allow for even more complex synthetic biology and may someday lead to applications of this science to solve urgent problems in medicine, agriculture, and the environment.

MINIQUIZ

- What are biobricks?
- How was *Escherichia coli* modified to produce a photograph?

BIG IDEAS

11.1 • Restriction enzymes recognize specific short sequences in DNA and make cuts in the DNA. The products of restriction enzyme digestion can be separated using gel electrophoresis.

11.2 • Complementary nucleic acid sequences may be detected by hybridization. Probes composed of single-stranded DNA or RNA and labeled with radioactivity or a fluorescent dye are hybridized to target DNA or RNA sequences.

11.3 • The polymerase chain reaction is a procedure for amplifying DNA *in vitro* and employs heat-stable DNA polymerases. Heat is used to denature the DNA into two single-stranded molecules, each of which is copied by the polymerase. After each cycle, the newly formed DNA is denatured and a new round of copying proceeds. After each cycle, the amount of target DNA doubles.

11.4 • The isolation of a specific gene or region of a chromosome by molecular cloning is done using a plasmid or virus as the cloning vector. Restriction enzymes and DNA ligase are used *in vitro* to produce a chimeric DNA molecule composed of DNA from two or more sources. Once introduced into a suitable host, the cloned DNA can be produced in large amounts under the control of the cloning vector. Identification of cloned genes is performed by a range of molecular techniques.

11.5 • Synthetic DNA molecules of desired sequence can be made *in vitro* and used to construct a mutated gene directly or to change specific base pairs within a gene by site-directed mutagenesis. Also, genes can be disrupted by inserting DNA fragments, called cassettes, into them, generating knockout mutants.

11.6 • Reporter genes are genes whose products, such as β -galactosidase or GFP, are easy to assay or detect. They are used to simplify and increase the speed of genetic analysis. In gene fusions, segments from two different genes, one of which is usually a reporter gene, are spliced together.

11.7 • Plasmids are useful cloning vectors because they are easy to isolate and purify and are often able to multiply to high copy numbers in bacterial cells. Antibiotic resistance genes on the plasmid are used to select bacterial cells containing the plasmid, and color-screening systems are used to identify colonies containing cloned DNA.

11.8 • The choice of a cloning host depends on the final application. In many cases the host can be a prokaryote, but in others, it is essential that the host be a eukaryote. Any host must be able to take up DNA, and there are a variety of techniques by which this can be accomplished, both natural and artificial.

11.9 • Many cloned genes are not expressed efficiently in a foreign host. Expression vectors have been developed for prokaryotic and eukaryotic hosts that contain genes or regulatory sequences that both increase transcription of the cloned gene and control the level of transcription. Signals to improve the efficiency of translation may also be present in the expression vector.

11.10 • Specialized cloning vectors such as bacteriophages, cosmids, and artificial chromosomes have been constructed for cloning very large fragments of DNA. Recombinant bacteriophages can be packaged *in vitro* for efficient transfer to a host cell, while cosmids are plasmid vectors that contain lambda *cos* sites. Artificial chromosomes can be used to clone DNA fragments approaching a megabase in size.

11.11 • To achieve very high levels of expression of eukaryotic genes in prokaryotes, the expressed gene must be free of introns. This can be accomplished by synthesizing cDNA from the mature mRNA encoding the protein of interest or by making an entirely synthetic gene. Protein fusions are often used to stabilize or solubilize the cloned protein.

11.12 • The first human protein made commercially using engineered bacteria was human insulin. Recombinant bovine

somatotropin is widely used in the United States to increase milk yield in dairy cows.

11.13 • Genetic engineering can make plants resistant to disease and improve product quality. The Ti plasmid of the bacterium *Agrobacterium tumefaciens* can transfer DNA into plant cells. Genetically engineered commercial plants are called genetically modified organisms (GMOs).

11.14 • Many recombinant vaccines have been produced or are under development. These include live recombinant, vector, and subunit vaccines.

11.15 • Genes for useful products may be cloned directly from DNA or RNA in environmental samples without first isolating the organisms that carry them.

11.16 • In pathway engineering, genes that encode the enzymes for a metabolic pathway are assembled. These genes may come from one or more organisms, but the engineering must achieve regulation of the coordinated sequence of expression required in the pathway.

11.17 • Instead of modifying or improving a single existing pathway, synthetic biology focuses on engineering novel biological systems by linking known biological components together in various combinations.

REVIEW OF KEY TERMS

Artificial chromosome a single copy vector that can carry extremely long inserts of DNA and is widely used for cloning segments of large genomes

Bacterial artificial chromosome (BAC) a circular artificial chromosome with bacterial origin of replication

Biotechnology the use of organisms, typically genetically altered, in industrial, medical, or agricultural applications

Cassette mutagenesis creating mutations by the insertion of a DNA cassette

DNA cassette an artificially designed segment of DNA that usually carries a gene for resistance to an antibiotic or some other convenient marker and is flanked by convenient restriction sites

Expression vector a cloning vector that contains the necessary regulatory sequences

to allow transcription and translation of cloned genes

Gel electrophoresis a technique for separation of nucleic acid molecules by passing an electric current through a gel made of agarose or polyacrylamide

Gene disruption (also called gene knockout) the inactivation of a gene by insertion of a DNA fragment that interrupts the coding sequence

Gene fusion a structure created by joining together segments of two separate genes, in particular when the regulatory region of one gene is joined to the coding region of a reporter gene

Genetically modified organism (GMO) an organism whose genome has been altered using genetic engineering; the abbreviation

GM is also used in terms such as GM crops and GM foods

Genetic engineering the use of *in vitro* techniques in the isolation, alteration, and expression of DNA or RNA and in the development of genetically modified organisms

Genomic library (DNA library) a collection of cloned DNA segments that is big enough to contain at least one copy of every gene from a particular organism

Green fluorescent protein (GFP) a protein that glows green and is widely used in genetic analysis

Hybridization the formation of a double helix by the base pairing of single strands of DNA or RNA from two different (but related) sources

Modification enzyme an enzyme that chemically alters bases within a restriction enzyme recognition site and thus prevents the site from being cut

Molecular cloning the isolation and incorporation of a fragment of DNA into a vector where it can be replicated

Northern blot a hybridization procedure where RNA is the target and DNA or RNA is the probe

Nucleic acid probe a strand of nucleic acid that can be labeled and used to hybridize to a complementary molecule from a mixture of other nucleic acids

Operon fusion a gene fusion in which a coding sequence that retains its own translational signals is fused to the transcriptional signals of another gene

Pathway engineering the assembly of a new or improved biochemical pathway using genes from one or more organisms

Polymerase chain reaction (PCR) artificial amplification of a DNA sequence by repeated cycles of strand separation and replication

Polyvalent vaccine a vaccine that immunizes against more than one disease

Protein fusion a gene fusion in which two coding sequences are fused so that they share the same transcriptional and translational start sites

Recombinant DNA a DNA molecule containing DNA originating from two or more sources

Reporter gene a gene used in genetic analysis because the product it encodes is easy to detect

Restriction enzyme an enzyme that recognizes a specific DNA sequence and then cuts the DNA; also known as a restriction endonuclease

Reverse transcription the conversion of an RNA sequence into the corresponding DNA sequence

Shotgun cloning making a genomic library by random cloning of DNA fragments

Shuttle vector a cloning vector that can replicate in two or more dissimilar hosts

Site-directed mutagenesis construction in vitro of a gene with a specific mutation

Southern blot a hybridization procedure where DNA is the target and RNA or DNA is the probe

T-DNA the segment of the *Agrobacterium tumefaciens* Ti plasmid that is transferred into plant cells

Ti plasmid a plasmid in *Agrobacterium tumefaciens* capable of transferring genes from bacteria to plants

Transgenic organism a plant or an animal with foreign DNA inserted into its genome

Vector (as in cloning vector) a self-replicating DNA molecule that is used to carry cloned genes or other DNA segments for genetic engineering

Vector vaccine a vaccine made by inserting genes from a pathogenic virus into a relatively harmless carrier virus

Yeast artificial chromosome (YAC) an artificial chromosome with yeast origin of replication and a centromere sequence

REVIEW QUESTIONS

- What are restriction enzymes? Why does the presence of a restriction enzyme in a cell not cause the degradation of that cell's DNA? (Section 11.1)
- How could you detect a colony containing a cloned gene if you already knew the sequence of the gene? (Section 11.2)
- Describe the basic principles of gene amplification using the polymerase chain reaction (PCR). How have thermophilic and hyperthermophilic prokaryotes simplified the use of PCR? (Section 11.3)
- Genetic engineering depends on vectors. Describe the properties needed in a well-designed plasmid cloning vector. (Section 11.4)
- How could you detect a colony containing a cloned gene if you did not know the gene sequence but had available purified protein encoded by the gene? (Section 11.4)
- What are the major uses for artificially synthesized DNA? (Section 11.5)
- What does site-directed mutagenesis allow you to do that normal mutagenesis does not? (Section 11.5)
- What is a reporter gene? Describe two widely used reporter genes. (Section 11.6)
- How are gene fusions used to investigate gene regulation? (Section 11.6)
- How does the insertional inactivation of β -galactosidase allow the presence of foreign DNA in a plasmid vector such as pUC19 to be detected? (Section 11.7)
- Describe two prokaryotic cloning hosts and the beneficial and detrimental features of each. (Section 11.8)
- Describe the similarities and differences between expression vectors and shuttle vectors. (Section 11.9)
- How has bacteriophage T7 been used in expressing foreign genes in *Escherichia coli*, and what desirable features does this regulatory system possess? (Section 11.9)
- What advantages are there to using a lambda-based cloning vector rather than a plasmid vector? (Section 11.10)
- What are the essential characteristics of an artificial chromosome? What is the difference between a BAC and a YAC? (Section 11.10)
- What is the significance of reverse transcriptase in the cloning of animal genes for expression in bacteria? (Section 11.11)
- What classes of mammalian proteins are produced by biotechnology? How are the genes for such proteins obtained? (Section 11.12)
- What is the Ti plasmid and how has it been of use in genetic engineering? (Section 11.13)
- What is a subunit vaccine and why are subunit vaccines considered a safer way of conferring immunity to viral pathogens than attenuated virus vaccines? (Section 11.14)
- How has metagenomics been used to find novel useful products? (Section 11.15)
- What is pathway engineering? Why is it more difficult to produce an antibiotic than to produce a single enzyme via genetic engineering? (Section 11.16)
- How does synthetic biology differ from pathway engineering? (Section 11.17)

APPLICATION QUESTIONS

1. Suppose you are given the task of constructing a plasmid expression vector suitable for molecular cloning in an organism of industrial interest. List the characteristics such a plasmid should have. List the steps you would use to create such a plasmid.
2. Suppose you have just determined the DNA base sequence for an especially strong promoter in *Escherichia coli* and you are interested in incorporating this sequence into an expression vector. Describe the steps you would use. What precautions are necessary to be sure that this promoter actually works as expected in its new location?
3. Many genetic systems use the *lacZ* gene encoding β-galactosidase as a reporter. What advantages or problems would there be if (a) luciferase or (b) green fluorescent protein were used instead of β-galactosidase as reporters?
4. You have just discovered a protein in mice that may be an effective cure for cancer, but it is present only in tiny amounts. Describe the steps you would use to produce this protein in therapeutic amounts. Which host would you want to clone the gene into and why? Which host would you use to express the protein in and why?

12 • Microbial Evolution and Systematics

microbiologynow

Gene Exchange and the Evolution of Marine *Vibrio*

Vibrio cholerae is a bacterium present in coastal marine habitats around the world, and some strains cause cholera, a devastating diarrheal disease. Cholera is caused by strains of *V. cholerae* that have acquired genes encoding cholera toxin through horizontal gene transfer. Horizontal gene transfer has powerful effects on microbial evolution. In fact, many traits of bacteria, including their pathogenicity, can be altered by the acquisition of genes from other species.

Microbiologists are still struggling to understand the effects of horizontal gene transfer on microbial evolution. In *V. cholerae*, patterns of gene transfer vary with respect to the core genome and the dispensable genome. Housekeeping genes, which carry out important cellular processes and are a component of the core genome, are exchanged among strains of *V. cholerae* but are not exchanged between species. In contrast, integron genes, a component of the dispensable genome, can be exchanged across species boundaries and are readily exchanged between the species *V. cholerae* and *V. metecus* (photo inset).

It turns out that the exchange of integron genes is governed more by geographic co-occurrence than by species boundaries.¹ For example, *V. cholerae* strains isolated from a salt pond (photo) in Falmouth, Massachusetts, share more integron genes with *Vibrio metecus* strains isolated from the same pond than with other *V. cholerae* strains isolated from a geographically remote location in Bangladesh.

When it comes to gene exchange in the dispensable genome it may be all about (as a real estate agent would put it) “location, location, location.” Integron genes can alter certain aspects of metabolism and cell surface characteristics. It is likely that these can help all *Vibrio* species adapt to their local environments and can impact the evolution of pathogenicity.

¹Boucher, Y., et al. 2011. Local mobile gene pools rapidly cross species boundaries to create endemicity within global *Vibrio cholerae* populations. *mBio*. 2:e00335–10.

- III Microbial Evolution 363
- IV Microbial Systematics 369

Evolution is the unifying theme that underlies all of biology. Charles Darwin was the first to observe that living things change over time, and he proposed that this process of evolution resulted from natural selection acting on random variations between offspring. Today we know that these random variations occur as a result of mutation and recombination in DNA sequence. The history of evolution is written in our genetic code and DNA sequences provide a record of evolution that spans billions of years. We now know that microorganisms have dominated much of the history of life on Earth. Microorganisms were

teeming in the seas for billions of years before the appearance of the first plants and animals, and their activities have shaped our biosphere.

This chapter focuses on the evolution of microbial life. We will explore the evolutionary history of life and the manner in which DNA sequences can be used to classify microorganisms and to discern their evolutionary relationships. Overall, the goal of this chapter is to provide an evolutionary and systematic framework with which to comprehend the diversity of microbial life that we will explore in the next four chapters.

I • Early Earth and the Origin and Diversification of Life

In these first sections, we consider the possible conditions under which life arose, the earliest evidence for cellular life, and its divergence into three evolutionary lineages, *Bacteria*, *Archaea*, and *Eukarya*. Although much about these events and processes remains speculative, geological and molecular evidence has combined to build a plausible scenario for the earliest events in the evolution of life and for the fundamental impacts that microbes have had on the history of our Earth.

12.1 Formation and Early History of Earth

The Earth of 4 billion years ago would be foreign and inhospitable to human eyes, but this sterile wasteland of blasted rock and boiling seas was the incubator from which all life sprang. The story of life begins not long after the dawn of our solar system with the formation of Earth itself.

Origin of Earth

Earth formed about 4.5 billion years ago, based on analyses of slowly decaying radioactive isotopes (Figure 12.1). Our planet and the other planets of our solar system arose from materials making up a disc-shaped nebular cloud of dust and gases released by the supernova of a massive old star. As a new star—our sun—formed within this cloud, it began to compact, undergo nuclear fusion, and release large amounts of energy in the form of heat and light. Materials left in the nebular cloud began to clump and fuse due to collisions and gravitational attractions, forming tiny accretions that gradually grew larger to form clumps that eventually coalesced into planets. Energy released in this process heated the emerging Earth as it formed, as did energy released by radioactive decay within the condensing materials, forming a planet Earth of fiery hot magma. As Earth cooled over time, a metallic core, rocky mantle, and a lower-density, thin surface crust formed.

The inhospitable conditions of early Earth, characterized by a molten surface under intense bombardment by asteroids and other objects from space, are thought to have persisted for over 500 million years. Water on Earth originated from innumerable collisions with icy comets and asteroids and from volcanic outgassing of the planet's interior. Given Earth's heat at the time, water would have been present only as water vapor. No rocks dating to the origin of planet Earth have yet been discovered, presumably because they have undergone geological metamorphosis. Ancient crystals of the

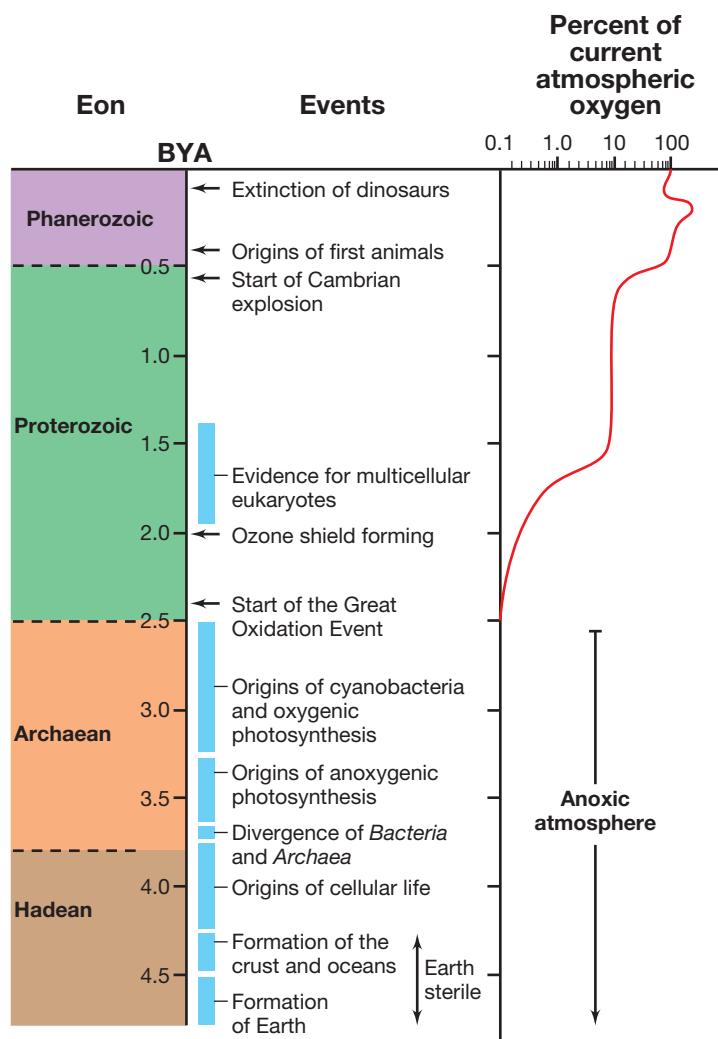

Figure 12.1 Major landmarks in biological evolution, Earth's changing geochemistry, and microbial metabolic diversification. The oldest date for the origin of life is fixed by the time of Earth's origin, and the minimum time for the origin of oxygenic photosynthesis is fixed by the Great Oxidation Event, about 2.4 billion years ago (BYA). Note how the oxygenation of the atmosphere from cyanobacterial metabolism was a gradual process, occurring over a period of about 2 billion years. Compare this figure with the introduction to the antiquity of life on Earth shown in Figure 1.4.

mineral zircon (ZrSiO_4) have been discovered, however, and these materials give us a glimpse of conditions on Earth at this time. Impurities trapped in the crystals and isotopic ratios of oxygen in the minerals (➡ Section 18.9) indicate that solid crust began forming and water began condensing into oceans perhaps as early as 4.3 billion years ago. The presence of liquid water implies that conditions could have been compatible with life within a couple of hundred million years after Earth was formed.

Some of the oldest sedimentary rocks discovered thus far are in southwestern Greenland; these rocks date to about 3.86 billion years ago. The sedimentary composition of these rocks indicates that oceans were present at this time. The fossilized remains of what appear to be cells (Figure 12.2) and the isotopically “light” carbon abundant in these rocks provide the earliest evidence for microbial life (we discuss the use of isotopic analyses of carbon and sulfur as indications of living processes in Section 18.9).

Origin of Cellular Life

The origin of life on Earth remains the greatest of mysteries, obscured by the depths of time. There are few rocks that survive unaltered to testify about this period of Earth’s history. Experimental evidence indicates that organic precursors to living cells can form spontaneously under certain conditions, providing the preconditions needed for the first living systems. However, conditions on Earth’s surface more than 4 billion years ago, in particular the extremely hot temperatures and levels of ultraviolet radiation, were likely hostile to the formation of life as we know it. One hypothesis holds that life may have originated well below Earth’s surface at hydrothermal springs on the ocean floor (Figure 12.3). Deep on the ocean floor, conditions would have been less hostile and more stable than on Earth’s surface. A steady and abundant supply of energy in the form of reduced inorganic compounds—hydrogen (H_2) and hydrogen sulfide (H_2S), for example—would have been available at these hydrothermal springs. The unique geochemistry of these sites may have allowed for the formation of molecules critical for the emergence of life and the formation of compartmentalized structures necessary for conserving energy.

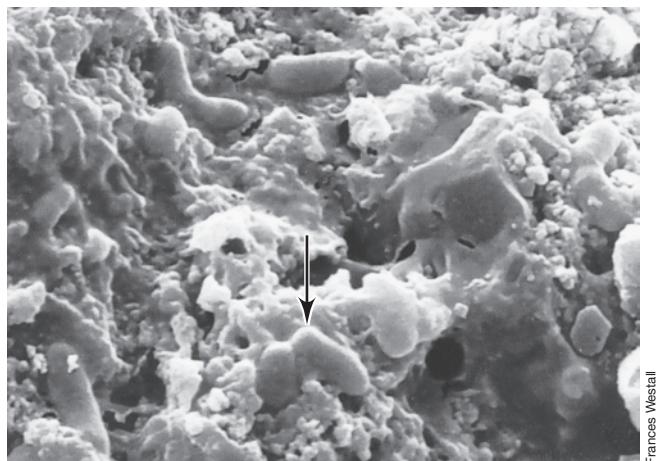

Figure 12.2 Ancient microbial life. Scanning electron micrograph of microfossil bacteria from 3.45-billion-year-old rocks of the Barberton Greenstone Belt, South Africa. Note the rod-shaped bacteria (arrow) attached to particles of mineral matter. The cells are about 0.7 μm in diameter.

Eventually, lipid bilayers took the place of mineral compartments, allowing the first cells to disperse to new habitats.

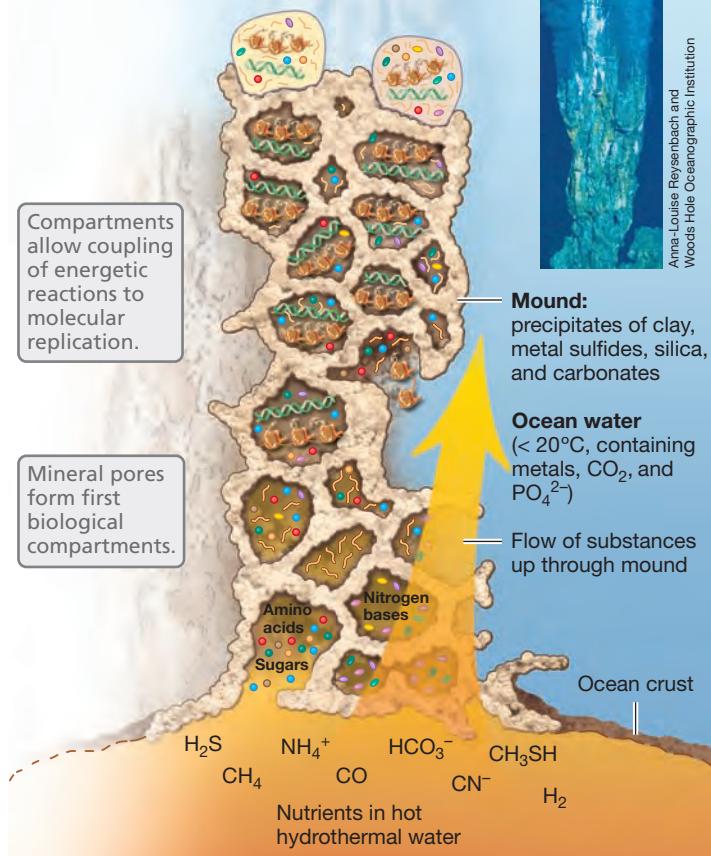

Figure 12.3 Submarine mounds and their possible link to the origin of life. Model of the interior of a hydrothermal mound with hypothesized transitions from prebiotic chemistry to cellular life depicted. Inset: photo of an actual hydrothermal mound. Hot mineral-rich hydrothermal fluid mixes with cooler, more oxidized, ocean water, forming precipitates of Fe and S compounds, clays, silicates, and carbonates. Mineral precipitates form pores that could have served as energy-rich compartments that facilitated the evolution of precellular forms of life.

Whether on the seafloor or elsewhere, some form of prebiotic chemistry must have facilitated the development of the first self-replicating systems, the precursors to cellular life.

Molecules of RNA were likely a central component of the first self-replicating systems and it is possible that life began in an *RNA world* (Figure 12.4). RNA is a component of certain essential cofactors and molecules found in all cells (such as ATP, NADH, and coenzyme A); it can bind small molecules (such as ATP, amino acids, and other nucleotides); and it can have catalytic activity, as RNA is known to catalyze protein synthesis through the activities of rRNA, tRNA, and mRNA (➡ Section 4.13). It is possible that certain RNA molecules might once have had the ability to catalyze their own synthesis. Later, as different types of proteins emerged, some with catalytic abilities, proteins began to take over the catalytic role of RNAs. Eventually, DNA, a molecule that is inherently more stable than RNA and therefore a better repository of genetic (coding) information, arose and assumed the template role for RNA synthesis (Figure 12.4). The earliest cellular forms of life likely possessed

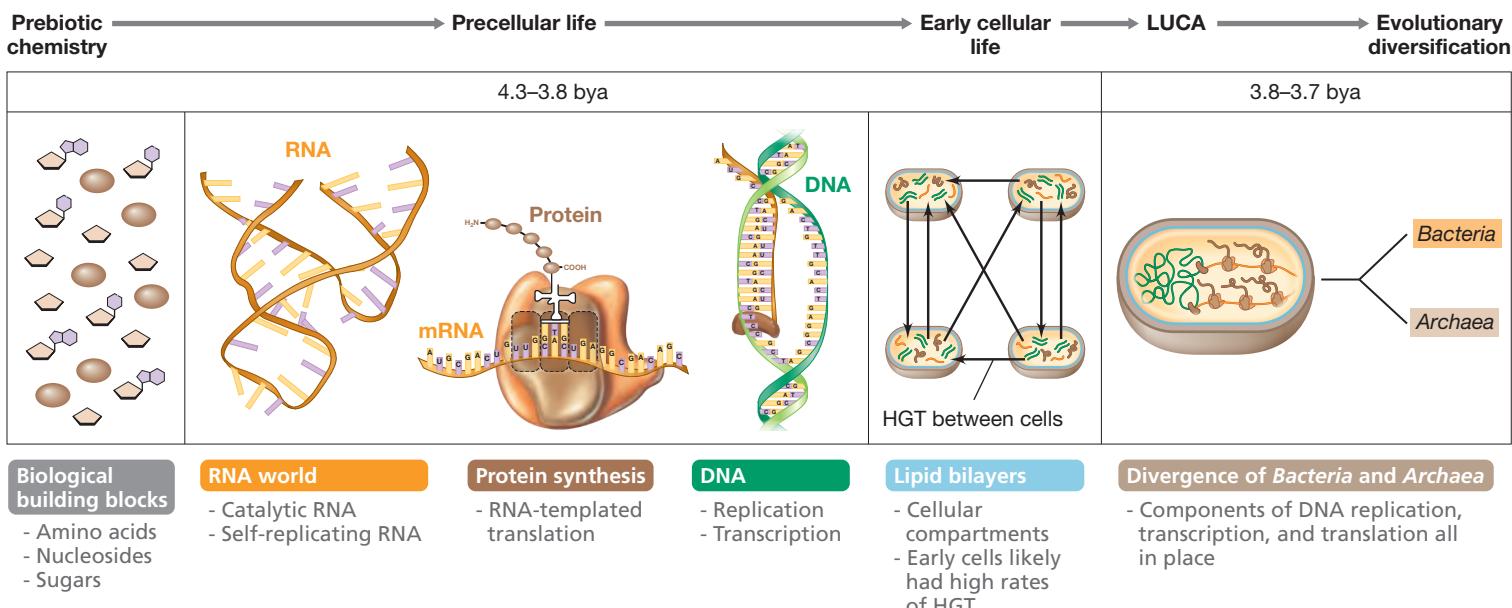

Figure 12.4 Events hypothesized to precede the origin of cellular life. The earliest self-replicating biological systems may have been based on catalytic RNA. At some point RNA enzymes evolved the capability to synthesize proteins, and proteins became the main catalytic molecules. Conversion from RNA- to DNA-based genomes required the evolution of DNA and RNA polymerases. The lipid bilayer is the site of electron transport and the evolution of this structure was likely important for energy conservation, in addition to containing and protecting biomolecules. The last universal common ancestor (LUCA), which preceded the divergence of *Bacteria* and *Archaea*, was a cellular organism that had a lipid bilayer and used DNA, RNA, and protein. Horizontal gene transfer (HGT) may have allowed rapid transfer of beneficial genes among early forms of life.

elements of this three-part system of DNA, RNA, and protein, in addition to a membrane system capable of conserving energy (see Figure 12.5). The *last universal common ancestor* (LUCA) must have existed at 3.8–3.7 billion years ago, the point at which *Bacteria* and *Archaea* diverged and life began to diversify into the forms we recognize today. One can envision a time of intensive biochemical innovation and experimentation in which much of the structural and functional machinery of these earliest self-replicating systems evolved and was refined by natural selection.

Metabolic Diversification: Consequences for Earth's Biosphere

Following the origin of cells, microbial life experienced a long period of metabolic diversification, exploiting the various resources available on Earth. The earth and all of its oceans were anoxic for much of its history. Molecular oxygen (O_2) was absent in any significant quantities until oxygenic photosynthesis by cyanobacteria evolved. Thus, the energy-generating metabolism of primitive cells would have been exclusively anaerobic and would likely have had to be heat-stable because of the temperature of early Earth.

During this era CO_2 may well have been the major source of carbon for cells (autotrophy, \Leftrightarrow Section 13.5) because abiotic sources of organic carbon would quickly have become limiting. It is widely thought that H_2 was a major fuel for energy metabolism of early cells. This hypothesis is also supported by the tree of life (see Figure 12.13), in that virtually all of the earliest branching organisms in the *Bacteria* and *Archaea* use H_2 as an electron donor in energy metabolism and are autotrophs. Elemental sulfur (S^0) may have been one of the earliest electron acceptors, as the reduction of S^0

to yield H_2S is exergonic and would likely have required relatively few enzymes (Figure 12.5). Moreover, because of the abundance of H_2 and sulfur compounds on early Earth, this scheme would have provided cells with a nearly limitless supply of energy.

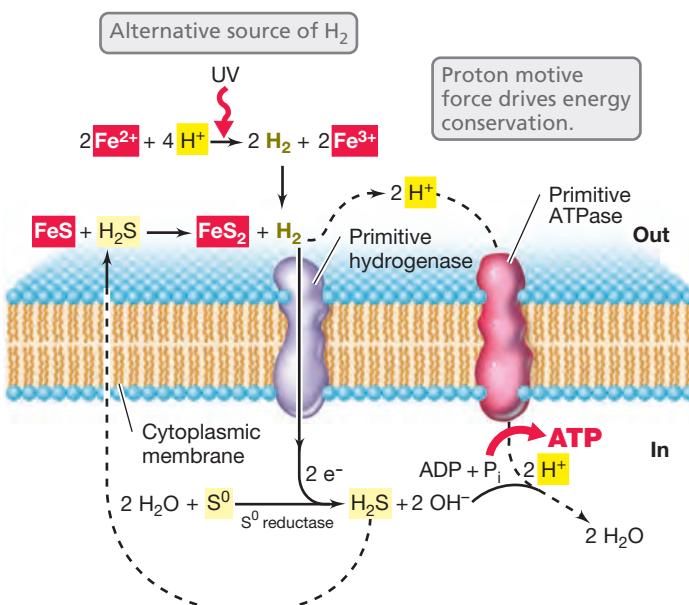

Figure 12.5 A possible energy-generating scheme for primitive cells. Formation of pyrite leads to H_2 production and S^0 reduction, which fuels a primitive ATPase. Note how H_2S plays only a catalytic role; the net substrates would be FeS and S^0 . Also note how few different proteins would be required. $\Delta G^{0'} = -42 \text{ kJ}$ for the reaction $FeS + H_2S \rightarrow FeS_2 + H_2$.

Evidence suggests that ancestors of modern-day *Bacteria* and *Archaea* had already diverged by about 3.7 billion years ago (Figure 1.4b). Early *Bacteria* may have used H₂ and CO₂ to produce acetate (Section 13.19). At the same time, early *Archaea* developed the ability to use H₂ and CO₂, or possibly acetate as it accumulated, as substrates for methanogenesis (Section 13.20). These early forms of chemolithotrophic metabolism driven by H₂ would likely have supported the production of large amounts of organic compounds from autotrophic CO₂ fixation. Over time, these organic materials would have accumulated and could have provided the conditions needed for the evolution of new chemo-organotrophic bacteria with diverse metabolic strategies to conserve energy from the oxidation of organic compounds.

MINIQUIZ

- What characteristics would have made the surface of Earth inhospitable to the formation of life 4.5 billion years ago?
- How do we know when oceans were first present on Earth? Why is the presence of oceans significant to the origins and diversification of life?
- What lines of reasoning support the hypothesis that the first self-replicating systems were based on RNA molecules?

12.2 Photosynthesis and the Oxidation of Earth

The evolution of photosynthesis revolutionized the chemistry of Earth. Phototrophic organisms use energy from the sun to oxidize molecules such as H₂S, S⁰, or H₂O and to synthesize complex organic molecules from carbon dioxide or simple organic molecules (Section 13.5). Over time, the products of photosynthesis accumulated in the biosphere, stimulating the further diversification of microbial life. Earth's first phototrophs were anoxygenic (Sections 13.3 and 14.4–14.7), but from these evolved the *Cyanobacteria*, the earliest oxygenic phototrophs (Figure 12.1, Section 14.3).

Fossilized microbial formations called **stromatolites** can be found in rocks that are 3.5 billion years old, providing the earliest conclusive evidence of life on Earth (Figure 12.6a). Stromatolites, or “layered rocks,” are formed when certain kinds of microbial mats cause the deposition of carbonate or silicate minerals that promote fossilization (we discuss microbial mats in Section 19.5). Stromatolites were diverse and common on Earth between 2.8 and 1 billion years ago, but declined dramatically in abundance over the last billion years. Stromatolites are largely gone from Earth today, and yet modern examples of this ancient microbial ecosystem can still be found in certain shallow marine basins (Figure 12.6c, e) or in hot springs (Figure 12.6d; Figure 19.9). Phototrophic bacteria, such as oxygen-producing cyanobacteria (Section 14.3) and the green nonsulfur bacterium *Chloroflexus* (Section 14.7), play a central role in the formation of modern stromatolites. Likewise, ancient stromatolites contain microfossils that appear remarkably similar to modern species of cyanobacteria and green algae (Figure 12.7). Hence, the earliest phototrophic organisms may have evolved more than 3.5 billion years ago and apparently only in *Bacteria*, giving rise to the stromatolites we observe in the fossil record.

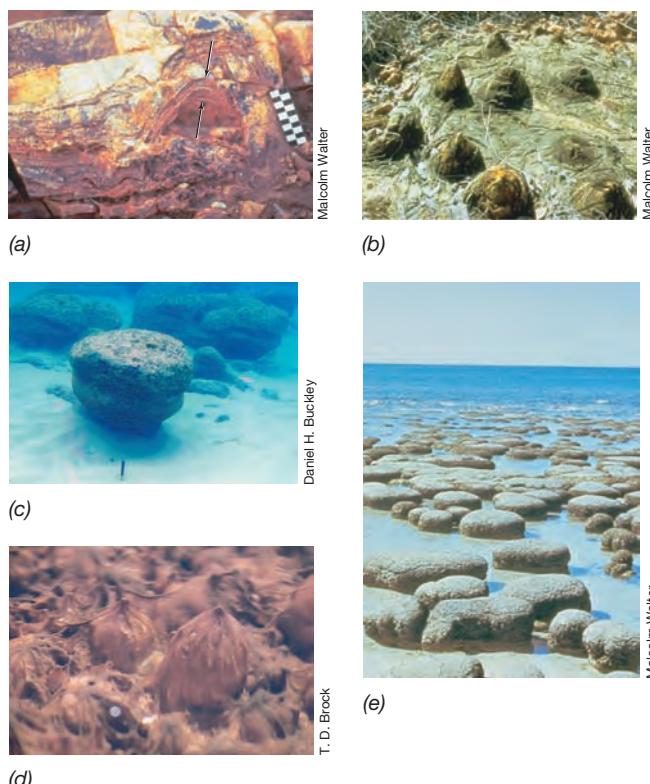

Figure 12.6 Ancient and modern stromatolites. (a) The oldest known stromatolite, found in a rock about 3.5 billion years old, from the Warrawoona Group in Western Australia. Shown is a vertical section through the laminated structure preserved in the rock. Arrows point to the laminated layers. (b) Stromatolites of conical shape from 1.6-billion-year-old dolomite rock from northern Australia. (c) Modern stromatolites, Darby Island, Bahamas. The large stromatolite in the foreground is about 1 m in diameter. (d) Modern stromatolites composed of thermophilic cyanobacteria growing in a thermal pool in Yellowstone National Park. Each structure is about 2 cm high. (e) Modern stromatolites from Shark Bay, Australia. Individual structures are 0.5–1 m in diameter.

Early forms of photosynthesis were anoxygenic, using electron donors such as H₂S and generating elemental sulfur (S⁰) as a waste product (Section 13.3). The ability to use solar radiation as an energy source allowed phototrophs to diversify extensively. By 2.5–3.3 billion years ago, the cyanobacterial lineage evolved a photosystem capable of oxygenic photosynthesis (Section 13.4) in which H₂O supplanted H₂S in the photosynthetic reduction of CO₂, thereby generating O₂ as a waste product. As we will see in the next section, the origin of oxygenic photosynthesis and the rise of O₂ in Earth's atmosphere caused the greatest change in the history of our biosphere and set the stage for the evolution of even newer forms of life that evolved to exploit the energy available from O₂ respiration.

The Rise of Oxygen: Banded Iron Formations

In the absence of O₂, all of Earth's iron would have been present in reduced forms and there would have been abundant iron dissolved in Earth's oceans, likely making them red rather than blue. Molecular and chemical evidence indicates that oxygenic photosynthesis first appeared on Earth at least 300 million years before significant levels of O₂ appeared in the atmosphere. The O₂ that

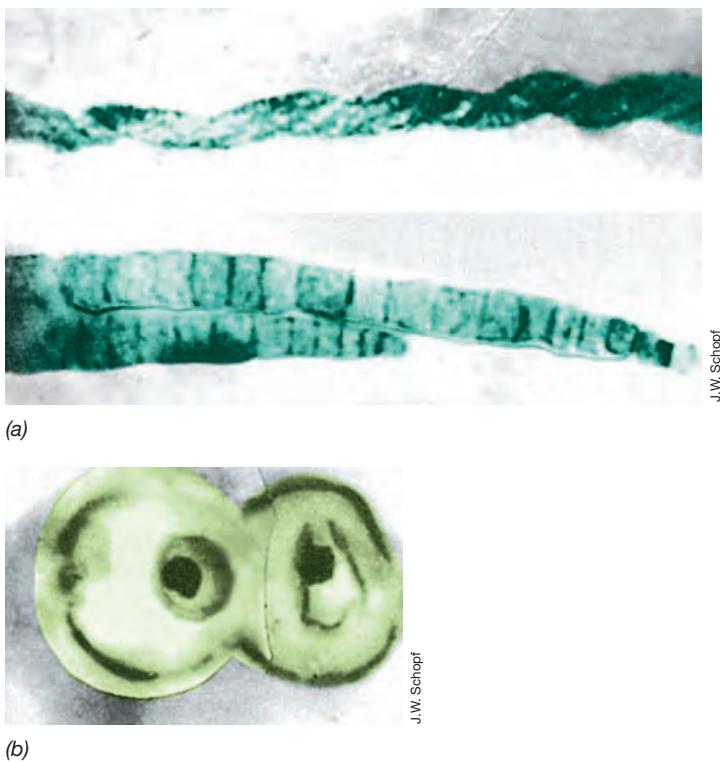

Figure 12.7 More recent fossil bacteria and eukaryotes. (a) One-billion-year-old microfossils from central Australia that resemble modern filamentous cyanobacteria. Cell diameters, 5–7 μm . (b) Microfossils of eukaryotic cells from the same rock formation. The cellular structure is similar to that of certain modern green algae, such as *Chlorella* species. Cell diameter, about 15 μm . Color was added to make cell form more apparent.

cyanobacteria produced could not accumulate in the atmosphere because it reacted spontaneously with the reduced iron minerals in the oceans to make iron oxides. By 2.4 billion years ago, O_2 levels had risen to one part per million, a tiny amount by present-day standards, but enough to initiate what has come to be called the *Great Oxidation Event* (Figure 12.1).

The metabolism of cyanobacteria yielded O_2 that oxidized reduced minerals containing Fe^{2+} to iron oxides containing Fe^{3+} . These iron oxide minerals became a prominent marker in the geological record. Iron oxides are poorly soluble in water and would have precipitated in the oceans, raining down onto the seafloor and forming sedimentary structures known as **banded iron formations** (Figure 12.8), laminated sedimentary rocks formed in deposits of iron- and silica-rich materials. Much of the iron in rocks of Precambrian origin (>0.5 billion years ago, see Figure 12.1) exists in these banded iron formations, and today these minerals represent a major source of iron ore. Only after the abundant Fe^{2+} on Earth was consumed could O_2 accumulate in the atmosphere, and not until 600–900 million years ago did atmospheric O_2 reach present-day levels (~21%, Figure 12.1).

As O_2 accumulated on Earth, the atmosphere gradually changed from anoxic to oxic (Figure 12.1). Species of *Bacteria* and *Archaea* unable to adapt to this change were increasingly restricted to anoxic habitats because of the toxicity of O_2 and because it chemically oxidized the reduced substances upon which their metabolisms

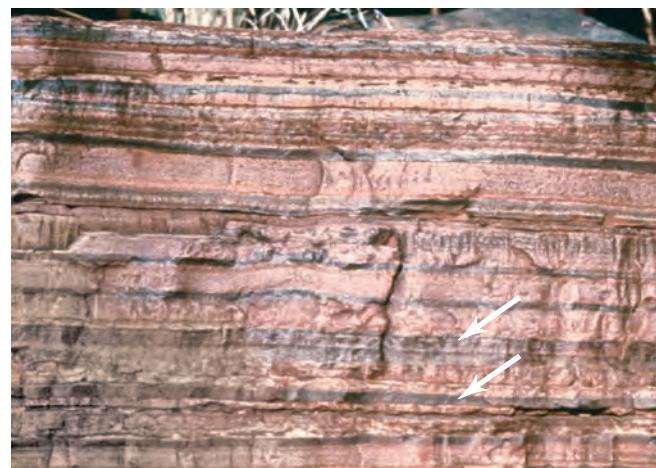

Figure 12.8 Banded iron formations. An exposed cliff made of sedimentary rock about 10 m in height in Western Australia contains layers of iron oxides (arrows) interspersed with layers containing iron silicates and other silica materials. The iron oxides contain iron in the ferric (Fe^{3+}) form produced from ferrous iron (Fe^{2+}) primarily by the oxygen released by cyanobacterial photosynthesis.

depend. However, the oxic atmosphere also created conditions for the evolution of various new metabolic schemes, such as sulfide oxidation, nitrification, and the various other aerobic chemolithotrophic processes (Chapters 13, 14). Microorganisms that evolved the capacity to respire O_2 gained a tremendous energetic advantage because of the high reduction potential of the $\text{O}_2/\text{H}_2\text{O}$ couple (Section 3.6), and with more energy at their disposal, aerobes could reproduce far more rapidly than anaerobes.

The Ozone Shield

An important consequence of O_2 for the evolution of life was the formation of *ozone* (O_3). The sun bathes Earth in intense amounts of ultraviolet (UV) radiation, which is lethal to cells and can cause severe DNA damage. When O_2 is subject to UV radiation from the sun, it is converted to ozone, which strongly absorbs UV radiation in wavelengths up to 300 nm. The conversion of O_2 to O_3 creates an ozone shield, a barrier that protects the surface of Earth from much of the UV radiation from the sun. Prior to the generation of the ozone shield, the punishing UV irradiation from the sun would have made Earth's surface fairly inhospitable for life, restricting life to environments that provided protection from UV radiation, such as in the oceans or in the subsurface. However, as Earth developed an ozone shield, organisms could range over the surface of Earth, exploiting new habitats and evolving ever-greater diversity. Figure 12.1 summarizes some landmarks in biological evolution and Earth's geochemistry as Earth transitioned from an anoxic to a highly oxic planet.

MINIQUIZ

- Why is the origin of cyanobacteria considered a critical step in evolution?
- What caused the formation of banded iron formations?
- What lines of evidence indicate that microbial life was present on Earth 3.5 billion years ago?

12.3 Endosymbiotic Origin of Eukaryotes

Until about 2 billion years ago, all cells apparently lacked a membrane-enclosed nucleus and organelles, the key characteristics of eukaryotic cells (domain *Eukarya*). Here we consider the origin of the *Eukarya* and show how eukaryotes are genetic chimeras containing genes from at least two different phylogenetic domains.

Endosymbiosis

As Earth became more oxic, organelle-containing eukaryotic microorganisms arose, and the rise in O₂ spurred their rapid evolution. While the exact origins of the eukaryotic cell remain unclear, the oldest microfossils that have recognizable nuclei are about 2 billion years old. Multicellular and increasingly complex microfossils of algae are evident from 1.9 to 1.4 billion years ago (Figure 12.7b). By 0.6 billion years ago, with O₂ near present-day levels, large multicellular organisms, the Ediacaran fauna, were present in the sea (Figure 12.1). In a relatively short time, multicellular eukaryotes diversified into the ancestors of modern-day algae, plants, fungi, and animals (Section 12.4).

A well-supported explanation for the origin of organelles in the eukaryotic cell is the **endosymbiotic hypothesis** (Figure 12.9). The hypothesis states that the mitochondria of modern-day eukaryotes arose from the stable incorporation of a respiration bacterium into other cells and that chloroplasts arose similarly from the incorporation of a cyanobacterium-like organism that performed oxygenic photosynthesis. Oxygen was almost certainly a driving force in endosymbiosis through its consumption by the ancestor of the mitochondrion and its production by the ancestor of the chloroplast. The greater energy released by aerobic respiration

undoubtedly contributed to rapid evolution of eukaryotes, as did the ability to exploit sunlight for energy.

The overall physiology and metabolism of mitochondria and chloroplasts and the sequence and structures of their genomes support the endosymbiotic hypothesis. For example, both mitochondria and chloroplasts contain ribosomes of prokaryotic size (70S), including a 16S ribosomal RNA (**16S rRNA**) molecule. The 16S RNA gene sequences (Section 12.4) of mitochondria and chloroplasts are also characteristic of *Bacteria*. Phylogenetic trees constructed from the 16S rRNA genes of mitochondria place their ancestor in the phylum *Alphaproteobacteria*, while the 16S rRNA genes of chloroplasts place their ancestor in the phylum *Cyanobacteria*. Moreover, the same antibiotics that inhibit ribosome function in free-living *Bacteria* inhibit ribosome function in these organelles. Mitochondria and chloroplasts also contain small amounts of DNA arranged in a covalently closed, circular form, which is typical of *Bacteria*, and the phylogeny of these sequences indicates a bacterial ancestry. Indeed, these and many other telltale signs of *Bacteria* are present in organelles from modern eukaryotic cells (🔗 Section 6.5).

Formation of the Eukaryotic Cell

The exact origin of the eukaryotic cell remains a major unresolved question in evolution; however, it seems clear that the modern eukaryotic cell is a genetic chimera, a cell made up of genes from both *Bacteria* and *Archaea*. There is strong support for the endosymbiotic origin of mitochondria and chloroplasts from *Bacteria* as described above, and the transfer of certain genes from these endosymbionts to the cell nucleus. Eukaryotic cells share some

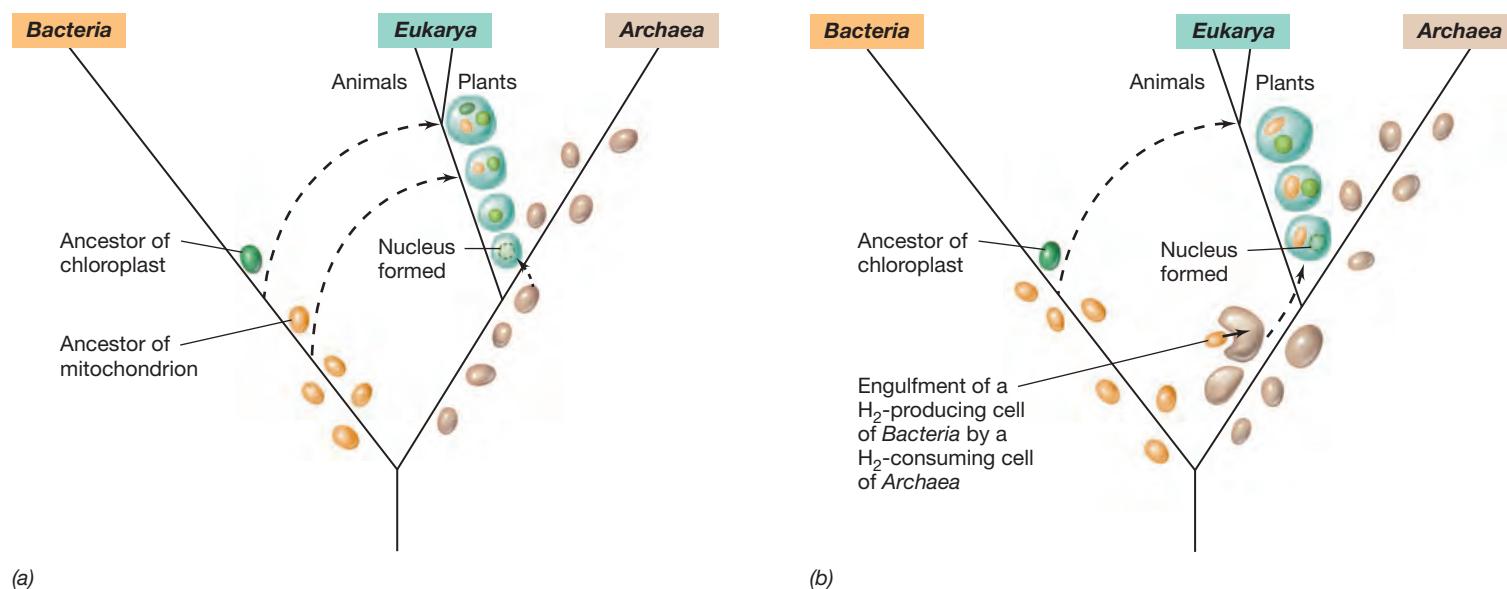

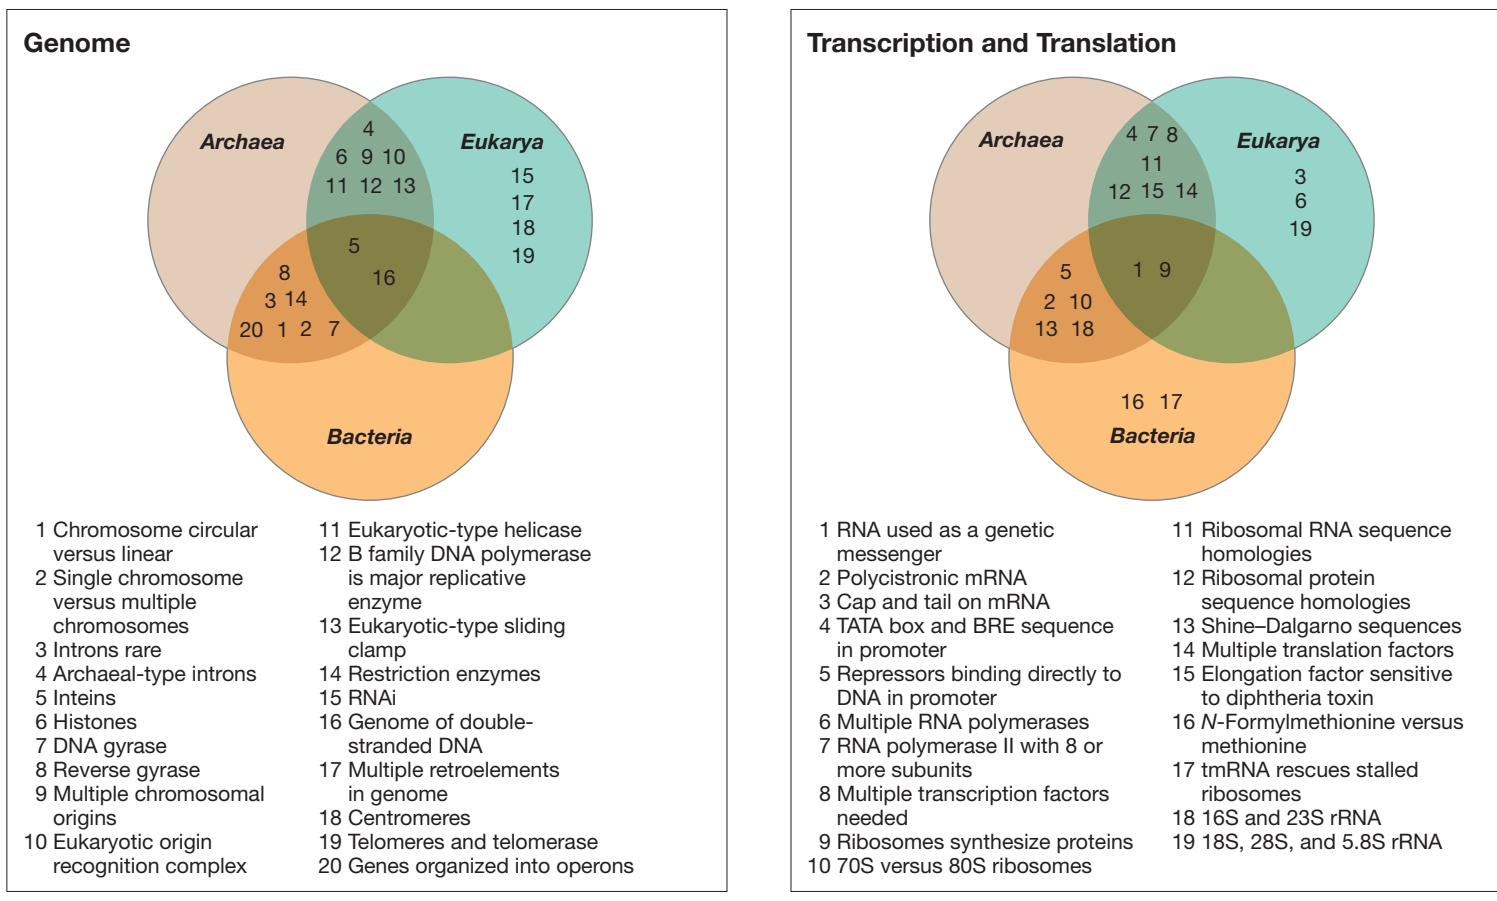

Figure 12.9 Endosymbiotic models for the origin of the eukaryotic cell. (a) The nucleated line diverged from the archaeal line and later acquired by endosymbiosis the bacterial ancestor of the mitochondrion and then the cyanobacterial ancestor of the chloroplast, at which point the nucleated line diverged into the lineages giving rise to plants and animals. (b) The hydrogen hypothesis: the hydrogen-producing cell of *Bacteria* was engulfed by a hydrogen-consuming cell of *Archaea*, and the nucleus developed later. The cyanobacterial ancestor of the chloroplast was later taken up endosymbiotically by the ancestor of plants and algae (not shown). Note the position of the mitochondrion and plastids (chloroplasts are a type of plastid) on the universal phylogenetic tree in Figure 12.13.

(a)

(b)

Figure 12.10 Molecular features of the three domains. Venn diagrams show which features are shared by the domains and which are unique. (a) Genomic features. (b) Features of transcription and translation.

other features with *Bacteria*, such as their ester-linked membrane lipids, and others with *Archaea*, such as molecular features of transcription and translation. In addition, *Bacteria* and *Archaea* share some molecular properties to the exclusion of *Eukarya* (see Table 12.1 and Figure 12.10). These features of *Bacteria* and *Archaea* suggest that endosymbiosis and gene transfer may have played an important role in the origins of *Eukarya*.

Two hypotheses have been put forward to explain the formation of the eukaryotic cell (Figure 12.9). In one, eukaryotes originally arose as a nucleus-bearing cell line that later acquired mitochondria and chloroplasts by endosymbiosis (Figure 12.9a). In this hypothesis, the nucleus-bearing cell line arose in a lineage of cells that split from the *Archaea*; the nucleus is thought to have arisen in this cell line during evolutionary experimentation with increasing cell and genome size, probably in response tooxic events that were transforming the geochemistry of Earth (Section 12.2). However, a major problem with this hypothesis is that it does not easily account for the fact that *Bacteria* and *Eukarya* have similar membrane lipids, in contrast to those of *Archaea* (Section 2.7).

The second hypothesis, called the *hydrogen hypothesis*, proposes that the eukaryotic cell arose from an association between a H₂-producing species of *Bacteria*, the symbiont, which eventually gave rise to the mitochondrion, and a species of H₂-consuming

Archaea, the host (Figure 12.9b). In this hypothesis, the nucleus arose after genes for lipid synthesis were transferred from the symbiont to the host. This transfer led to the synthesis of lipids containing fatty acids by the host, lipids that may have been more conducive to the formation of internal membranes, such as the nuclear membrane system (Section 2.20). The simultaneous increase in size of the host genome led to sequestering DNA within a membrane, which better organized it and made replication and gene expression more efficient.

In the next section we trace the evolutionary path of both eukaryotic and prokaryotic cells in detail. Analyses of molecular evolution provide direct evidence of the evolutionary history of cells, leading to the modern “tree of life.”

MINIQUIZ

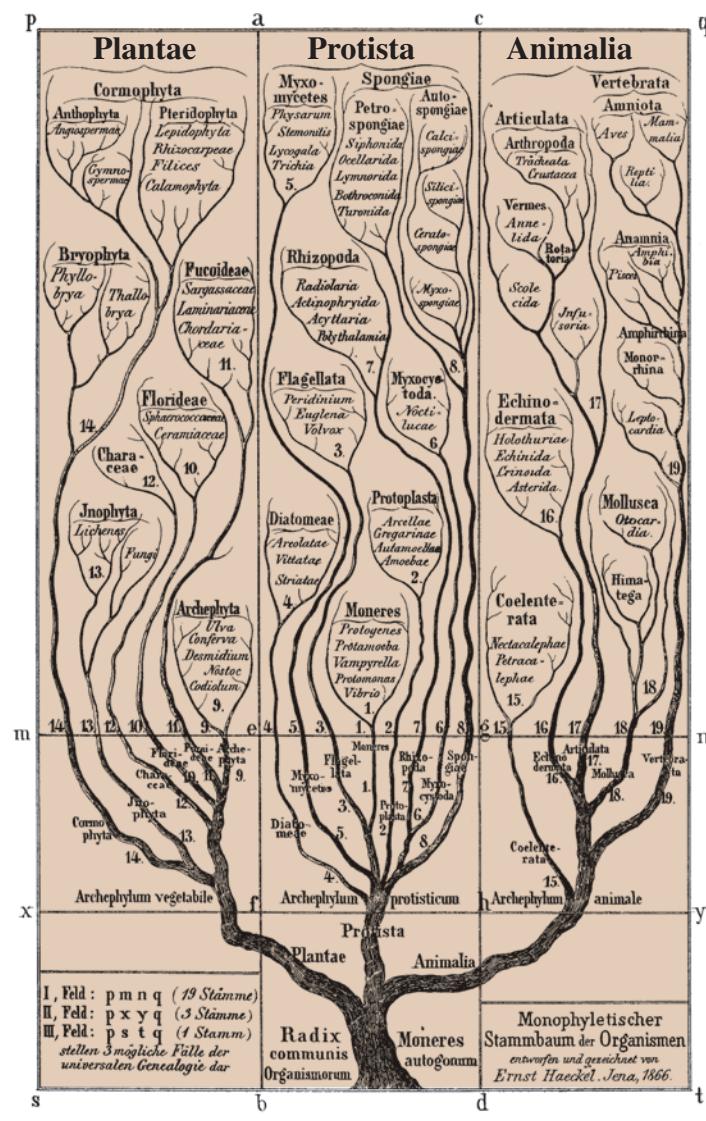

- What evidence supports the idea that the mitochondrion and chloroplast were once free-living members of the domain *Bacteria*?
- What major events in the evolution of microbial life had to occur before the origin of the acquisition of chloroplasts and mitochondria by eukaryotic cells?
- In what ways are modern eukaryotes a combination of attributes of *Bacteria* and *Archaea*?

II • Living Fossils: DNA Records the History of Life

DNA sequences provide a record of past evolutionary events and can be used to determine **phylogeny**, which is the evolutionary history of organisms. In the following sections we explore how molecular sequences can be used to build **phylogenetic trees**, diagrams that depict evolutionary history. We will consider how molecular phylogenetic analysis has changed our understanding of the history of life.

12.4 Molecular Phylogeny and the Tree of Life

The evolutionary origins of microorganisms remained a mystery until it was discovered that molecular sequences serve as a record of evolutionary history. In this section we will learn how the sequence of **ribosomal RNA (rRNA)** genes, which are found in all cells, revolutionized the understanding of microbial evolution and made it possible to construct the first **universal tree of life**.

Molecular Sequence Data Has Revolutionized Microbial Phylogeny

Following the 1859 publication of Charles Darwin's *Origin of Species*, for a hundred years and more, evolutionary history was studied primarily with the tools of paleontology, through examining fossils, and comparative biology, through comparing the traits of living organisms. These approaches led to much progress in understanding the evolution of plants and animals, but they were powerless to explain the evolution of microorganisms. The vast majority of microorganisms do not leave behind fossils, and their morphological and physiological traits provide few clues about their evolutionary history. Moreover, microorganisms do not share any morphological traits with plants and animals; thus it was impossible to create a robust evolutionary framework that included microorganisms.

The first attempt to depict the common evolutionary history of all living cells was published by Ernst Haeckel in 1866 (Figure 12.11a).

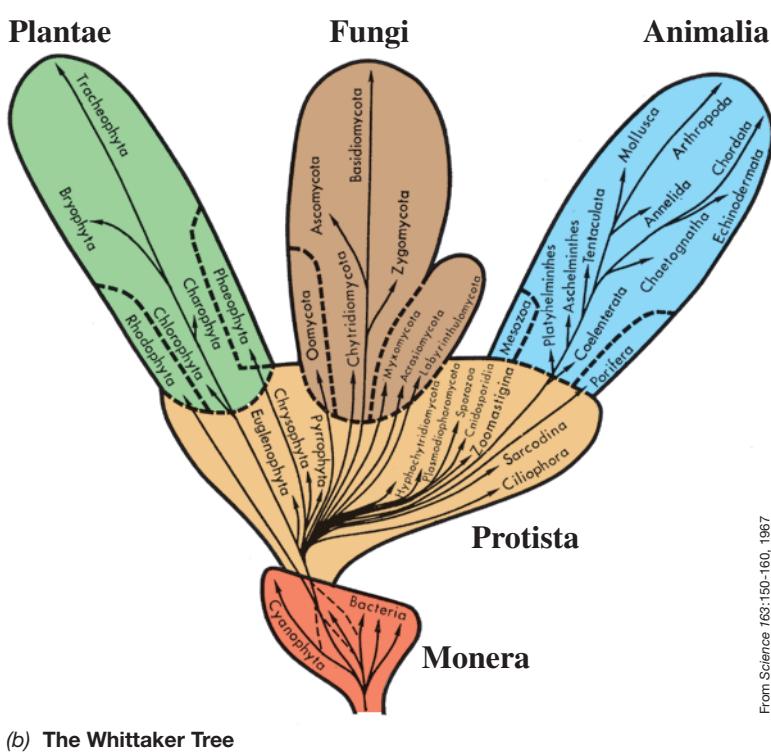

Figure 12.11 Early efforts to depict the universal tree of life. (a) Tree of life published in 1866 by Ernst Haeckel in *Generelle Morphologie der Organismen*. (b) Tree of life published by Robert H. Whittaker in 1969. The terms "Monera" and "Moneres" are antiquated terms used to refer to prokaryotic cells. Compare these conceptual trees with the tree generated from SSU rRNA gene sequences in Figure 12.13.

Haeckel correctly suggested that single-cell organisms, which he called *Monera*, were ancestral to other forms of life, but his scheme, which included plants, animals, and protists, did not attempt to resolve evolutionary relationships among microorganisms. The situation was little changed as late as 1967 when Robert Whittaker proposed a five-kingdom classification scheme (Figure 12.11b). Whittaker's scheme distinguished the fungi as a distinct lineage, but it was still largely impossible to resolve evolutionary relationships among most microorganisms. Hence, microbial phylogeny had made little progress since Haeckel's day.

Everything changed after the structure of DNA was discovered and it was recognized that evolutionary history is recorded in DNA sequence. Carl Woese realized in the 1970s that the sequence of rRNA molecules and their genes could be used to infer evolutionary relationships between organisms. Woese recognized that

rRNA genes are excellent candidates for phylogenetic analysis because they are (1) universally distributed, (2) functionally constant, (3) highly conserved (that is, slowly changing), and (4) of adequate length to provide a deep view of evolutionary relationships. Woese compared the sequences of **small subunit rRNA (SSU rRNA)** molecules (Figure 12.12) from many microorganisms and found that the sequences from methane-producing prokaryotes (methanogens) were vastly different from those of *Bacteria*. To his astonishment, he found that these sequences were as different from those of *Bacteria* as the latter were from those of *Eukarya*. He named this new group of prokaryotes the *Archaea* (originally *Archaeabacteria*) and recognized them as the third **domain** of life alongside the *Bacteria* and the *Eukarya* (Section 1.3 and Figure 12.13). More importantly, Woese demonstrated that the analysis of SSU rRNA gene sequences could be used to reveal evolutionary

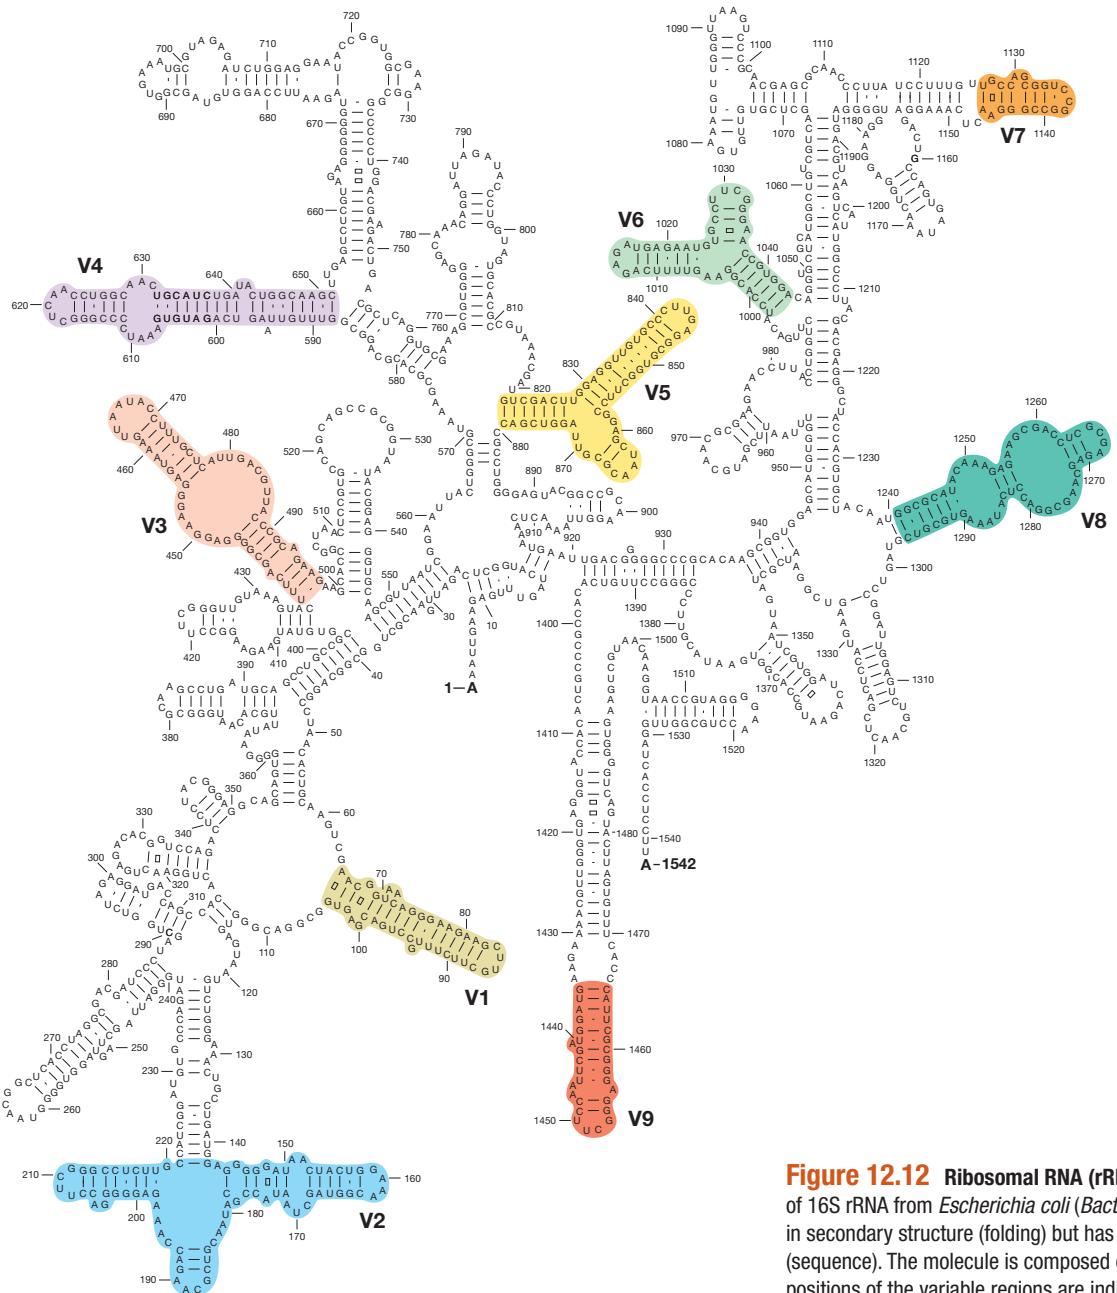

Figure 12.12 Ribosomal RNA (rRNA). Primary and secondary structure of 16S rRNA from *Escherichia coli* (*Bacteria*). The 16S rRNA from *Archaea* is similar in secondary structure (folding) but has numerous differences in primary structure (sequence). The molecule is composed of conserved and variable regions. The positions of the variable regions are indicated in color.

relationships between all cells, providing the first effective tool for the evolutionary classification of microorganisms.

Since 1977 more than 2.3 million SSU rRNA sequences have been generated and used to characterize the vast diversity of the microbial world. The Ribosomal Database Project (RDP; <http://rdp.cme.msu.edu>) contains an ever-growing collection of these sequences and provides computational programs for their analysis and for the construction of phylogenetic trees, a topic we will consider in Section 12.5.

The Tree of Life Based on SSU rRNA Genes

The universal phylogenetic tree of life based on SSU rRNA gene sequences (Figure 12.13) is a genealogy of all life on Earth. It depicts the evolutionary history of all cells and clearly reveals the three domains. The root of the universal tree represents a point in time when all extant life on Earth shared a common ancestor, the last universal common ancestor, LUCA (Figure 12.13 and Section 12.1). Genome analysis has revealed that the three-domain concept is supported not only by SSU rRNA sequences, but also by phylogenetic

analysis of most genes that encode enzymes of transcription, translation, or DNA replication. Although there are many examples of **horizontal gene transfer** (Sections 6.12 and 12.1) between lineages within and between domains, it remains clear that the three domains represent the major evolutionary cell lineages that exist on Earth.

The manner in which the three domains were established remains a topic of debate. There are many examples of genes shared by *Bacteria*, *Archaea*, and *Eukarya*, or shared by two of the three domains (Figure 12.10). One hypothesis is that early in the history of life, before the primary domains had diverged, horizontal gene transfer was extensive, and many of the genes that encoded information-handling functions had yet to evolve. The evolution of genes that improved information handling, such as genes that encode transcription and translation proteins, would have conveyed a strong benefit and may have been transferred rapidly among early forms of life (Figure 12.4).

It is further hypothesized that over time, barriers to unrestricted horizontal gene transfer evolved. As a result, the previously promiscuous population began slowly to sort out into the

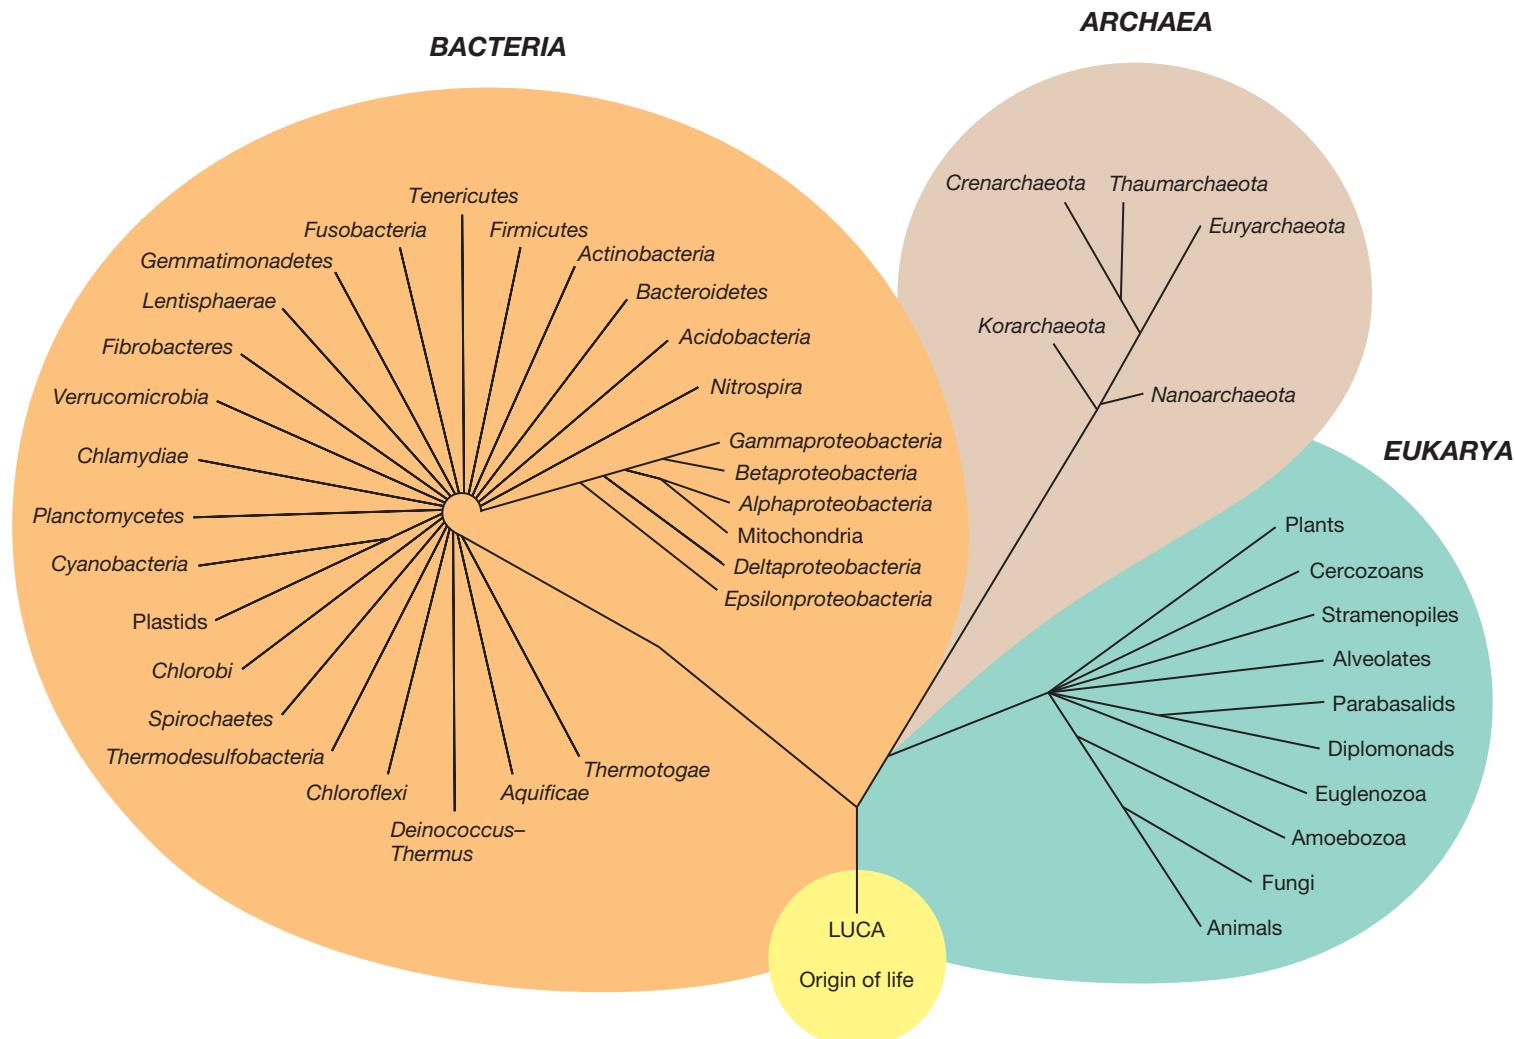

Figure 12.13 Universal phylogenetic tree as determined from comparative SSU rRNA gene sequence analysis. Only a few key organisms or lineages are shown in each domain. At least 84 phyla of *Bacteria* have now been identified although many of these have not yet been cultured. LUCA, last universal common ancestor.

primary lines of evolutionary descent, the *Bacteria* and *Archaea* (Figure 12.4 and Figure 12.13). There was a further bifurcation, about 2.8 billion years ago, as the *Archaea* and *Eukarya* diverged as distinct domains. As each lineage continued to evolve, certain traits became fixed within each group, giving rise to the genetic differences (Figure 12.10) and physiological and structural differences (**Table 12.1**) we observe between the three domains today. After nearly 4 billion years of microbial evolution, we see the grand result: three domains of cellular life that are each evolutionarily distinct and yet share certain features indicative of their common descent from a universal cellular ancestor.

Bacteria

Among *Bacteria*, at least 84 lineages (called phyla, singular **phylum**, or divisions) have been discovered thus far; only some key ones are shown in the universal tree in Figure 12.13. The *Bacteria* are discussed in detail in Chapters 14 and 15. Many lineages of *Bacteria* are known only from SSU rRNA gene sequences recovered from environmental samples (*phylogenotypes*, [Section 18.5](#)). Only 32 of the phyla contain species described on the basis of strains in cultivation, and more than 90% of strains in cultivation belong to one of only four phyla, the *Actinobacteria*, the *Firmicutes*, the *Proteobacteria*, and the *Bacteroidetes*. While the exact ages of these phyla are difficult to determine, it is likely that many of these phyla were established around the time at which the *Bacteria* and *Archaea* diverged.

Although the species in some of these phyla are characterized by unique phenotypic traits, such as the morphology of the

spirochetes or the physiology of the cyanobacteria, most bacterial phyla contain a wide diversity of species and show tremendous physiological diversity. The *Proteobacteria* illustrate this concept well as they include organisms with a diverse array of physiological traits including aerobic respiration, fermentation, nitrification, nitrogen fixation, denitrification, sulfate reduction, sulfur and sulfide oxidation, phototrophy, dissimilatory metal reduction and oxidation, methane oxidation, and many others (Chapters 13 and 14). Species of *Proteobacteria* also possess a wide range of ecological strategies and can be found in all but the hottest and most salty environments on Earth. It is important to remember that while most phyla of plants and animals originated within the last 400 million years, bacterial phyla are billions of years old and this time has allowed for extensive experimentation and diversification.

Archaea

The domain *Archaea* consists of seven major phyla, only five of which contain species described on the basis of cultivated strains. Most described species fall within the phyla *Crenarchaeota* and *Euryarchaeota*, while only a handful of species have been described for the *Nanoarchaeota*, the *Korarchaeota*, and the *Thaumarchaeota* (Figure 12.13). We discuss *Archaea* in detail in Chapter 16. Branching close to the root of the universal tree are hyperthermophilic species of *Crenarchaeota*, such as *Pyrolobus* (Figure 12.13), as well as thermophilic species of *Nanoarchaeota* and *Korarchaeota*. These are followed by the phylum *Euryarchaeota*, which includes the methanogenic *Archaea* and

Table 12.1 Major structural and physiological characteristics of Bacteria, Archaea, and Eukarya^a

Characteristic	Bacteria	Archaea	Eukarya
Morphological			
Prokaryotic cell structure	Yes	Yes	No
Cell wall	Peptidoglycan present	No peptidoglycan	No peptidoglycan
Membrane lipids	Ester-linked	Ether-linked	Ester-linked
Membrane-enclosed nucleus	Absent	Absent	Present
Flagella mechanism	Rotation	Rotation	Whiplike
Sensitivity to chloramphenicol, streptomycin, kanamycin, and penicillin	Yes	No	No
Physiological/special structures			
Dissimilative reduction of S ⁰ or SO ₄ ²⁻ to H ₂ S, or Fe ³⁺ to Fe ²⁺	Yes	Yes	No
Nitrification (ammonia oxidation)	Yes	Yes	No
Chlorophyll-based photosynthesis	Yes	No	Yes (in chloroplasts)
Denitrification	Yes	Yes	No
Nitrogen fixation	Yes	Yes	No
Rhodopsin-based energy metabolism	Yes	Yes	No
Chemolithotrophy (Fe ²⁺ , NH ₃ , S ⁰ , H ₂)	Yes	Yes	No
Endospores	Yes	No	No
Gas vesicles	Yes	Yes	No
Storage granules of poly-β-hydroxyalkanoates	Yes	Yes	No
Growth above 70°C	Yes	Yes	No
Growth above 100°C	No	Yes	No

^aNote that for many features, only particular representatives within a domain show the property.

the extreme halophiles and extreme acidophiles, such as *Thermoplasma* (Figure 12.13). The phylum *Thaumarchaeota* was first observed in the deep ocean in the 1990s but has subsequently been found in soils and marine systems all over the world. The first species of *Thaumarchaeota* were shown to be capable of ammonia oxidation. Several different species have since been isolated and all share this physiological trait (☞ Section 16.6). As for *Bacteria*, many lineages of *Archaea* are known only from SSU rRNA genes recovered from the environment and there remains great opportunity for the discovery of new lineages in the future.

Eukarya

Phylogenetic trees for *Eukarya* have been constructed from comparative sequence analysis of the 18S rRNA gene, the eukaryotic equivalent of the 16S rRNA gene in *Bacteria* and *Archaea*. As we discussed (Section 12.3), major eukaryotic organelles were clearly derived by endosymbiosis from the domain *Bacteria*, with the ancestors of mitochondria coming from within the *Proteobacteria* and those of chloroplasts from within the cyanobacteria (Figure 12.13). However, some microbial eukaryotes lack mitochondria (☞ Section 2.21). In Chapter 17 where we consider microbial eukaryotes in detail, we will see that the phylogeny of ancient eukaryotes is difficult to determine. Multigene phylogenetic trees (Section 12.9) indicate the primary eukaryotic lineages originated during a burst of evolutionary radiation about 600 million years ago that led to most lineages of microbial eukaryotes (☞ Figure 17.3). It is likely that this burst in eukaryotic evolution was triggered by the onset of oxic conditions on Earth and subsequent development of the ozone shield (Section 12.2). The latter would have greatly expanded the number of surface habitats available for colonization.

MINIQUIZ

- What kinds of evidence support the three-domain concept of life?
- How does the universal tree in Figure 12.13 support the hypothesis of endosymbiosis (Figure 12.9)?
- List three reasons that SSU rRNA genes are suitable for phylogenetic analyses.

12.5 Molecular Phylogeny: Making Sense of Molecular Sequences

All cells contain DNA as their genetic material, and DNA is passed from parent to offspring. Heritable mutations accumulate in DNA sequences over time. These mutations occur naturally and are a major cause of the random variations upon which selection acts, as described in Darwin's theory of evolution. Hence, the difference in nucleotide sequence between any two organisms will be a function of the number of mutations that have accumulated since they shared a common ancestor. As a result, differences in DNA sequences can be used to infer evolutionary relationships. In this section we will learn how DNA sequences are used in the phylogenetic analysis of microbial life.

Obtaining DNA Sequences

While analysis of microbial phylogeny relies heavily on analysis of SSU rRNA gene sequences, advances in DNA sequencing

technology (☞ Section 6.2) have made genome sequencing a standard tool employed in analyses of microbial phylogeny. Obtaining gene sequence from a microorganism is relatively easy if the organism can be cultivated in isolation in the laboratory. In this case, genomic DNA is isolated and the genome sequenced directly or used to amplify one or more specific genes, using the polymerase chain reaction (PCR, ☞ Section 11.3).

PCR primers can be designed to target any region of DNA from any organism. Standard primers exist for many highly conserved genes, such as the SSU rRNA gene (Figure 12.12). Primers for the SSU rRNA gene can have different levels of phylogenetic specificity targeting discrete species, genera, and phyla, and there are even "universal" primers that will amplify the SSU rRNA gene from any organism. PCR products are visualized by agarose gel electrophoresis, excised from the gel, extracted and purified from the agarose, and then sequenced, often using the same oligonucleotides as primers for the sequencing reactions. These steps are summarized in Figure 12.14. Alternatively, it is also possible to amplify SSU rRNA genes from DNA that has been extracted directly from an environmental sample or to sequence directly this environmental DNA using a metagenomic approach (☞ Sections 6.10 and 18.7). These latter approaches are used widely to characterize microorganisms that are difficult to grow in laboratory culture. Once sequences are obtained, they must be aligned and analyzed, issues we turn to now.

Sequence Alignment

Phylogeny can be inferred only from genes that have **homology**, that is, genes that have been inherited from a common ancestor. Thus homology is a binary trait; sequences are either homologous or they are not. The concept of homology is often confused with that of sequence similarity. The latter is a continuous trait defined as a percentage of nucleotide positions shared between any two sequences. Sequence similarity is used to infer homology, but a similarity value can be calculated between any two sequences regardless of their function or evolutionary relationship. Thus, the terms similarity and homology are not interchangeable. Genes that have homology can be either **orthologs**, if they originate from a single ancestral gene in a common ancestor, or **paralogs**, if they are related as a result of a gene duplication (☞ Section 6.11). Phylogenetic analyses typically focus on analysis of orthologous genes that have similar function.

Phylogenetic analyses estimate evolutionary changes from the number of sequence differences across a set of homologous nucleotide positions. Some mutations introduce nucleotide insertions or deletions, and these cause gene sequences to differ in length, making it necessary to *align* nucleotide positions prior to phylogenetic analysis of gene sequences. The purpose of **sequence alignment** is to add gaps to molecular sequences in order to establish positional homology, that is, to be sure that each position in the sequence was inherited from a common ancestor of all organisms under consideration (Figure 12.15). Proper sequence alignment is critical to phylogenetic analysis because the assignment of mismatches and gaps caused by deletions is in effect an explicit hypothesis of how the sequences have diverged from a common ancestral sequence.

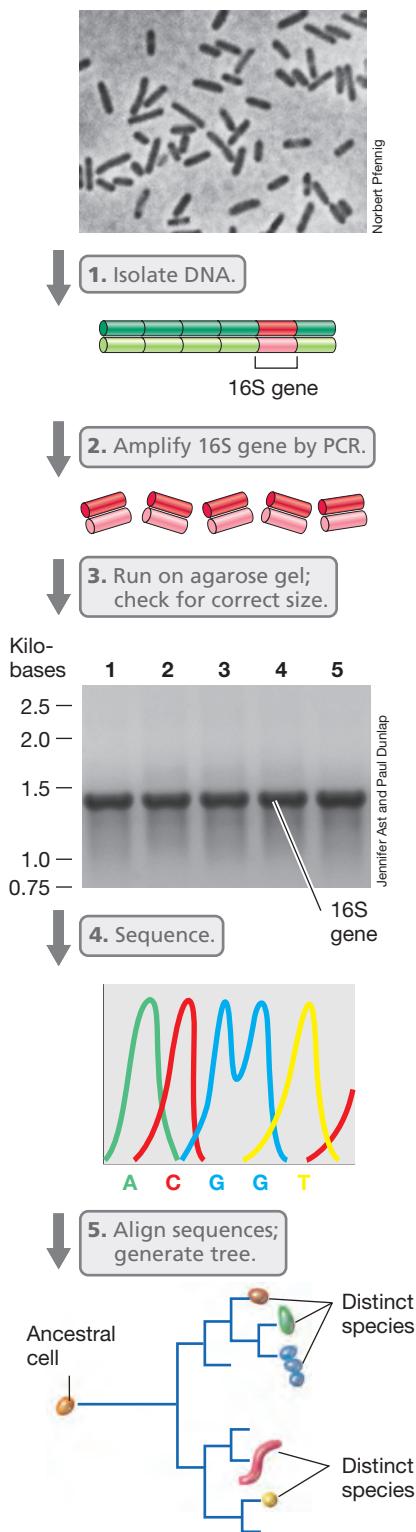

Figure 12.14 PCR amplification of the 16S rRNA gene. Following DNA isolation, primers complementary to the ends of the 16S rRNA (see Figure 12.12) are used to PCR-amplify the 16S rRNA gene from genomic DNA of five different unknown bacterial strains and the products are run on an agarose gel (photo). The bands of amplified DNA are approximately 1465 nucleotides in length. Positions of DNA kilobase size markers are indicated at the left. Excision from the gel and purification of these PCR products is followed by sequencing and analysis to identify the bacteria.

Sequences before alignment			Sequence differences			
	1	2	3	1	2	
1	GGA	CCT	AAA	TTT	ATA	CCC
2	GGA	AAA	GGG	CCC	AAA	CGC
3	GGA	GGG	CCT	TTT	ATA	CCC

Sequences after alignment			Sequence differences					
	1	2	3	1	2			
1	GGA	-----	CCT	AAA	TTT	ATA	CCC	
2	GGA	AAA	GGG	CCC	-----	AAA	CGC	
3	GGA	---	GGG	CCT	---	TTT	ATA	CCC

Figure 12.15 Alignment of DNA sequences. (a) Sequences for a hypothetical region of a gene are shown for three species before alignment and after alignment. A sequence alignment should display homologous positions in vertical columns. Sequence alignment is achieved by adding gaps, indicated by hyphens, to maximize local sequence similarity between the species in the alignment. (b) The distance matrices show the number of sequence differences that would be inferred for each species pair both before and after alignment.

Phylogenetic Trees

A phylogenetic tree is a diagram that depicts the evolutionary history of an organism and bears some resemblance to a family tree. Most microorganisms do not leave fossils and so their ancestors are unknown, but ancestral relationships can be inferred from the DNA sequences of organisms that are alive today. Organisms that share a recent ancestor are likely to share characteristics, and thus phylogenetic trees allow us to make hypotheses about an organism's characteristics. Phylogenetic trees are also of great use in taxonomy and species identification, as we will discuss later in this chapter (Section 12.9).

A phylogenetic tree is composed of *nodes* and *branches* (Figure 12.16). The tips of the branches in a phylogenetic tree represent species that exist today. Phylogenetic trees can be constructed that are either *rooted trees* or *unrooted trees*. Rooted trees show the position of the ancestor of all organisms being examined. Unrooted trees depict the relative relationships among the organisms under study but do not provide evidence of the most ancestral node in the tree. The nodes represent a past stage of evolution where an ancestor diverged into two new lineages. The branch length represents the number of changes that have occurred along that branch. In a phylogenetic tree, only the position of nodes and the branch lengths are informative; rotation around nodes has no effect on the tree's topology (Figure 12.16b).

Tree Construction

There is only one correct phylogenetic tree that accurately depicts the evolutionary history of a group of gene sequences, but inferring the true tree from sequence data can be a challenging task. The complexity of the problem is revealed by considering the total number of trees that can represent a random set of sequences. For example, there are only three possible trees that can be drawn for any four arbitrary sequences. But if one doubles to eight the number of sequences, now 10,395 trees are possible. This complexity continues to expand exponentially such that 2×10^{182} different trees can be drawn to represent 100 arbitrary sequences.

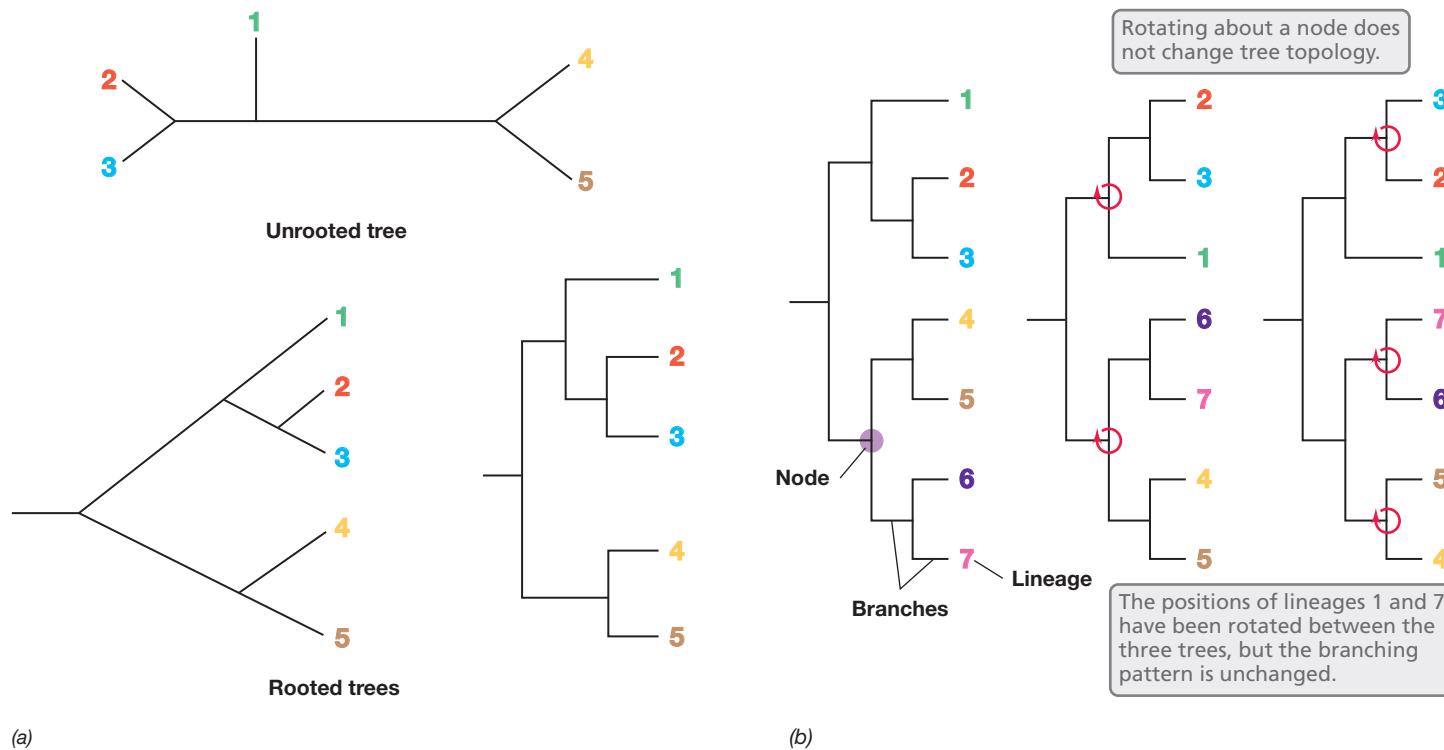

Figure 12.16 Phylogenetic trees and their interpretation. (a) Unrooted and rooted examples of phylogenetic trees. The tips of the branches are species (or strains) and the nodes are ancestors. Ancestral relationships are revealed by the branching order in rooted trees. (b) Three equivalent versions of the same phylogenetic tree are shown. The only difference between the trees is that their nodes have been rotated at the points indicated by red arrows. The vertical position of species is different between the trees but the pattern of ancestry (the nodes shared by each species) remains unchanged.

Phylogenetic analysis uses molecular sequence data in an attempt to identify the one correct tree which accurately represents the evolutionary history of a set of sequences.

A variety of methods are available for inferring phylogenetic trees from molecular sequence data. The structure of a phylogenetic tree is generally inferred by applying either an *algorithm* or some set of *optimality criteria*. An algorithm is a programmed series of steps designed to construct a single tree (Figure 12.17). Algorithms used to build phylogenetic trees include the *Unweighted Pair Group Method with Arithmetic Mean* (UPGMA) and *Neighbor Joining* methods. Alternatively, phylogenetic methods that employ optimality criteria include *parsimony*, *maximum likelihood*, and *Bayesian* analyses. These latter methods evaluate many possible trees and select the one tree that has the best optimality score, that is, they select the tree that best fits the sequence data given a discrete model of molecular evolution. Optimality scores are calculated on the basis of evolutionary models that describe how molecular sequences change over time. For example, evolutionary models can account for variation in substitution rates and base frequencies between sequence positions.

Limitations of Phylogenetic Trees

Molecular phylogeny provides powerful insights into evolutionary history, but it is important to consider the limitations of building and interpreting phylogenetic trees. For example, it can be difficult to choose the true tree based on available sequence data if several different trees fit the data equally well. *Bootstrapping*, a

statistical method in which information is resampled at random, is an approach used to deal with uncertainty in phylogenetic trees. Bootstrap values indicate the percentage of the time that a given node in a phylogenetic tree is supported by the sequence data. High bootstrap values indicate that a node in the tree is likely to be correct, while low bootstrap values indicate that the placement of a node cannot be accurately determined given the data.

Homoplasy, also known as *convergent evolution*, occurs when organisms share a trait that was not inherited from a common

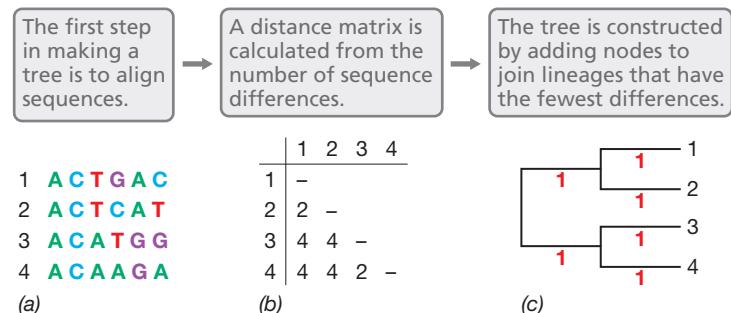

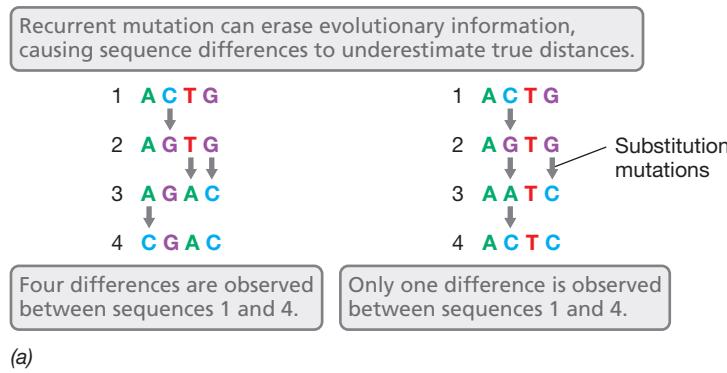

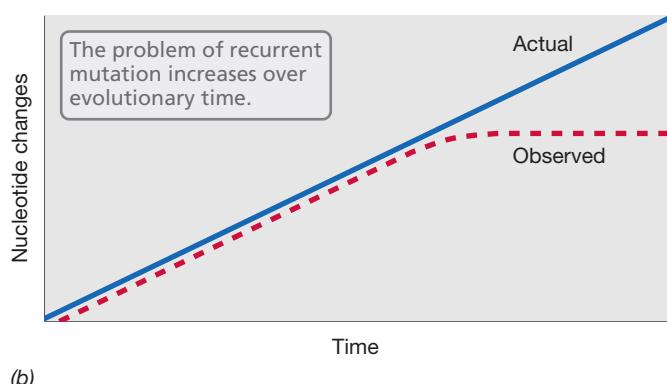

Figure 12.17 Building phylogenetic trees. The number of nucleotide differences between gene sequences can be used to build a phylogenetic tree. In the sequence alignment (a) we can count the number of differences between each pair of sequences to build a distance matrix (b). This distance matrix can be used to build a tree (c) where the cumulative lengths of the horizontal branches (labeled with a red "1") between any two species in the tree are proportional to the number of nucleotide differences between these species.

(a)

(b)

Figure 12.18 The problem of homoplasy due to recurrent mutation. It is possible for recurrent mutation to obscure the true number of mutations that have occurred since a pair of sequences have shared a common ancestor. (a) We observe two series of mutations during the evolution of a gene sequence. On the left side, the number of mutations is equal to the number observed between species 1 and 4. However, if there is recurrent mutation (right side), the number of mutations observed between species 1 and 4 can be less than the number that actually occurred. (b) The likelihood of recurrent mutation increases as more and more mutations accumulate over time.

ancestor. An example is the evolution of wings in insects and birds. These traits evolved separately and do not indicate that a winged ancestor was shared among insects and birds. Homoplasy occurs in molecular sequences as well, when similar sequence positions result from recurrent mutation rather than due to inheritance from a common ancestor. The problem of homoplasy in molecular phylogeny then increases in proportion to evolutionary time (Figure 12.18).

The prevalence of horizontal gene transfer (Section 6.12) also creates complications when considering the evolutionary history of microorganisms. When the sequence of a gene is used to infer the phylogeny of an organism, it must be assumed that the gene is inherited *vertically* from mother to daughter throughout the evolutionary history of the organism. The *horizontal* exchange of genes between unrelated organisms violates this assumption (Figure 12.19). Hence, it is important to consider the difference between a *gene phylogeny*, which depicts the evolutionary

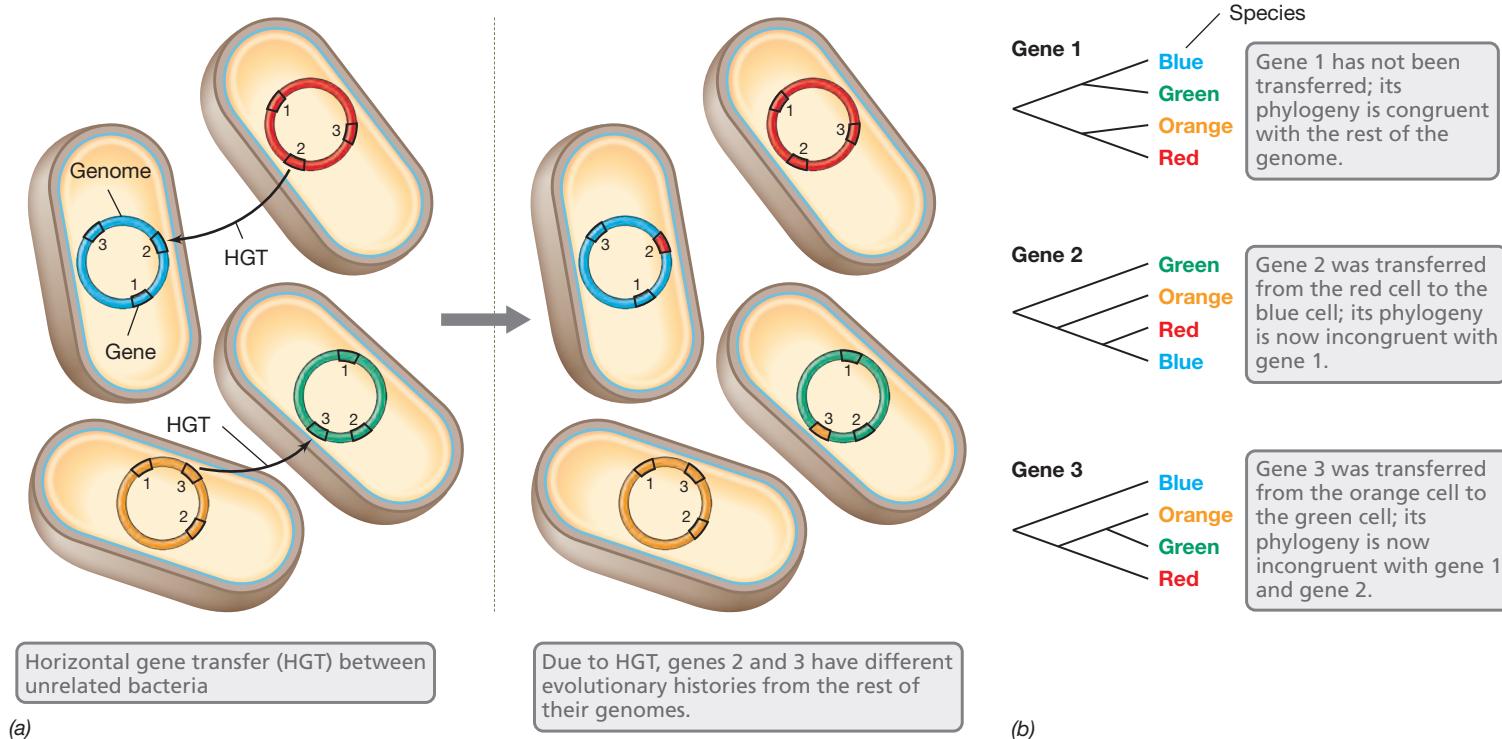

Figure 12.19 Horizontal gene transfer. The horizontal transfer of a gene will cause it to have a different evolutionary history from the rest of the genome. (a) Genes are transferred horizontally between distantly related microorganisms. Colors are used to match microorganisms with their genetic material. (b) As a result of the horizontal transfer events in part a, we now observe different phylogenetic trees for gene 1, gene 2, and gene 3. Only the gene tree for gene 1, which was not transferred, remains congruent with the organismal phylogeny.

history of an individual gene, and an *organismal phylogeny*, which depicts the evolutionary history of the cell. In general, SSU rRNA sequences appear to be transferred horizontally at very low frequencies, and rRNA gene phylogenies agree largely with those of most genes that encode genetic informational functions in the cell. Thus, SSU rRNA gene sequences are generally considered to provide a record of organismal phylogeny. Nevertheless, many genes in microbial genomes have been acquired by horizontal gene transfer at some point in their evolutionary history and this

process has important implications for microbial evolution, as we will see in the following section.

MINIQUIZ

- How are DNA sequences obtained for phylogenetic analysis?
- What does a phylogenetic tree depict?
- Why is sequence alignment critical to phylogenetic analysis?

III • Microbial Evolution

While many of the basic principles of evolution are conserved across all domains of life, certain aspects of microbial evolution are uncommon in plants and animals. For example, *Bacteria* and *Archaea* are generally haploid and asexual, they have several mechanisms for horizontal gene transfer that result in the asymmetrical exchange of genetic material uncoupled from reproduction, and their genomes can be remarkably heterogeneous and highly dynamic. In this section we consider the processes that cause the diversification of microbial lineages and how these forces impact evolution of microbial genomes.

12.6 The Evolutionary Process

In its simplest form, evolution is a change in **allele** frequencies in a set of organisms over time. Alleles are alternate versions of a given gene. New alleles arise due to mutation and recombination, and changes in allele frequencies can occur through a variety of changes, including selection and genetic drift. How do these simple mechanisms give rise to the origin and divergence of microbial species?

Origins of Genetic Diversity

Mutations are random changes in DNA sequence that accumulate in all DNA sequences over time; they are a fundamental source of the natural variation that drives the evolutionary process. Most mutations are neutral or deleterious, though some can be beneficial. Mutations take several forms including *substitutions*, *deletions*, *insertions*, and *duplications* (Chapter 10). Duplication events produce a redundant copy of a gene that can be modified by further mutation without losing the function encoded by the original gene. Hence, duplications allow for the diversification of gene function.

Recombination is a process by which segments of DNA are broken and rejoined to create new combinations of genetic material (☞ Section 10.5). Recombination can cause reassortment of genetic material already present in a genome and is also required for the integration into the genome of DNA acquired through horizontal gene transfer. Recombination can be broadly classified as either *homologous* or *nonhomologous*. Homologous recombination requires short segments of highly similar DNA sequence flanking the region of DNA being transferred (☞ Section 10.5). By contrast, nonhomologous recombination is mediated by several mechanisms (☞ Section 10.5) that share in common the fact that they do not require high levels of sequence similarity to initiate successful DNA integration.

Selection and Genetic Drift

New alleles result when mutation and recombination cause variation in gene sequences. Evolution occurs when different alleles change in frequency in a population over a span of many generations. Evolutionary biologists have described many different mechanisms that may govern this evolutionary process but chief among them are the forces of selection and genetic drift.

Selection is defined on the basis of **fitness**, the ability of an organism to produce progeny and contribute to the genetic makeup of future generations. Most mutations are *neutral* with respect to fitness and they have no effect on the cell due to the degeneracy of the genetic code (☞ Section 4.11). These mutations generally accumulate in DNA over time. Some mutations are *deleterious*; these decrease the fitness of an organism by disrupting gene function. Deleterious mutations are generally purged from populations over time by natural selection. Some mutations can be *beneficial*, increasing the fitness of an organism, and these mutations are favored by natural selection, increasing in frequency in a population over time. An example of a beneficial mutation would be a mutation that induces antibiotic resistance in a pathogenic bacterium infecting a person undergoing antibiotic therapy. It is important to remember that all mutations occur by chance; the selective nature of the environment does not *cause* adaptive mutations but simply *selects* for the growth and reproduction of those organisms that have incurred mutations that provide a fitness advantage.

While Darwin proposed natural selection as the mechanism by which gene frequencies change over time, evolutionary change can occur through mechanisms other than selection. A chief example is **genetic drift** (Figure 12.20), a random process that can cause gene frequencies to change over time, resulting in evolution in the absence of natural selection. Genetic drift occurs because some members of a population will have more offspring than others simply as a result of chance; over time these chance events can result in evolutionary change in the absence of selection. Genetic drift is most powerful in small populations and in populations that experience frequent “bottleneck” events. The latter occur when a population experiences a severe reduction in population size followed by regrowth from the cells that remain. For example, genetic drift can be very important in the evolution of pathogens since each new infection is caused by a small number of cells colonizing a new host. Hence, pathogen populations can change rapidly as a result of random genetic drift as illustrated in Figure 12.20.

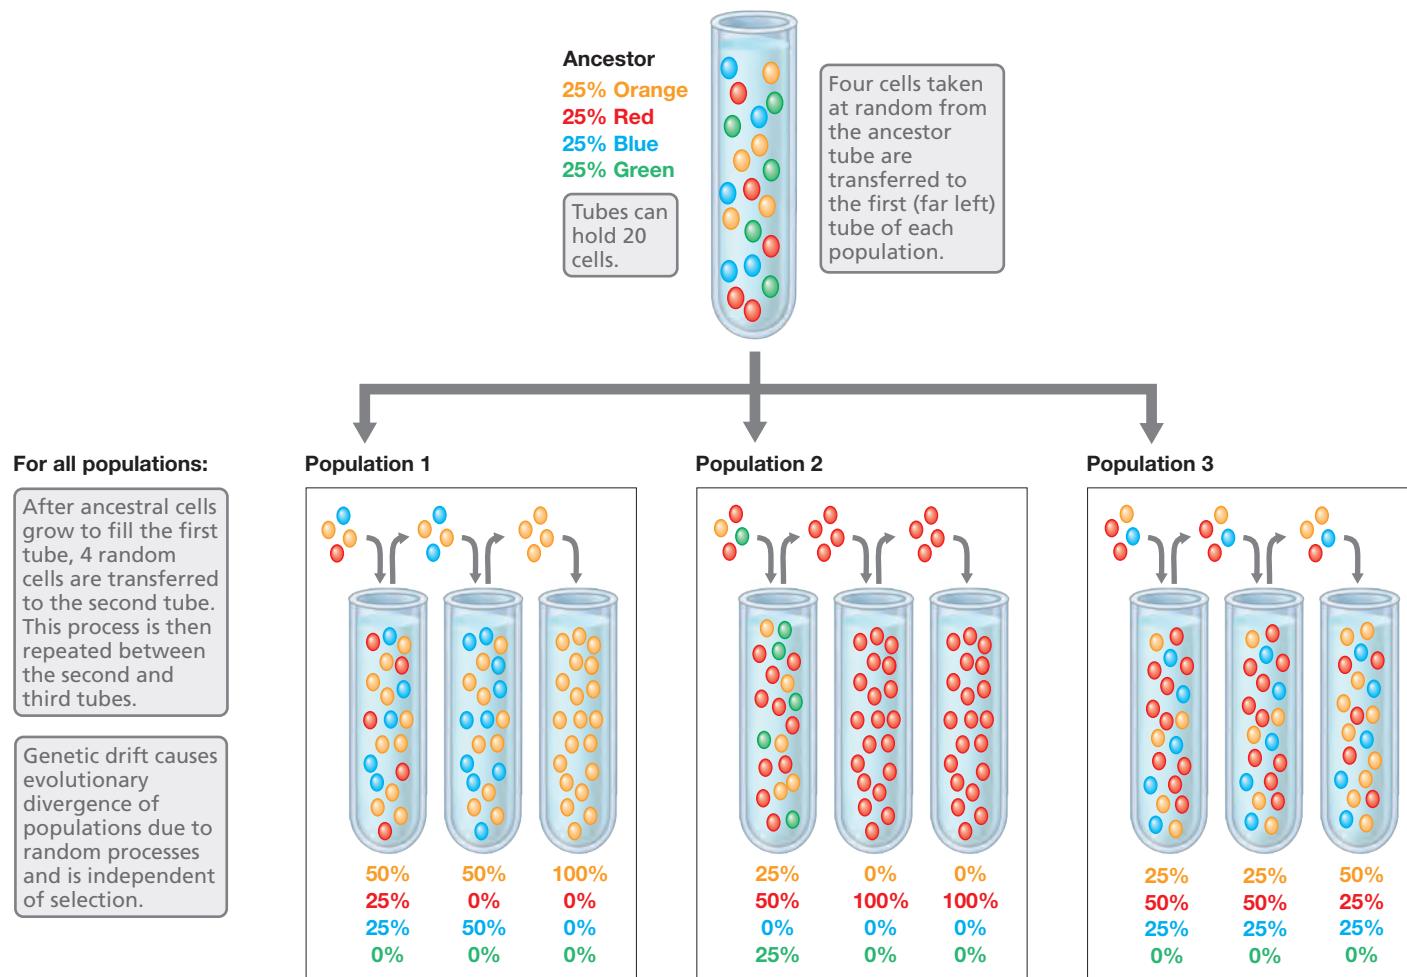

Figure 12.20 Genetic drift. Genetic drift is a random process that can cause gene frequencies in a population to change over time, causing evolution without natural selection. In this example, a population containing four different bacterial genotypes (indicated by colors), each at equal frequency, is present in the ancestor tube. Four cells at random are then transferred to each of three new tubes and the cells allowed to grow to fill each tube. There is no difference in fitness between the cells and so they grow equally. Cells taken at random are then transferred in two successive rounds. Striking differences in genotype frequencies between the populations are observed after only three rounds of transfers.

New Traits Can Evolve Quickly in Microorganisms

A change in the environment or the introduction of cells to a new environment can cause rapid evolutionary changes in microbial populations. Microorganisms typically form large populations and can reproduce quickly, producing a new generation in as few as 20 minutes for some species, and thus evolutionary events in microbial populations can often be observed in the laboratory on relatively short time scales. The heritable variation already present in a population provides the raw material upon which natural selection acts following such a change in the selective environment. Here we consider two examples of rapid evolutionary change in bacteria, one involving the rapid loss of a trait in *Rhodobacter*, and one involving the acquisition of a new trait in *Escherichia coli*.

Rhodobacter is a phototrophic purple bacterium that carries out anoxygenic photosynthesis (Section 13.3) in illuminated anoxic environments. When cultured anaerobically in either the light or the dark, the cells synthesize bacteriochlorophyll and carotenoids.

It is the absence of O₂, not the presence of light, that signals pigment synthesis in purple bacteria. In the light these pigments participate in photosynthetic reactions that lead to ATP synthesis, but in darkness, these pigments provide no benefit to the cell.

Random mutations occasionally generate *Rhodobacter* cells that produce either reduced levels of photopigments or no photopigments at all. In nature, the ability to carry out photosynthesis is an adaptive trait of significant value, and thus photosynthetic mutants are lost and wild-type cells dominate. However, in contrast to natural conditions, there is no selection against *Rhodobacter* cells that have a reduced capacity to photosynthesize if they are cultured in the laboratory in constant darkness. Mutants that produce reduced levels of photopigments arise in dark cultures just as they do in phototrophic cultures, but in the dark, these mutants are selected for and quickly take over the population (Figure 12.21).

Photopigments are useless in the dark, and mutants conserve energy by avoiding the metabolic cost of synthesizing them.

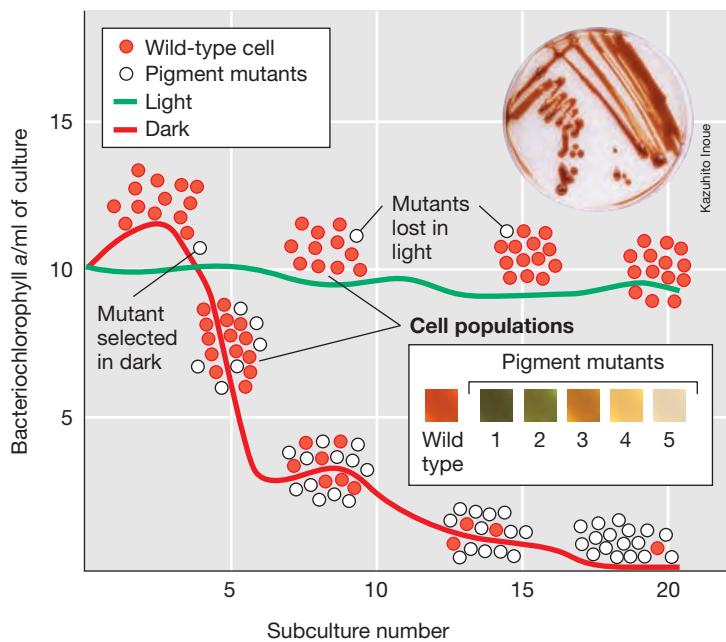

Figure 12.21 Survival of the fittest and natural selection in a population of phototrophic purple bacteria. Serial subculture of the purple bacterium *Rhodobacter capsulatus* in the dark quickly selects for nonphototrophic mutants that outcompete and grow faster than cells still making bacteriochlorophyll and carotenoids. Photos: top, plate culture showing colonies of phototrophic cells of *R. capsulatus*; bottom, close-up photos of colonies of wild type and five pigment mutants (1–5) obtained during serial dark subculture. Wild-type cells are reddish-brown from their assortment of carotenoid pigments. The color of mutant colonies reflects the absence (or reduced synthesis) of one or more carotenoids. Mutant strain 5 lacked bacteriochlorophyll and was no longer able to grow phototrophically. Mutant strains 1–4 could grow phototrophically but at reduced growth rates from the wild type. Data adapted from Madigan, M.T., et al. 1982. *J. Bacteriol.* 150: 1422–1429.

Hence, the photosynthetic mutants are able to outcompete wild-type cells that produce a full complement of photopigments. Although these mutants have reduced phototrophic capacities or in some cases have completely lost the ability to grow phototrophically (see photo inset in Figure 12.21), in permanent darkness they quickly become the fittest organisms in the population and therefore enjoy the greatest reproductive success. Mutations affecting photosynthesis occur at the same rate in the light as in the dark, but in the light the selection for phototrophy is so strong that such mutants are quickly lost from the population.

Experimental evolution is a growing field of study enabled by the rapid growth of bacterial populations and the ability to preserve bacteria indefinitely by freezing. The latter makes it possible to maintain a living “fossil record” of ancestral organisms that can be thawed later and compared to evolved strains. For example, the *Escherichia coli* long-term evolution experiment (LTEE), which has been running since 1988, has tracked the evolution of 12 parallel lines of *E. coli* through more than 50,000 generations. The *E. coli* LTEE cultures have been grown aerobically on a minimal medium with glucose as a sole source of carbon and energy. *E. coli* is typically propagated in a rich medium that contains an excess of all the nutrients cells need to grow and so the minimal glucose medium used in the LTEE represents a new adaptive environment in which *E. coli* can evolve over time.

In the LTEE, both the ancestor and the evolved lines were genetically engineered to contain a neutral marker that made their colonies either red or white. The marker made it possible to measure the fitness of evolved strains relative to the ancestor by competing them against one another (Figure 12.22a). Genome sequencing during the experiment revealed that mutations accumulated randomly over time in the evolved lines. However, the relative fitness of the evolved lines on minimal glucose medium increased dramatically over the first 500 generations as a result of selection acting on mutations beneficial in this new environment (Figure 12.22b). The fitness of the evolved lines continued to increase, albeit at a reduced rate, as a result of further selection over the course of the experiment. Most remarkably, after 31,500 generations, one of the evolved lines obtained the ability to use citrate as an energy source (Figure 12.22c). Citrate was present as a pH buffer in the media used in this experiment and was not considered a potential carbon source for *E. coli* because the inability to grow aerobically on citrate is a diagnostic trait for *E. coli*. However, the random accumulation of mutations in this one evolved line modified preexisting genes in such a way as to allow for the evolution of a new adaptive trait. The diverged strains can now exploit a new resource that was unavailable to the ancestral population. Since they can now use both citrate and glucose, these cells grow to a much higher cell density than the ancestor (Figure 12.22c). The fact that only one of the 12 parallel lines evolved the ability to grow on citrate demonstrates the chance nature of evolution.

The transitions shown in these experiments remind us of how quickly evolutionary pressures can shift even major properties (such as metabolic strategies) of a microbial cell population. In the case of *Rhodobacter*, a mutation that is deleterious in the wild provides a selective advantage when the organism is grown in the laboratory in a continuously dark environment. Under this new condition, evolution causes *Rhodobacter* to lose unneeded metabolic machinery. In the case of *E. coli*, the accumulation of random mutations allows for the accumulation of genetic diversity in a population. Billions of different mutations were sampled by the population over thousands of generations and some rare combination of mutations, by chance, gave the cells the ability to exploit citrate as a resource. Natural variation caused by chance mutation generated a new trait, the ability to use citrate, and since the environment in which the cells were grown happened to contain citrate, this mutation provided a selective advantage to those cells. In the absence of citrate, these mutations would still occur at the same rate. However, in the absence of a selective benefit, cells able to use citrate would likely disappear from the population over time.

Speciation of Microorganisms Can Take a Long Time

Species can possess a wide variety of individuals with different traits. As we discussed above, microorganisms can evolve new traits with remarkable speed and as a result, microbial species can be genetically and phenotypically diverse.

Sequence changes can be used as a **molecular clock**, in order to estimate the time since two lineages have diverged. Major assumptions of the molecular clock approach are that nucleotide changes accumulate in a sequence in proportion to time, that

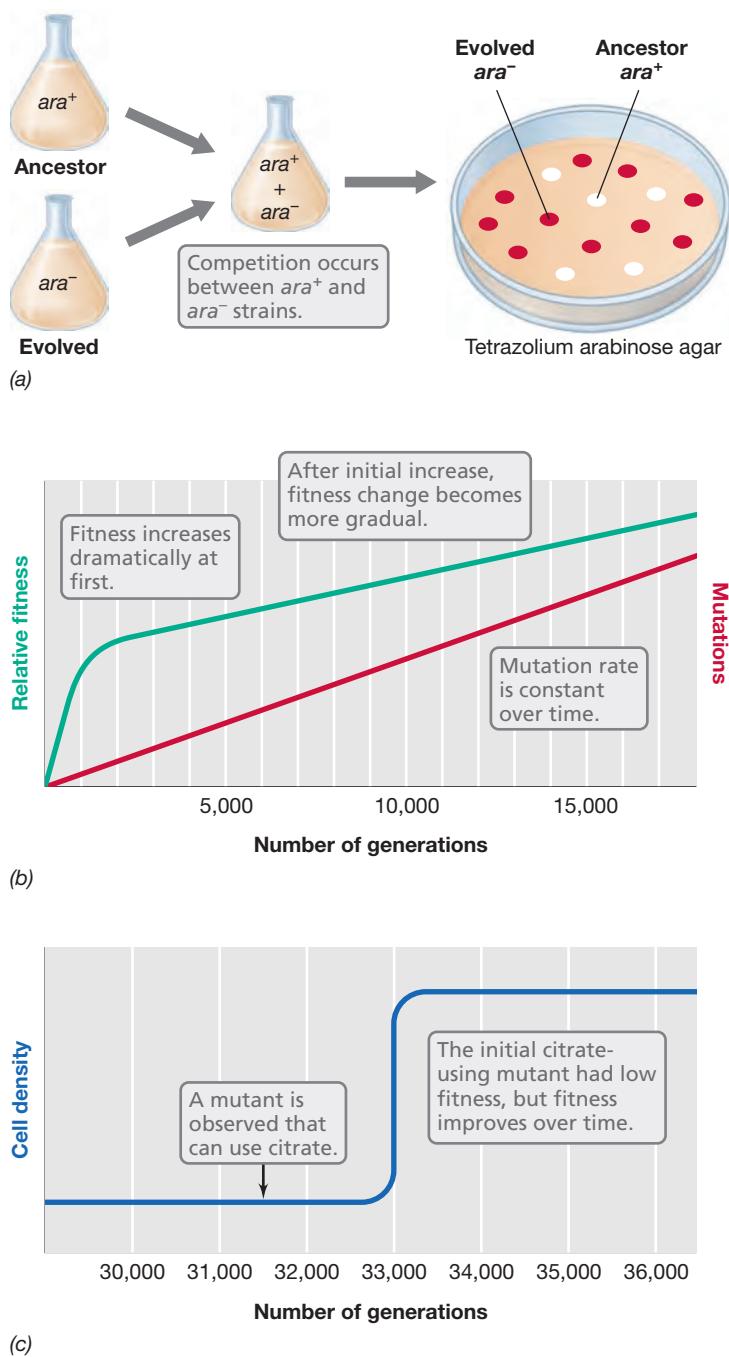

Figure 12.22 Long-term evolution of *E. coli*. (a) In the *Escherichia coli* long-term evolution experiment (LTEE), ancestral and derived lines differ in a mutation that affects their ability to use arabinose, allowing them to be differentiated by their colony color when grown on tetrazolium arabinose agar. (b) Competition experiments between evolved and ancestral strains show that relative fitness in minimal glucose media increases dramatically for evolved lines. (c) The ability to use citrate aerobically evolved in one of 12 LTEE lines. Cells growing on minimal glucose typically grow to low cell density, but the ability to use both glucose and citrate allowed the mutant cell line to reach significantly higher cell densities. Relative fitness is a measure of the growth rate of the evolved strain to that of the ancestral strain.

such changes are generally neutral and do not interfere with gene function, and that they are random. Molecular clock estimates are most reliable when they can be calibrated with evidence

from the geological record. The molecular clock approach has been used to estimate the time of divergence of distantly related organisms, such as the domains *Archaea* and *Eukarya* (about 2.8 billion years ago, Figure 1.4b). These data have been combined with evidence from the geological record from stable isotopes (Section 18.9) and specific biological markers to approximate when different metabolic patterns may have emerged in bacteria (Sections 12.1, 12.2; Figure 12.1). Molecular clock estimates have been calibrated on more contemporary time scales using obligate bacterial symbionts of insects (Section 22.9) for which the insect host provides a suitable fossil record to date evolutionary events. From such calculations it is possible to estimate that two well-characterized strains of *E. coli*, the harmless strain K-12 and the foodborne pathogenic strain O157:H7, diverged about 4.5 million years ago. Likewise, it is estimated that the closely related *E. coli* and *Salmonella enterica* serovar Typhimurium, which have 2.8% dissimilarity in their 16S rRNA genes, last shared a common ancestor some 120–140 million years ago. Hence, while microorganisms can evolve new traits rapidly, most microbial species are ancient and microbial speciation appears to take a very long time.

MINIQUIZ

- What are the different processes that give rise to genetic variation?
- What is the difference between selection and genetic drift and how do they promote evolutionary change?
- In the experiment of Figure 12.21, why did the dark cell population lose its pigments?

12.7 The Evolution of Microbial Genomes

The dynamic nature of microbial genomes was revealed in dramatic fashion when the first genomes were sequenced from multiple strains of a single species. Genome sequencing of *Escherichia coli* strain K-12 and two pathogenic strains showed that only 39% of their genes were shared among all three genomes (Figure 12.23). The three genomes varied in size by more than a million base pairs in length and each contained a unique and diverse complement of genes acquired through horizontal gene transfer. Genomes of many microbial species have now been examined in this way and have revealed that genes in microbial genomes can be placed into two classes: the **core genome**, genes shared by all members of a species, and the **pan genome**, the core genome plus genes that are not shared by all members of a species and which are often acquired through horizontal gene transfer (Figure 12.19). In Chapter 6 we introduced this concept and here we consider the forces that drive these patterns of genome evolution.

The Dynamic Nature of the *Escherichia coli* Genome

More than 20 genomes have been sequenced from different strains of *E. coli*, providing further insights into the nature of the core and pan genome. *E. coli* genomes have on average 4721 genes, with individual strains having as few as 4068 or as many as

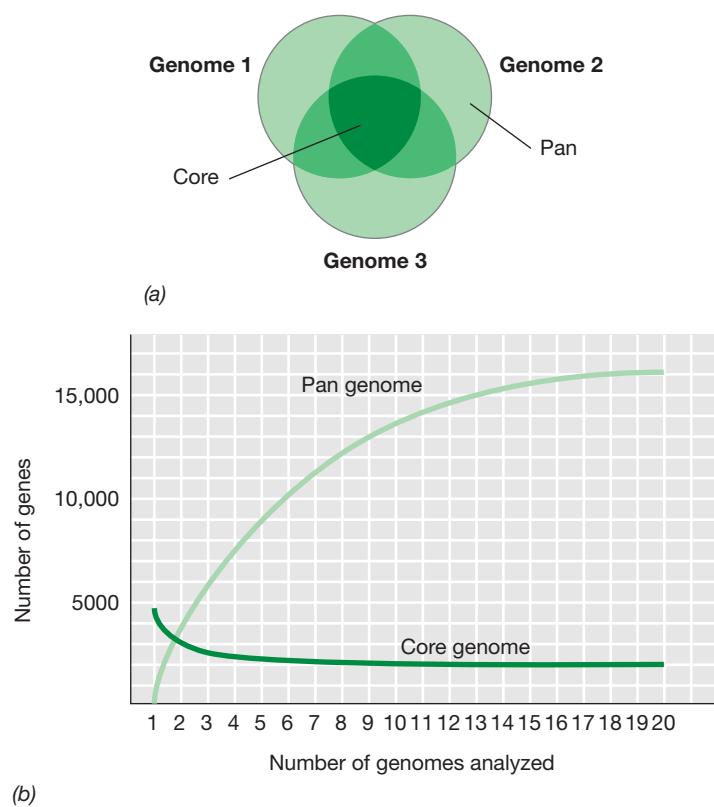

Figure 12.23 The core and pan genome concept. Microbial genomes are dynamic and heterogeneous. The first three genomes sequenced from different strains of *E. coli* were found to have only 39% of their genes in common. The core genome is considered the set of genes that are shared by all members of species (darkest green in part a), while the pan genome is the core genome plus that set of genes found unique to one strain or found in only a subset of strains (light green in part a). The size of the core and pan genome can vary between species. In *E. coli* the core genome is composed of approximately 1976 genes (b). The size of the pan genome in *E. coli* is not fixed, as each different strain has a unique complement of genes acquired from horizontal gene exchange. Data adapted from Touchon, M., et al. 2009. *PLoS Genetics* 5: (1) e1000344.

5379 total genes. The core genome consists of only 1976 genes present in all strains, accounting for less than half the genes present in the average *E. coli* genome. The size of the core genome can be expected to decrease as the evolutionary distance of strains increases. Taking this prediction to its extreme, only 50 to 250 genes are predicted to be universally present in all species of *Bacteria* and *Archaea*.

The number of unique genes observed continued to increase with each new *E. coli* genome sequenced such that a total of 17,838 unique genes are present in the 20 genomes (Figure 12.23b). Subtracting the contribution from the core genome, this indicates more than 15,862 genes not shared by all strains. A great many of these genes have clearly been inherited through horizontal gene exchange rather than through vertical patterns of inheritance. Genome analysis reveals that the core and pan genome concept is a general feature of microbial genomes, though the relative number of genes present in each pool can vary between species. The dramatic change in genome size and

gene content between strains of a single species indicates that microbial genomes are highly dynamic; that is, genomes can shrink or enlarge relatively quickly over time. The existence of a pan genome suggests that *Bacteria* and *Archaea* are constantly sampling genetic information from their environment through horizontal gene transfer.

The dynamic nature of microbial genomes is a manifestation of the evolutionary mechanisms that we have already described (Section 12.6). Variations between genomes arise due to the forces of mutation and recombination, and the evolutionary dynamics of genomes are governed by selection and genetic drift. Moreover, evidence for horizontal gene transfer is widespread in microbial genomes. Patterns of gene exchange appear to be governed by phylogenetic distance, with rates of gene exchange between genomes declining as phylogenetic distance increases. In the core genome of *E. coli*, most horizontal gene transfer takes place between close relatives and occurs by replacement of homologous DNA segments of 50 to 500 base pairs in length. While many horizontal gene transfer events are due to homologous replacements, insertions resulting from nonhomologous recombination are also common in microbial genomes. Comparative analysis of *E. coli* genomes indicates that insertions average 4 genes in length but in some cases contain 10 or more genes.

Gene Deletions in Microbial Genomes

Deletions play an important role in microbial genome dynamics (see Explore the Microbial World, “The Black Queen Hypothesis”). Deletions occur with far greater frequency than insertions in microbial genomes, and this bias toward deletions is the force that maintains the small size of microbial genomes. Selection is the main force that counters the effect of deletions, preserving those genes that provide a fitness benefit to the cell. Nonessential and nonfunctional material is deleted over evolutionary time, which is why microbial genomes are tightly packed with genes and contain relatively few noncoding sequences. Most genes acquired by horizontal gene transfer, like most mutations in general, can be expected to be neutral or deleterious to the cell. Hence, it is likely that new genes are acquired from the environment and those that do not convey a fitness benefit are eroded from the genome over time due to the relentless accumulation of deletions. In addition, genetic drift (Figure 12.20) can promote the rapid accumulation of deletion events when population sizes are small or when populations pass through a bottleneck. Deletions are thought to cause the extremely small genomes found in many obligate intracellular symbionts and pathogens (🔗 Sections 6.4 and 22.9).

- What effects do deletions have on the evolution of microbial genomes?

EXPLORE THE MICROBIAL WORLD

The Black Queen Hypothesis

It is a common misconception that evolution inevitably causes organisms to increase in complexity over time. In reality, evolution is both a give and a take proposition. Fitness changes are completely dependent on the environment, and fitness in some environments may actually be improved by a loss, rather than a gain, of specific genes.

The *Black Queen hypothesis*¹ posits a mechanism and a rationale for this loss of function whose end result is the evolution of mutual dependence in microbial communities. The term *Black Queen* refers to the card game Hearts in which there are two winning strategies. One winning strategy is to avoid getting stuck with the queen of spades. In this strategy each player seeks to lose as many contests ("tricks") as possible so as not to be forced to collect the black queen. The second winning strategy is to "shoot the moon" by collecting all of the trump cards including the black queen. In its microbial context, the Black Queen hypothesis embraces these card game strategies by proposing that some organisms optimize fitness (that is, "win") by the selective loss of specific genes while others optimize fitness by keeping them all.

The Black Queen hypothesis proposes that certain microbial genes encode extracellular products, such as metabolites or enzymes, which can be used by all or most members of the community. If an organism remains in the community, then selection will be relaxed on genes that encode the synthesis of products that are provided by other members of the community. The presence of such shared products in the community renders genes with similar functions nonessential for some community members (**Figure 1**). The mutation bias toward deletions can then cause these genes to be lost from the genome (Section 12.7).

The fitness of organisms that lose functions and develop dependencies will actually increase in the community since these organisms no longer bear the costs of production. Such organisms will remain competitive as long as they remain within the community, but they may be unable to grow if separated from the community in which they coevolved. In this way, mutual dependencies accumulate within microbial communities over time. The Black Queen hypothesis also explains the not-uncommon observation that some microorganisms can only be grown in the laboratory

in coculture with one or more other species from their environment.

In contrast to the gene loss strategy, organisms that preserve all essential functions (those that shoot the moon in the Hearts analogy) bear the costs of maintaining all gene functions, which puts them at a disadvantage to mutually dependent competitors when competing in the native community. However, cells that maintain their ability to grow independently still have a winning strategy because, unlike their mutually dependent competitors, they retain the option of dispersing to new habitats and growing outside of the native community.

Finally, in addition to describing how microbial community interdependencies might come about, the Black Queen hypothesis also reminds us of how interwoven microbial communities actually are. We will see in later chapters that several molecular tools are available to unwind this complexity and reveal both the diversity of the community and its genetic and metabolic potential.

¹Morris J.J., R.E. Lenski, and E.R. Zinser 2012. The Black Queen hypothesis: Evolution of dependencies through adaptive gene loss. *mBio* 3: e00036-12.

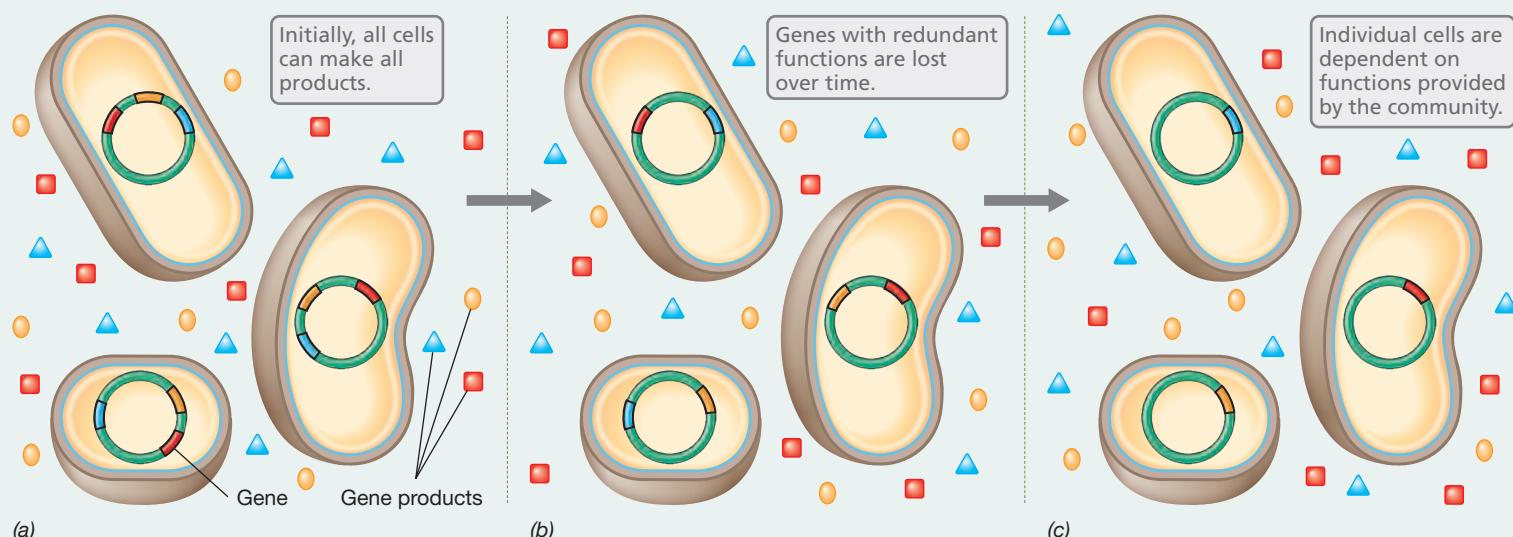

Figure 1 The Black Queen hypothesis and the evolution of dependence in microbial communities. (a) Three species in a community each have three different genes that make extracellular products that benefit the whole community (a gene and its product are shown in the same color). (b) Over time, random mutations cause functions to be lost from the genomes. (c) As long as some members of the community continue to make each product, there will be no fitness cost when a single species loses a single gene. Over time, the three species thus become mutually dependent.

IV • Microbial Systematics

Systematics is the study of the diversity of organisms and their relationships. It links phylogeny with **taxonomy**, the science in which organisms are characterized, named, and classified according to several defined criteria. Bacterial taxonomy traditionally has focused on practical aspects of identification and description, activities that rely heavily on comparisons of visible properties (phenotype). At present, the growing use of genetic information, especially DNA sequence data, is increasingly allowing taxonomy to reflect phylogenetic relationships as well.

Bacterial taxonomy has changed substantially in the past few decades, embracing a combination of methods for the identification of bacteria and description of new species. This *polyphasic approach* to taxonomy uses three kinds of methods—*phenotypic*, *genotypic*, and *phylogenetic*—for the identification and description of bacteria. Phenotypic analysis examines the morphological, metabolic, physiological, and chemical characteristics of the cell. Genotypic analysis considers characteristics of the genome. These two kinds of analysis categorize organisms based on similarities. They are complemented by phylogenetic analysis, which seeks to place organisms within an evolutionary framework using molecular sequence data (Sections 12.4, 12.5).

12.8 The Species Concept in Microbiology

At present, there is no universally accepted concept of **species** for microorganisms; this has been referred to as the “species problem” in microbiology. Species are the fundamental units of biological diversity, and how we distinguish and classify species in microbiology greatly affects our ability to explain the diversity of the microbial world. Microbial systematics combines phenotypic, genotypic, and sequence-based phylogenetic data within a framework of standards and guidelines for describing and identifying microorganisms in a taxonomic framework, but the issue of what actually constitutes a species remains controversial.

Current Definition of Microbial Species

From a taxonomic standpoint, all members of a species should be genetically and phenotypically cohesive, and their traits should be distinct from those described for other species. In addition, a species should be **monophyletic**, that is, the strains composing the species should all share a recent common ancestor to the exclusion of other species. For most of the history of microbiology it was impossible to resolve phylogenetic relationships, and thus species descriptions did not take into account the evolutionary history of a microorganism. The recognition that molecular sequences record evolutionary history created a crisis in microbial systematics as it became necessary to reconcile more classical species descriptions with insights gained through phylogenetic analyses. In addition, the discovery that microbial genomes are highly heterogeneous and contain many horizontally acquired genes poses a challenge to any definition of microbial species.

The prevailing concept for describing microbial species is best described as a *phylogenetic species concept*. The phylogenetic species concept defines a microbial species pragmatically as a group

of strains that share certain diagnostic traits and that are genetically cohesive and share a unique recent common ancestor. This species concept requires that a majority of genes in the species have congruent phylogenies and share a recent common ancestor. The phylogenetic species concept is not based on an evolutionary model of speciation, and thus species described in this way do not necessarily reflect meaningful units in terms of ecological or evolutionary processes. The phylogenetic species concept was developed to facilitate taxonomy, and species justifications derived from this concept are based largely on the expert judgment of taxonomists.

Under the phylogenetic species concept for *Bacteria* and *Archaea*, species are defined operationally as a group of strains sharing a high degree of similarity in many traits and sharing a recent common ancestor for their 16S rRNA genes. Species characterization employs a polyphasic approach that considers a range of different traits in making taxonomic judgments. Traits currently considered most important for identifying species include genomic similarity based on DNA hybridization, and comparisons of small subunit rRNA sequences.

The degree of **DNA–DNA hybridization** between the genomes of two organisms (Figure 12.24) provides a measure of their genomic similarity. We discussed nucleic acid hybridization in Section 11.2. In a hybridization experiment, *probe DNA* obtained from one organism is labeled with a fluorescent or radioactive label, sheared into small pieces, and heated to separate the two DNA strands. The probe is then added to single-stranded and sheared *target DNA* from a second organism and the mixture cooled to allow the DNA strands to reanneal. The genomic similarity between the two organisms is calculated as a percentage of probe hybridized to target relative to a control (probe DNA hybridized to target DNA from the same organism).

A value of 70% or less genomic hybridization and a difference in 16S rRNA gene sequence (Sections 12.3, 12.4) of 3% or more between two organisms is taken as evidence that the two are distinct species. Experimental data suggest that these criteria are valid, reliable, and consistent in identifying new microbial species for taxonomic purposes (Figure 12.25). On the basis of the current phylogenetic species concept, over 10,000 species of *Bacteria* and *Archaea* have been formally recognized. The criteria that should be used to define a genus, the next highest taxon (see Table 12.3), is more a matter of judgment, but discrete genera typically have greater than 5% dissimilarity in their 16S rRNA gene sequences. There are no consensus criteria for defining taxonomic ranks above the level of genera.

How Many Microbial Species Are There?

The result of nearly 4 billion years of evolution is the microbial world we see today (Figure 12.13). Microbial taxonomists agree that no firm estimate of the number of species can be given at present, in part because of uncertainty about what defines a species. However, they also agree that in the final analysis, this number will be very large. Owing to the difficulty in visualizing and characterizing microorganisms, only about 10,000 species

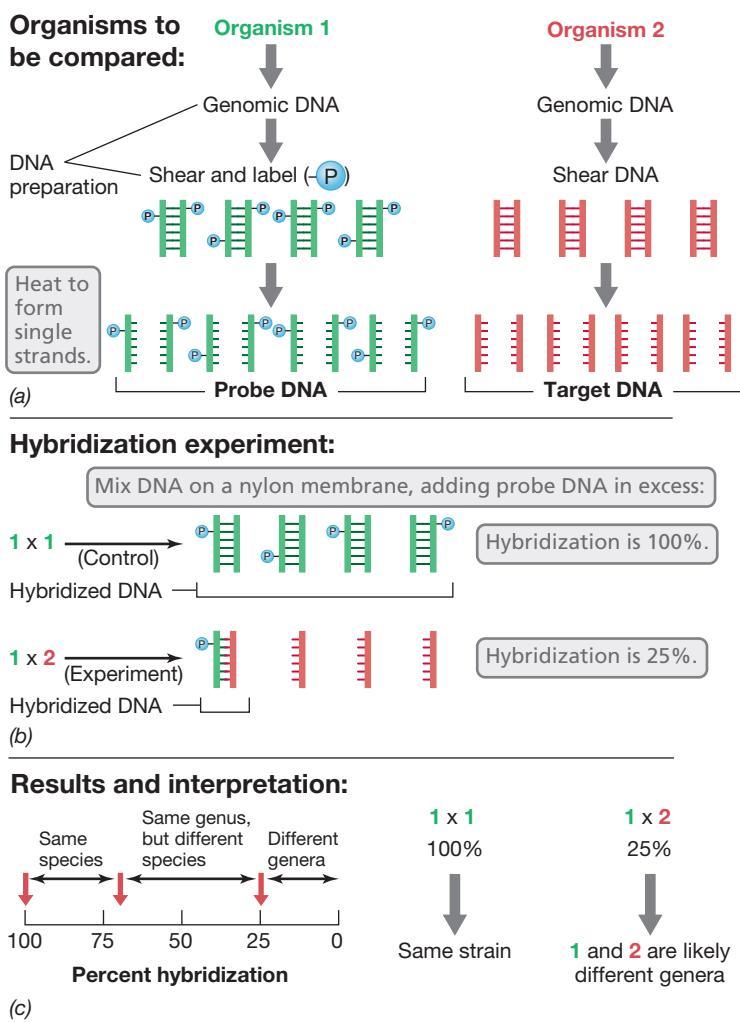

Figure 12.24 Genomic hybridization as a taxonomic tool. (a) Genomic DNA is isolated from the organisms to be compared and then sheared and denatured. Probe DNA is prepared from organism 1 by shearing, denaturing, and labeling the DNA (shown here as radioactive phosphate). (b) Sheared single-stranded target DNA from each genome is immobilized on a membrane and then hybridized with the labeled probe DNA from organism 1. Radioactivity in the hybridized DNA is measured. (c) Radioactivity in the control (organism 1 DNA hybridizing to itself) is taken as the 100% hybridization value.

of *Bacteria* and *Archaea* have been named using the taxonomic species concept. At this time it is impossible to accurately estimate the total number of bacterial and archaeal species on Earth, but their diversity is unquestionably higher than that of all plant and animal species combined and their total species numbers are likely several orders of magnitude higher than the 10,000 already characterized.

Every environment on Earth contains a diverse community of microorganisms. Analyses of 16S rRNA gene sequences indicate that over 10,000 different species can coexist in a single gram of soil! Nearly all plants and animals have some number of unique microorganisms associated with them as either pathogens or commensals on their surfaces or internal structures. Thus, microorganisms are not only the oldest but also the most diverse forms of life on our planet.

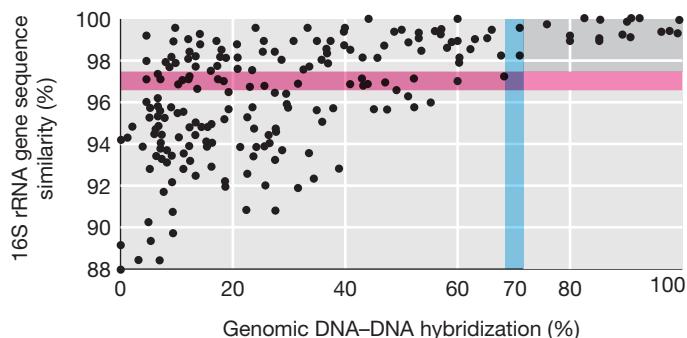

Figure 12.25 Relationship between 16S rRNA gene sequence similarity and genomic DNA–DNA hybridization for pairs of organisms. Pairs of microorganisms are compared on the basis of their 16S rRNA similarities and genomic hybridization values. Points in the upper right region represent pairs of strains that share greater than 97% 16S rRNA gene sequence similarity and 70% genomic hybridization values, and thus are likely members of the same species. Data adapted from Rosselló-Mora, R., and R. Amann. 2001. *FEMS Microbiol. Revs.* 25: 39–67, and Stackebrandt, E., and J. Ebers. 2006. *Microbiology Today*. 11: 153–155.

MINIQUIZ

- What is the difference between taxonomy and phylogeny?
- What are some key criteria from the phylogenetic species concept used to determine whether two strains belong to the same species?
- How many species of *Bacteria* and *Archaea* have been named? How many likely exist?

12.9 Taxonomic Methods in Systematics

A *polyphasic approach*, that is, an approach that uses many different methods in combination, is used to identify and name species of *Bacteria* and *Archaea* in accordance with the currently accepted taxonomic species concept. In this section we describe methods commonly used for characterizing microbial, and primarily prokaryotic, species.

Gene Sequence Analyses

As we have described, gene sequences are commonly determined from PCR-amplified fragments of DNA, and the sequences are analyzed using phylogenetic analyses (Section 12.5). Small subunit rRNA gene sequences are highly conserved, however, and while they provide valuable phylogenetic information, they are not always useful for distinguishing closely related species. By contrast, other highly conserved genes, such as *recA*, which encodes a recombinase protein, and *gyrB*, which encodes a DNA gyrase protein, can be useful for distinguishing bacteria at the species level. The DNA sequences of protein-encoding genes accumulate mutations more rapidly than rRNA genes; for this reason, sequences from such genes can distinguish bacterial species that cannot be resolved by rRNA gene sequence analyses alone (Figure 12.26).

Multilocus Sequence Typing

Multilocus sequence typing (MLST) is a method in which several different “housekeeping” genes from several related organisms

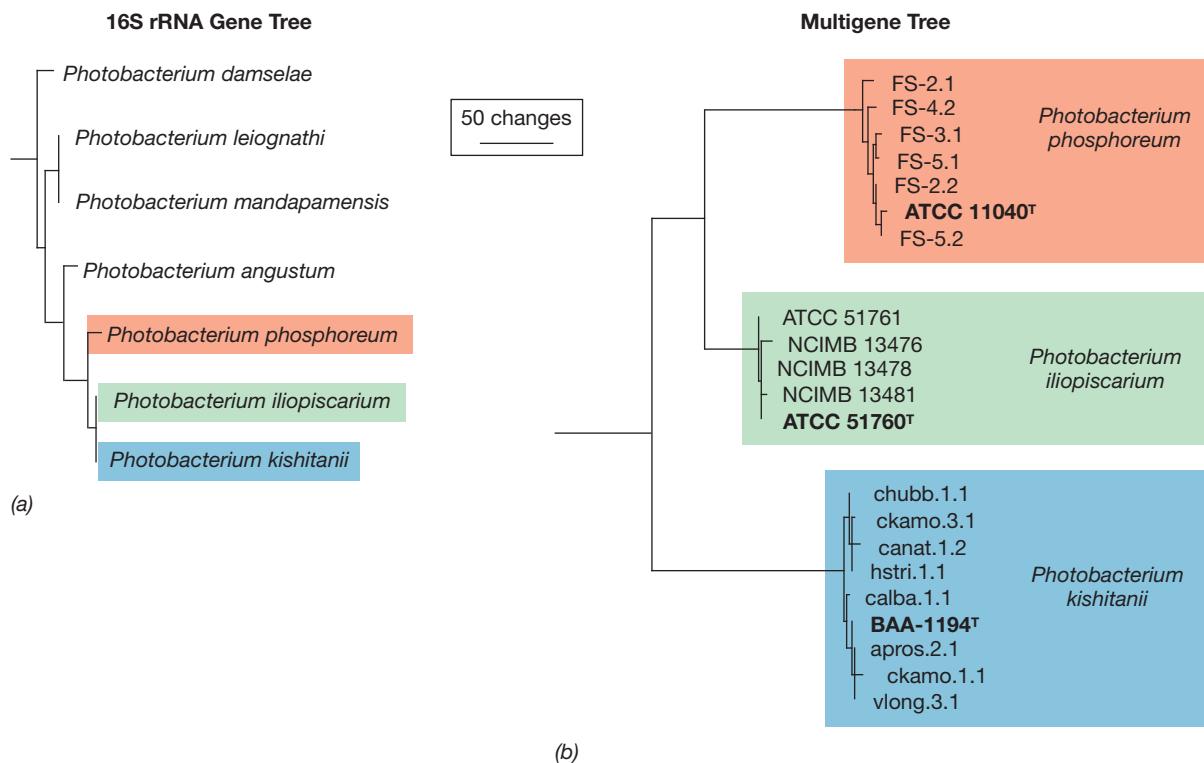

Figure 12.26 **Multigene phylogenetic analysis.** A phylogeny is shown for species in the genus *Photobacterium*. (a) 16S rRNA gene tree, showing the species to be poorly resolved. (b) Multigene analysis based on combined analysis of the 16S rRNA gene and *gyrB* and *luxABFE* genes in 21 isolates from three *Photobacterium* species. Multigene analysis clearly resolves the strains into three distinct phylogenetic species, *P. phosphoreum*, *P. iliopiscarium*, and *P. kishitanii*. The scale bar indicates the branch length equal to a total of 50 nucleotide changes. The type strain of each species is listed in bold. (All abbreviations are part of strain designations.) Phylogenetic analyses courtesy of Tory Hendy and Paul V. Dunlap, University of Michigan.

are sequenced and the sequences used collectively to distinguish the organisms. Housekeeping genes encode essential functions in cells and are always located on the chromosome rather than on a plasmid. For each gene, an approximately 450-base-pair sequence is amplified and then sequenced. The alleles of each gene (variants that differ by at least one nucleotide) are each assigned a number. The strain being studied is then assigned an allelic profile, or multilocus sequence type, consisting of a series of numbers representing its particular combination of alleles (Figure 12.27). In MLST, strains with identical sequences for a given gene have the same allele number for that gene, and two strains with identical sequences for all the genes have the same allelic profile (and would be considered identical by this method). The relatedness between each allelic profile is expressed in a dendrogram

of genetic distances that vary from 0 (strains are identical) to 1 (strains are only distantly related, if at all).

MLST has sufficient resolving power to distinguish among even very closely related strains of a given species. In practice, strains can be discriminated on the basis of a single nucleotide change in just one of the analyzed genes. However, MLST is not useful for comparing organisms above the species level; its resolution is too sensitive to yield meaningful information for grouping higher-order taxa such as genera and families.

MLST has found its greatest use in clinical microbiology, where it has been used to differentiate strains of various pathogens. This is important because some strains within a species—*Escherichia coli* K-12, for example—may be harmless, whereas others, such as strain O157:H7, can cause serious and even

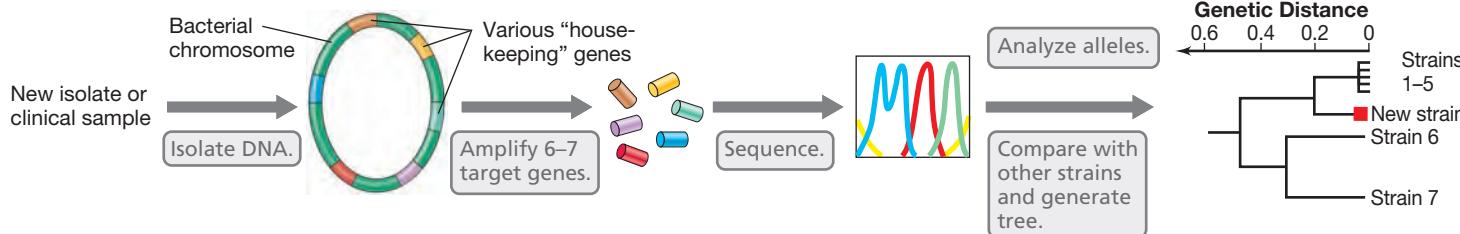

Figure 12.27 **Multilocus sequence typing.** Steps in MLST leading to a similarity phenogram are shown. Strains 1–5 are virtually identical, whereas strains 6 and 7 are distinct from one another and from strains 1–5.

fatal infections (Section 31.12). MLST is also widely used in epidemiological studies to track a virulent strain of a bacterial pathogen as it moves through a population and in environmental studies to define the geographic distributions of strains.

Genome Fingerprinting

Genome fingerprinting is a rapid approach for evaluating polymorphisms between strains. The fingerprints are generally fragments of DNA generated from individual genes or whole genomes. Gene sequencing is often enabled by PCR amplification of gene fragments. Characterization of SSU rRNA gene sequences is common, but a variety of different genes can be of use in species classification.

Ribotyping is a method of genome fingerprinting based on the localization of SSU rRNA genes on genome fragments. In this method, genomic DNA from an organism is digested by a restriction enzyme (Section 11.1) and the fragments are separated by gel electrophoresis, transferred to a nylon membrane, and labeled with an SSU rRNA gene probe (Figure 12.28). Different microbial species can have different numbers of rRNA operons, ranging from 1 to 15, and the number of rRNA operons present in a microbial genome is a conserved feature of all strains of a species. In addition, changes in genome sequence between strains can cause the endonuclease enzyme to cut in different locations, producing variation in the lengths of the restriction fragments that are visualized. Hence, the size and number of bands detected generates a specific pattern, a kind of genome fingerprint called a *ribotype*, and this pattern can be compared with patterns of reference organisms in a computer database. The ribotype of a particular organism can be unique and diagnostic, allowing rapid identification of different species and even different strains of a species. For these reasons, ribotyping has found many applications in clinical diagnostics and the microbial analyses of food, water, and beverages.

Other genome fingerprinting methods used commonly include *repetitive extragenic palindromic PCR* (*rep-PCR*) and *amplified fragment length polymorphism* (*AFLP*). The rep-PCR method is based on the presence of highly conserved repetitive DNA elements interspersed randomly around the bacterial chromosome. The number and positions of these elements differ between strains of a species. Oligonucleotide primers designed to be complementary to these elements enable PCR amplification of genomic fragments found between the

Figure 12.28 **Ribotyping.** Ribotype results for four different lactic acid bacteria. DNA was taken from a strain of each bacterium, digested into fragments by restriction enzymes, separated by gel electrophoresis, and then probed with a 16S rRNA gene probe. Variations in position and intensity of the bands are important in identification.

repeated elements. These PCR products can be visualized using gel electrophoresis to reveal a pattern of bands that can be used as a fingerprint (Figure 12.29). AFLP is based on the digestion of genomic DNA with one or two restriction enzymes and selective PCR amplification of the resulting fragments, which are then separated by agarose gel electrophoresis. Strain-specific banding patterns similar to those of rep-PCR or other DNA fingerprinting methods are generated, with the large number of bands giving a high degree of discrimination between strains within a species.

Multigene and Whole Genome Analyses

The use of multiple genes and whole genomes for the identification and description of bacteria is becoming increasingly common as DNA sequencing capacities improve and costs decline (Section 6.2). A wide range of sequence analyses can be performed on whole microbial genomes, providing insights into microbial physiology and microbial evolution. These analyses have provided important insights into the large role that horizontal gene exchange has played in microbial evolution and on the highly dynamic nature of microbial genomes (Section 12.7). Shared orthologs, that is, genes that are homologous and share the same function (Section 12.5), can be aligned and examined using phylogenetic methods and the average nucleotide identity of these genes determined. Comparative analysis of gene content (presence or absence of genes) and *synteny*, the order of genes in the genome, and genome GC content, provide further insights into relationships between strains. Whole genome sequences can also be used for metabolic reconstruction and characterization of genetic pathways. A range of methods in comparative genomics and population genomics (Chapter 6) have been developed for use in systematic analysis.

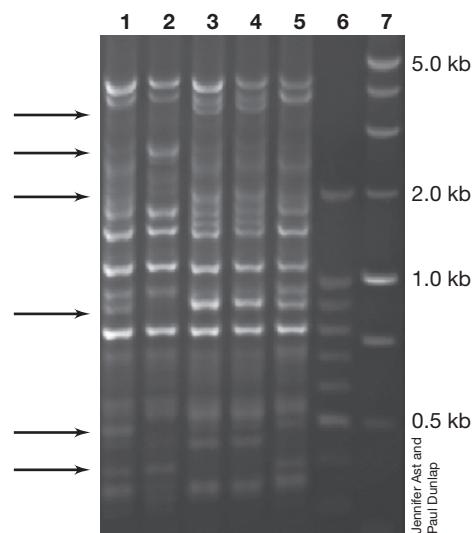

Figure 12.29 **DNA fingerprinting with rep-PCR.** Genomic DNAs from five strains (1–5) of a single species of bacteria were PCR-amplified using specific primers called *rep* (repetitive extragenic palindromic); the PCR products were separated in an agarose gel on the basis of size to generate DNA fingerprints. Arrows indicate some of the differing bands. Lanes 6 and 7 are 100-bp and 1-kbp DNA size markers, respectively, used for estimating sizes of the DNA fragments.

Phenotypic Analysis

The observable characteristics—the **phenotype**—of a bacterium provide many traits that can be used to differentiate species. Typically, for either describing a new species or identifying a bacterium, several of these traits are determined for the organism of interest. The results are then compared with phenotypes of known organisms, either examined in parallel with the unknowns or from published information. The specific traits used depend on the kind of organism, and which traits are chosen for testing may arise from the investigator's purpose and from substantial prior knowledge of the bacterial group to which the new organism likely belongs. For example, in applied situations, such as in clinical diagnostic microbiology, where identification may be an end in itself and time is of the essence, a well-defined subset of traits is typically used that quickly discriminates between likely possibilities. **Table 12.2** lists general categories and examples of some phenotypic traits used in identifications and species descriptions, and we examine one of these traits here.

The types and proportions of fatty acids present in cytoplasmic membrane lipids and the outer membrane lipids of gram-negative bacteria are phenotypic traits often used in taxonomic analyses. The technique for identifying these fatty acids has been nicknamed **FAME**, for *fatty acid methyl ester*, and is in widespread use in clinical, public health, and food- and water-inspection laboratories where pathogens routinely must be identified. The fatty acid composition of *Bacteria* varies from species to species in chain length and in the presence or absence of double bonds, rings, branched chains, or hydroxy groups (**Figure 12.30**). For the

Table 12.2 Some phenotypic characteristics of taxonomic value

Category	Characteristics
Morphology	Colony morphology; Gram reaction; cell size and shape; pattern of flagellation; presence of spores, inclusion bodies (e.g., PHB, ^a glycogen, or polyphosphate granules, gas vesicles, magnetosomes); capsules, S-layers, or slime layers; stalks or appendages; fruiting-body formation
Motility	Nonmotile; gliding motility; swimming (flagellar) motility; swarming; motile by gas vesicles
Metabolism	Mechanism of energy conservation (phototroph, chemoorganotroph, chemolithotroph); utilization of individual carbon, nitrogen, or sulfur compounds; fermentation of sugars; nitrogen fixation; growth factor requirements
Physiology	Temperature, pH, and salt ranges for growth; response to oxygen (aerobic, facultative, anaerobic); presence of catalase or oxidase; production of extracellular enzymes
Cell lipid chemistry	Fatty acids; ^b polar lipids; respiratory quinones
Cell wall chemistry	Presence or absence of peptidoglycan; amino acid composition of cross-links; presence or absence of cross-link interbridge
Other traits	Pigments; luminescence; antibiotic sensitivity; serotype; production of unique compounds, for example, antibiotics

^aPHB, poly-β-hydroxybutyric acid (Section 2.14).

Classes of Fatty Acids in Bacteria

Class/Example	Structure of example
I. Saturated: tetradecanoic acid	
II. Unsaturated: omega-7-cis hexadecanoic acid	
III. Cyclopropane: cis-7,8-methylene hexadecanoic acid	
IV. Branched: 13-methyltetradecanoic acid	
V. Hydroxy: 3-hydroxytetradecanoic acid	

(a)

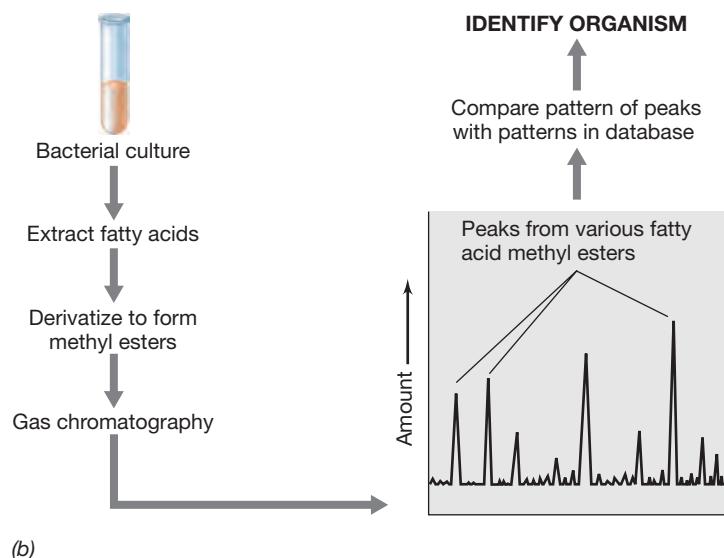

Figure 12.30 Fatty acid methyl ester (FAME) analysis in bacterial identification.

(a) Classes of fatty acids in *Bacteria*. Only a single example is given of each class, but in fact, more than 200 structurally distinct fatty acids are known from bacterial sources. A methyl ester contains a methyl group (CH_3) in place of the proton on the carboxylic acid group (COOH) of the fatty acid. **(b)** Procedure. Each peak from the gas chromatograph is due to one particular fatty acid methyl ester, and the peak height is proportional to the amount.

analyses, fatty acids extracted from cell hydrolysates of a culture grown under standardized conditions are chemically volatilized and analyzed by gas chromatography. A chromatogram showing the types and amounts of fatty acids from the unknown bacterium is then compared with a database containing the fatty acid profiles of thousands of reference bacteria grown under the same conditions.

Fatty acid profiles of an organism, like many other phenotypic traits, can vary as a function of temperature, growth phase (exponential versus stationary), and growth medium. Hence, for valid results, it is necessary to grow the unknown organism on a specific

medium and at a specific temperature. For many organisms this is impossible, of course, limiting the applicability of FAME analyses. In addition, the extent of variation in FAME profiles among strains of a species, a necessary consideration in studies to discriminate between species, is not yet well documented.

Phenotypic characteristics of strains are generally highly dependent on growth conditions, and phenotypes observed in the laboratory environment may not well represent phenotypes present in the natural environment; thus care must be taken in using phenotypic characteristics in systematic analyses. The systematic value of different phenotypic characteristics can vary with respect to the taxonomic groups being examined.

12.10 Classification and Nomenclature

We conclude our treatment of microbial evolution and systematics with a brief description of how *Bacteria* and *Archaea* are classified and named—the science of *taxonomy*. Information is also presented on culture collections, which are repositories for scientific deposition of live microbial cultures; on some key taxonomic resources available for microbiology; and on the procedures for

naming new microbial species. The formal description of a new microbial species and the deposition of cultures into a culture collection form an important foundation of prokaryotic systematics.

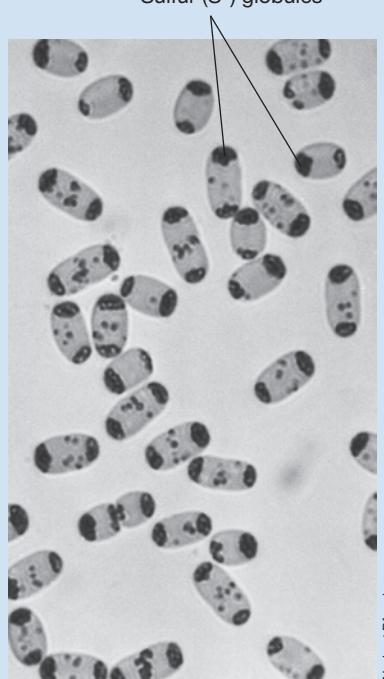

Taxonomy and Describing New Species

Classification is the organization of organisms into progressively more inclusive groups on the basis of either phenotypic similarity or evolutionary relationship. A species is made up of one to several strains, and similar species are grouped into genera (singular, genus). Similar genera are grouped into families, families into orders, orders into classes, up to the domain, the highest-level taxon based on a collection of phenotypic and genotypic information. This hierarchical scheme is illustrated in **Table 12.3**.

Nomenclature is the actual naming of organisms and follows the **binomial system** of nomenclature devised by the Swedish medical doctor and botanist Carl Linnaeus and used throughout biology; organisms are given genus names and species epithets. The names are Latin or Latinized Greek derivations, often descriptive of some key property of the organism, and are printed in *italics*. By classifying organisms into groups and naming them, we order the natural microbial world and make it possible to communicate effectively about all aspects of particular organisms, including their behavior, ecology, physiology, pathogenesis, and evolutionary relationships. The creation of new names must follow the rules described in the *International Code of Nomenclature of Bacteria*. This source presents the formal framework by which *Bacteria* and *Archaea* are to be officially named and the

Table 12.3 Taxonomic hierarchy for the purple sulfur bacterium *Allochromatium warmingii*

Taxon	Name	Properties	Confirmed by
Domain	<i>Bacteria</i>	Bacterial cells; rRNA gene sequences typical of <i>Bacteria</i>	Microscopy; 16S rRNA gene sequence analysis; presence of unique biomarkers, for example, peptidoglycan
Phylum	<i>Proteobacteria</i>	rRNA gene sequence typical of <i>Proteobacteria</i>	16S rRNA gene sequence analysis
Class	<i>Gammaproteobacteria</i>	Gram-negative bacteria; rRNA sequence typical of <i>Gammaproteobacteria</i>	Gram-staining, microscopy
Order	<i>Chromatiales</i>	Phototrophic purple bacteria	Characteristic pigments (► Figures 13.2, 13.3, and 13.9)
Family	<i>Chromatiaceae</i>	Purple sulfur bacteria	Ability to oxidize H ₂ S and store S ⁰ within cells; microscopic observation of S ⁰ (see photo); 16S rRNA gene sequence
Genus	<i>Allochromatium</i>	Rod-shaped purple sulfur bacteria; <95% 16S gene sequence identity with all other genera	Microscopy (see photo)
Species	<i>warmingii</i>	Cells 3.5–4.0 µm × 5–11 µm; storage of sulfur mainly in poles of cell (see photo); <97% 16S gene sequence identity with all other species	Cell size measured microscopically with a micrometer; observation of polar position of S ⁰ globules in cells (see photo); 16S rRNA gene sequence

The image shows a light micrograph of rod-shaped cells of *Allochromatium warmingii*. Within the cells, dark, granular structures representing sulfur (S⁰) globules are visible, particularly concentrated at the poles. A callout line points to one of these globules with the label "Sulfur (S⁰) globules". The cells are arranged in a loose, non-overlapping cluster.

procedures by which existing names can be changed, for example, when new data warrant taxonomic rearrangements.

When a new microorganism is isolated from nature and thought to be unique, a decision must be made as to whether it is sufficiently different from other prokaryotes to be described as a new taxon. To achieve formal validation of taxonomic standing as a new genus or species, a detailed description of the organism's characteristics and distinguishing traits, along with its proposed name, must be published, and, as just mentioned, viable cultures of the organism must be deposited in at least two international culture collections (Table 12.4). The manuscript describing and naming a new taxon undergoes peer review before publication. A major vehicle for the description of new taxa is the *International Journal of Systematic and Evolutionary Microbiology* (*IJSEM*), the official publication of record for the taxonomy and classification of *Bacteria*, *Archaea*, and microbial eukaryotes. In each issue, the *IJSEM* also publishes an approved list of newly validated names. By providing validation of newly proposed names, publication in *IJSEM* paves the way for their inclusion in taxonomic reference sources (see later). Two websites provide listings of valid, approved bacterial names: List of Prokaryotic Names with Standing in Nomenclature (<http://www.bacterio.net>), and Bacterial Nomenclature Up-to-Date (<http://www.dsmz.de>).

The International Committee on the Systematics of Prokaryotes (ICSP) oversees the nomenclature and taxonomy of *Bacteria* and *Archaea*. The ICSP also oversees the publication of *IJSEM* and the *International Code of Nomenclature of Bacteria* and gives guidance to several subcommittees that meet to establish and revise standards for the description of new species in the different groups of prokaryotes.

Bergey's Manual and The Prokaryotes

Because taxonomy is largely a matter of scientific judgment, there is no "official" classification of *Bacteria* and *Archaea*. However, the classification system most widely accepted by microbiologists is that of *Bergey's Manual of Systematic Bacteriology*, a major taxonomic treatment of *Bacteria* and *Archaea* (see Appendix 2 for a list of higher-order taxa from the most recent edition of *Bergey's Manual*). Widely used, *Bergey's Manual* has served the community of microbiologists since 1923 and is a compendium of information on all recognized prokaryotes. Each chapter, written by experts, contains tables, figures, and other systematic information useful for identification purposes.

A second major source describing the physiology, ecology, phylogeny, enrichment, isolation, and cultivation of *Bacteria* and *Archaea* is *The Prokaryotes*. This work is available online by subscription through university libraries. Collectively, *Bergey's Manual* and *The Prokaryotes* offer microbiologists both the concepts and the details of the biology of *Bacteria* and *Archaea* as we know it today; they are the primary resources for microbiologists characterizing newly isolated organisms.

Culture Collections

National microbial culture collections (Table 12.4) are an important foundation of microbial systematics. These permanent collections catalog and store microorganisms and provide cultures upon request (for a fee) to researchers in academia, medicine, and industry. The collections play an important role in protecting microbial biodiversity, just as museums do in preserving plant and animal specimens for future study. However, unlike museums, which maintain collections of chemically preserved or dried, dead specimens, microbial culture collections store microorganisms as *viable cultures*, typically frozen or in a freeze-dried state. These storage methods maintain the cells indefinitely in a living state and prevent genetic changes that might occur if the organisms were continually subcultured.

A related and key role of culture collections is as repositories for *type strains*. When a new species of bacteria is described in a scientific journal, a strain is designated as the nomenclatural type of the taxon for future taxonomic comparison with other strains of that species (see Figure 12.26). Deposition of this type strain in the national culture collections of at least two countries—thereby making the strain publicly available—is a prerequisite for validation of the new species name. Some of the large national culture collections are listed in Table 12.4. Their websites contain searchable databases of strain holdings together with information on the environmental sources of strains and their descriptions.

MINIQUIZ

- What roles do culture collections play in microbial systematics?
- What is the *IJSEM* and what taxonomic function does it fulfill?
- Why might viable cell cultures be of more use in microbial taxonomy than preserved specimens?

BIG IDEAS

12.1 • Planet Earth is about 4.5 billion years old and the first evidence for microbial life can be found in microfossils of prokaryotic cells present in rocks 3.86 billion years old.

12.2 • In rocks 3.5 billion years old or younger, microbial formations called stromatolites are abundant and show extensive microbial diversification. The evolution of oxygenic photosynthesis caused O₂ to accumulate 2.4 billion years ago, eventually leading to the formation of banded iron formations, the ozone shield, and an oxygenated atmosphere, which set the stage for rapid diversification of metabolic types and the evolution of multicellularity.

12.3 • The eukaryotic cell developed from endosymbiotic events. The modern eukaryotic cell is a chimera with genes and characteristics from both *Bacteria* and *Archaea*. SSU rRNA sequence analyses indicate the ancestors of mitochondria are found in the phylum *Proteobacteria* and those of chloroplasts are found in the phylum *Cyanobacteria*.

12.4 • Ribosomal RNA genes have been used to construct a universal tree of life revealing that life on Earth evolved in three major directions, forming the domains *Bacteria*, *Archaea*, and *Eukarya*. The main phyla of *Bacteria* and *Archaea* diverged billions of years ago, and the best-characterized phyla of *Eukarya* diverged within the last 600 million years. The universal tree of life shows that the domains *Bacteria* and *Archaea* split from each other eons ago, and that *Eukarya* split from *Archaea* later in the history of life.

12.5 • Molecular sequences accumulate random mutations over time and molecular phylogenetic analysis is used to determine the evolutionary history of life. A phylogenetic tree is a diagram that depicts the evolutionary history of a set of genes or organisms.

12.6 • Evolution is defined as a change in allele frequencies over time. New alleles are created through the processes of mutation and recombination. Mutations occur at random and most mutations are neutral or deleterious, but some are beneficial. Natural selection and genetic drift are two mechanisms that cause allele frequencies to change over time.

12.7 • Microbial genomes are dynamic, and genome size and gene content can vary considerably between strains of a species. The core genome is defined as the set of all genes shared by a species, while the pan genome is defined as the core genome plus genes whose presence varies among strains of a species.

12.8 • At present, species in *Bacteria* and *Archaea* are defined operationally based on shared genetic and phenotypic traits. The dynamic nature of microbial genomes and the abundance of genes acquired through horizontal gene transfer have raised questions about the nature of microbial species. While many mechanisms have been proposed to describe species formation, there is no consensus on the ecological and evolutionary forces that best explain the origin of microbial species.

12.9 • Systematics is the study of the diversity and relationships of living organisms. Polyphasic taxonomy is based on phenotypic, genotypic, and phylogenetic information. Bacterial species can be distinguished genotypically on the basis of DNA–DNA hybridization, DNA fingerprinting, MLST, or multigene or whole genome analyses. Phenotypic traits useful in taxonomy include morphology, motility, metabolism, and cell chemistry, especially lipid analyses.

12.10 • Nomenclature in microbiology follows the binomial system used in all of biology. Formal recognition of a new prokaryotic species requires depositing a sample of the organism in culture collections and publishing the new species name and description. *Bergey's Manual of Systematic Bacteriology* and *The Prokaryotes* are major taxonomic compilations of *Bacteria* and *Archaea*.

REVIEW OF KEY TERMS

Allele a sequence variant of a given gene
Archaea phylogenetically related prokaryotes distinct from *Bacteria*
Bacteria phylogenetically related prokaryotes distinct from *Archaea*
Banded iron formation iron oxide-rich ancient sedimentary rocks containing zones of oxidized iron (Fe^{3+}) formed by oxidation of Fe^{2+} by O_2 produced by cyanobacteria
Binomial system the system devised by the Swedish scientist Carl Linnaeus for naming living organisms in which an organism is given a genus name and a species epithet
Core genome those genes found in common in the genomes of all strains of a species
DNA–DNA hybridization the experimental determination of genomic similarity by measuring the extent of hybridization of DNA from one organism with that of another
Domain in a taxonomic sense, the highest level of biological classification
Endosymbiotic hypothesis the idea that a chemoorganotrophic bacterium and a cyanobacterium were stably incorporated into another cell type to give rise, respectively, to the mitochondria and chloroplasts of modern-day eukaryotes
Eukarya all eukaryotes: algae, protists, fungi, slime molds, plants, and animals
Evolution a change in allele frequencies over time with new alleles arising due to mutation and recombination
FAME fatty acid methyl ester; a technique for identifying microorganisms by their fatty acids
Fitness the capacity of an organism to survive and reproduce as compared to that of competing organisms
Genetic drift a process that results in a change in allele frequencies in a population as a result of random changes in the number of offspring from each individual over time
Homology having shared ancestry
Homoplasy when two organisms have the same trait as a result of recurrent mutation or convergent evolution

Horizontal gene transfer the asymmetrical and unidirectional transfer of DNA from one cell to another
Molecular clock a DNA sequence, such as a gene for rRNA, that can be used as a comparative temporal measure of evolutionary divergence
Monophyletic in phylogeny, a group descended from one ancestor
Multilocus sequence typing (MLST) a taxonomic tool for classifying organisms on the basis of gene sequence variations in several housekeeping genes
Mutation a heritable change in DNA sequence
Ortholog a gene in one organism that is similar to a gene in another organism because of descent from a common ancestor (see also *paralog*)
Pan genome the totality of the genes present in the different strains of a species
Paralog a gene whose similarity to one or more other genes in the same organism is the result of gene duplication (see also *ortholog*)
Phenotype the physical and chemical characteristics of an organism that can be observed or measured
Phylogenetic tree a diagram that depicts the evolutionary history of an organism; consists of nodes and branches
Phylogeny evolutionary history
Phylum a major lineage of cells in one of the three domains of life
Recombination resorting or rearrangement of DNA fragments resulting in a new sequence combination
Ribosomal RNA (rRNA) RNA molecules found in the small and large subunits of the ribosome
Ribotyping a means of identifying microorganisms from analysis of DNA fragments generated from restriction enzyme digestion of the genes encoding their ribosomal RNA
Selection in an evolutionary context, a process that results in a change in allele frequencies
in a population when individuals that are favored in a given environment are able to produce more offspring and make a greater contribution to the gene content of future generations
Sequence alignment the insertion of gaps into a set of molecular sequences organized in rows so that homologous positions are organized in vertical columns. Alignment is necessary prior to phylogenetic analysis because deletion and insertion mutations cause variations in the length of molecular sequences
16S rRNA a large polynucleotide (~1500 bases) that functions as part of the small subunit of the ribosome of *Bacteria* and *Archaea* and from whose gene sequence evolutionary information can be obtained; its eukaryotic counterpart is 18S rRNA
Small subunit (SSU) rRNA 16S rRNA found in the 30S ribosomal subunit of *Bacteria* and *Archaea* and its orthologous counterpart in *Eukarya*, the 18S rRNA of the 40S ribosomal subunit found in eukaryotes
Species defined in microbiology as a collection of strains that all share the same major properties and differ in one or more significant properties from other collections of strains; defined phylogenetically as a monophyletic, exclusive group based on DNA sequence
Stromatolite a laminated microbial mat, typically built from layers of filamentous *Bacteria* and other microorganisms, which can become fossilized
Systematics the study of the diversity of organisms and their relationships; includes taxonomy and phylogeny
Taxonomy the science of identification, classification, and nomenclature
Universal tree of life a phylogenetic tree that shows the positions of representatives of all domains of cellular life

REVIEW QUESTIONS

- What is the age of planet Earth? When did the oceans form? What is the age of the earliest known microfossil? (Section 12.1)
- What is a stromatolite and when can they be found in Earth's history? (Section 12.2)
- Why was the evolution of cyanobacteria of such importance to the further evolution of life on Earth? What component of the geological record is used to date the evolution of cyanobacteria? (Section 12.2)
- What is the endosymbiotic hypothesis for the origin of mitochondria and chloroplasts? What evidence supports this hypothesis? (Section 12.3)
- What evidence supports the classification of life into three domains? (Section 12.4)
- What major physiological and biochemical properties do *Archaea* share with *Eukarya* or with *Bacteria*? (Section 12.4)

7. Why are SSU rRNA genes good choices for phylogenetic studies, and what are their limitations? (Section 12.4)
8. Why is sequence alignment necessary prior to phylogenetic tree construction? (Section 12.5)
9. What is homoplasy and why does it create problems for molecular phylogenetic analyses? (Section 12.5)
10. What is the difference between a gene tree and an organismal tree? (Section 12.5)
11. Describe the steps for determining an SSU phylogeny of three bacteria you have isolated from nature. (Sections 12.4 and 12.5)
12. What is evolution? What processes give rise to genetic variation? What processes can cause allele frequencies to change over time? (Section 12.6)
13. What is fitness? To what degree does fitness depend on the environment in which organisms live? (Section 12.6)
14. What are some processes that influence the content of the pan genome? (Section 12.7)
15. Contrast the impacts of homologous and nonhomologous recombination on the evolution of the core genome and the pan genome. (Section 12.7)
16. What is the “species problem” and why is the concept of microbial species difficult to resolve? (Section 12.8)
17. How many bacterial species are there? Why do we not know this number more precisely? (Section 12.8)
18. What major phenotypic and genotypic properties are used to classify organisms in bacterial taxonomy? (Sections 12.8 and 12.9)
19. What is measured in FAME analyses? (Section 12.9)
20. How does 16S rRNA gene sequence analysis differ from multilocus sequence typing as an identification tool? (Section 12.9)
21. What roles do microbial culture collections play in microbial systematics? (Section 12.10)

APPLICATION QUESTIONS

1. Compare and contrast the physical and chemical conditions on Earth at the time life first arose with conditions today. From a physiological standpoint, discuss at least two reasons why *animals* could not have existed on early Earth. In what ways has microbial metabolism altered Earth’s biosphere? How might life on Earth be different if oxygenic photosynthesis had not evolved?
2. For the following sequences, construct the phylogenetic tree that best depicts their evolutionary relationships.

Taxon 1: GTTCCCTTA

Taxon 2: GTTCGGTAT

Taxon 3: GAAAAACCTAT

Taxon 4: CTTCCCTTT

Taxon 5: GTAAAACCCGAT

3. Imagine that you have been given several bacterial strains from various countries around the world and that all the strains are thought to cause the same gastrointestinal disease and to be genetically identical. Upon carrying out a DNA fingerprint analysis of the strains, you find that four different strain types are present. What methods could you use to test whether the different strains are actually members of the same species?
4. Imagine that you have discovered a new form of microbial life, one that appears to represent a fourth domain. How would you go about characterizing the new organism and determining if it actually is evolutionarily distinct from *Bacteria*, *Archaea*, and *Eukarya*?

13 • Metabolic Diversity of Microorganisms

microbiologynow

Unraveling Microbial Metabolisms

Once a bacterium is in laboratory culture, it is often straightforward to determine how it makes a living; that is, to determine its metabolic capacities. But how about organisms that have yet to be cultured; can we figure out what they are doing, too? We can, but by studying their *genes* rather than their *metabolisms*.

In order to probe microbial metabolic processes in an anoxic aquifer near the Colorado River (right photo), microbial ecologists isolated total DNA from the aquifer microbial community directly in the field (left photo) and from it, reconstructed and sequenced nearly 50 genomes.¹ Through sequence analyses, the scientists unraveled the metabolisms of the aquifer microbial community and examined other major aspects of the community's biology. To their surprise, they found that fermentations and H₂ metabolism rather than anaerobic respirations were the major catabolic strategies being employed. Moreover, certain metabolisms thought to be restricted to Archaea were also detected in aquifer *Bacteria*.

Many of the uncultivated *Bacteria* in the aquifer previously had been detected in diversity surveys of other anaerobic environments. However, because the approach in the aquifer study connected phylogeny with metabolism, the metabolic capacities of these uncultivated organisms were revealed. In fact, entire metabolic pathways could be reconstructed by examining the genetic blueprints of the microbial community. This background should assist in the design of enrichment culture experiments to cultivate the aquifer bacteria.

One of the goals of microbial ecology is to bring interesting microorganisms into laboratory culture. Meanwhile, it is still possible to probe the properties of uncultivated organisms using metagenomics. Once both the diversity and metabolic profiles of a microbial community are known, it becomes possible to predict how the ecosystem functions and how it might be disrupted by pollution or other perturbations.

¹Wrighton, K.C., et al. 2012. Fermentation, hydrogen, and sulfur metabolism in multiple uncultivated bacterial phyla. *Science* 337: 1661–1665.

- I Phototrophy 380
- II Chemolithotrophy 393
- III Fermentations 401
- IV Anaerobic Respirations 410
- V Hydrocarbon Metabolism 424

A major theme of microbiology is the great *phylogenetic* diversity of microbial life on Earth. We got a taste of this in the last chapter and will explore microbial diversity in detail in the following four chapters. In this chapter we focus on the *metabolic* diversity

of microorganisms, with special emphasis on the processes and mechanisms that underlie this diversity. We will then return to the organisms themselves and unveil the phylogenetic breadth of the microbial world in the context of metabolic diversity.

I • Phototrophy

Phototrophy—the use of light energy—is widespread in the microbial world. In this unit we examine the properties and energy-conserving strategies of phototrophic microorganisms and see how these support a lifestyle based on the use of CO₂ as the sole carbon source.

13.1 Photosynthesis and Chlorophylls

The most important biological process on Earth is **photosynthesis**, the conversion of light energy to chemical energy. Organisms that carry out photosynthesis are called **phototrophs**. Phototrophic organisms are also **autotrophs**, capable of growing with CO₂ as the sole carbon source. Energy from light is used in the reduction of CO₂ to organic compounds (*photoautotrophy*). Some phototrophs can also use organic carbon as their carbon source; this lifestyle is called *photoheterotrophy*.

Photosynthesis requires light-sensitive pigments, the **chlorophylls**, found in plants, algae, and the cyanobacteria, and **bacteriochlorophylls**, in the purple and green bacteria. Cyanobacteria and purple and green bacteria are all prokaryotic phototrophs. Absorption of light energy by chlorophylls and bacteriochlorophylls begins the process of photosynthetic energy conversion, and the net result is chemical energy, ATP.

Photoautotrophy requires that two distinct sets of reactions operate in parallel: (1) ATP production and (2) CO₂ reduction to cell material. For autotrophic growth, energy is supplied from ATP, and electrons for the reduction of CO₂ come from NADH (or NADPH). The latter originates from the reduction of

NAD(P⁺) by electron donors in the environment. In purple and green bacteria the donor could be a reduced sulfur compound such as hydrogen sulfide (H₂S), or molecular hydrogen (H₂). By contrast, green plants, algae, and cyanobacteria derive electrons from water (H₂O).

The oxidation of H₂O produces molecular oxygen (O₂) as a by-product; because of this, the photosynthetic process in cyanobacteria is called **oxygenic photosynthesis**. However, in purple and green bacteria O₂ is *not* produced, and thus the process is called **anoxygenic photosynthesis** (Figure 13.1). Oxygen produced by cyanobacteria billions of years ago converted Earth from an anoxic to an oxic world and set the stage for an explosion of eukaryotic microbial diversity that eventually gave rise to plants and animals.

Chlorophyll and Bacteriochlorophyll

Chlorophyll and **bacteriochlorophyll** are related to tetrapyrroles that are the parent structure of the cytochromes. But unlike cytochromes, chlorophylls contain *magnesium* instead of *iron* at the center of the ring. Chlorophylls also contain specific substituents on the tetrapyrrole ring and a hydrophobic alcohol that helps anchor the chlorophyll into photosynthetic membranes. The structure of chlorophyll *a*, the principal chlorophyll of oxygenic phototrophs, is shown in Figure 13.2a. Chlorophyll *a* is green because it *absorbs* red and blue light and *transmits* green light; its absorption spectrum shows strong absorbance near 680 nm and 430 nm (Figure 13.2b). Several different chlorophylls are known, each distinguished by its unique absorption spectrum. Cyanobacteria contain chlorophyll *a*

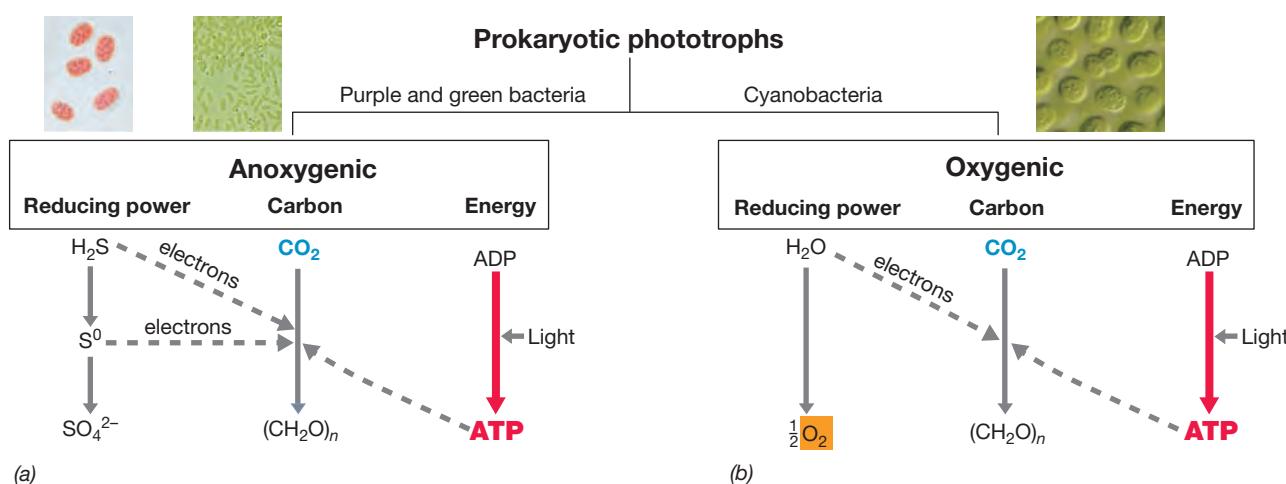

Figure 13.1 Patterns of photosynthesis. Energy and reducing power synthesis in (a) anoxygenic and (b) oxygenic phototrophs. Note that oxygenic phototrophs produce O₂, while anoxygenic phototrophs do not. Insets: Left, light photomicrographs of cells of a purple sulfur bacterium (*Chromatium*, cells 5 µm in diameter) and a green sulfur bacterium (*Chlorobium*, cells 0.9 µm in diameter). Note the sulfur globules inside or outside the cells produced from the oxidation of H₂S. Right, interference-contrast photomicrograph of cells of a coccoid-shaped cyanobacterium.

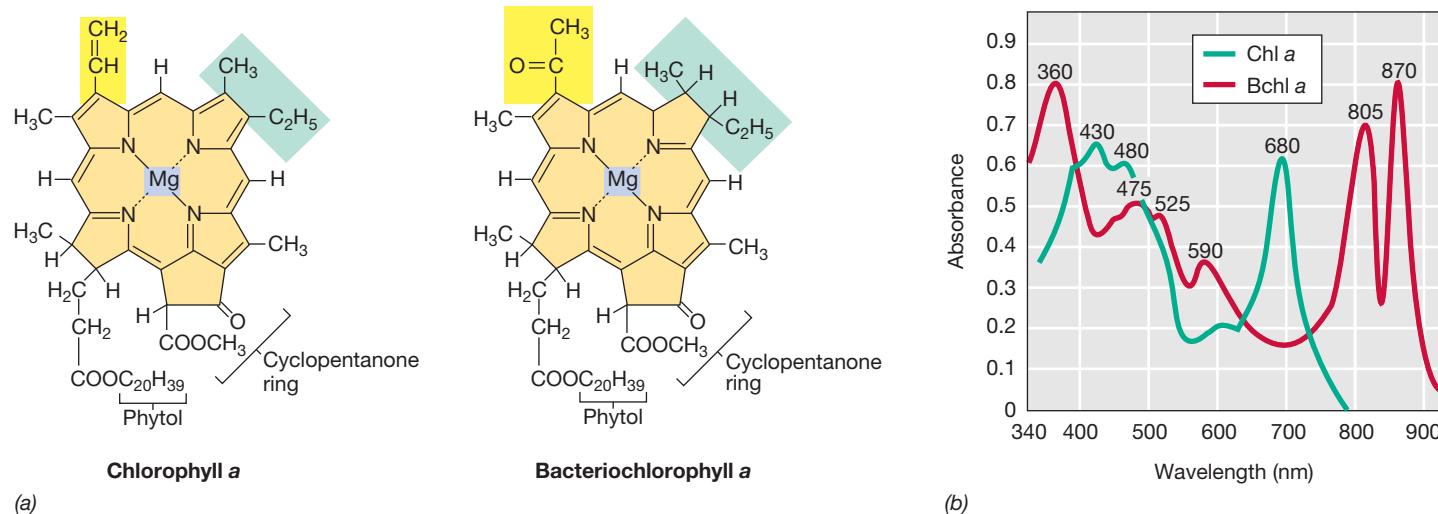

Figure 13.2 Structures and spectra of chlorophyll *a* and bacteriochlorophyll *a*. (a) The two molecules are identical except for those portions contrasted in yellow and green. (b) Absorption spectrum (green curve) of cells of the green alga *Chlamydomonas*. The peaks at 680 and 430 nm are due to chlorophyll *a*, and the peak at 480 nm is due to carotenoids. Absorption spectrum (red curve) of cells of the phototrophic purple bacterium *Rhodopseudomonas palustris*. Peaks at 870, 805, 590, and 360 nm are due to bacteriochlorophyll *a*, and peaks at 525 and 475 nm are due to carotenoids.

(a few species contain chlorophyll *d*), while their relatives the prochlorophytes produce chlorophylls *a* and *b*.

Phototrophic purple and green bacteria produce one or more bacteriochlorophylls (Figure 13.3). Bacteriochlorophyll *a* (Figure 13.2), present in most purple bacteria ([Sections 14.4 and 14.5](#)), absorbs maximally between 800 and 925 nm (different purple bacteria synthesize slightly different photocomplexes, and the absorption maxima of bacteriochlorophyll *a* in any given organism depend to some degree on how proteins in the photocomplexes are arranged in the photosynthetic membrane; see Figure 13.4). Other bacteriochlorophylls, whose distribution runs along phylogenetic lines, absorb in other regions of the visible and infrared spectrum (Figure 13.3).

The existence of different forms of chlorophyll or bacteriochlorophyll that absorb light of different wavelengths allows phototrophs to make better use of the available energy in the electromagnetic spectrum. By employing different pigments with distinct absorption properties, different phototrophs can coexist in the same habitat, each absorbing wavelengths of light that others are not. Thus, pigment diversity has *ecological* significance for the successful coexistence of different phototrophs in the same habitat.

Reaction Centers and Antenna Pigments

In oxygenic phototrophs and in purple anoxygenic phototrophs, chlorophyll/bacteriochlorophyll molecules do not exist freely in the cell but are attached to proteins and housed within membranes to form *photocomplexes* consisting of anywhere from 50 to 300 chlorophyll/bacteriochlorophyll molecules. Only a small number of these pigment molecules, called **reaction centers** (Figure 13.4), participate directly in reactions that lead to ATP synthesis. Reaction center chlorophylls/bacteriochlorophylls are surrounded by larger numbers of light-harvesting chlorophylls/bacteriochlorophylls. These so-called **antenna pigments** (also called *light-harvesting pigments*) function to absorb light and funnel some of the energy to the reaction center (Figure 13.4). At the

low light intensities that are often found in nature, this arrangement for concentrating energy allows reaction centers to receive light energy that would otherwise be missed.

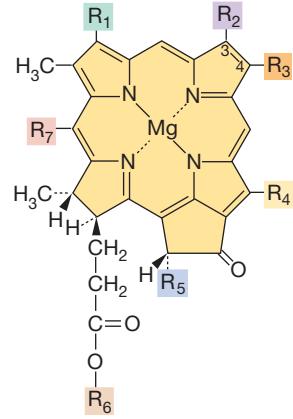

Photosynthetic Membranes, Chloroplasts, and Chlorosomes

The chlorophyll pigments and all the other components of the light-gathering apparatus exist within membranes in the cell. The location of these photosynthetic membranes differs between prokaryotic and eukaryotic microorganisms. In eukaryotic phototrophs, photosynthesis takes place in intracellular organelles, the *chloroplasts*, where the chlorophylls are attached to sheetlike membranes (Figure 13.5). These photosynthetic membrane systems are called **thylakoids**, and stacks of thylakoids form *grana*. The thylakoids are arranged so that the chloroplast is divided into two regions, the matrix space that surrounds the thylakoids, called the *stroma*, and the inner space within the thylakoid array. This arrangement makes possible the generation of a light-driven proton motive force that is used to synthesize ATP (Section 13.4).

Chloroplasts are absent from prokaryotic phototrophs. In purple bacteria, the photosynthetic pigments are integrated into internal membrane systems that arise from invagination of the cytoplasmic membrane. Membrane vesicles called *chromatophores* or membrane stacks called *lamellae* are common membrane arrangements in purple bacteria (Figure 13.6). In cyanobacteria, photosynthetic pigments reside in lamellar membranes (see Figure 13.10) also called *thylakoids* because of their resemblance to the thylakoids in the chloroplasts of algae (Figure 13.5).

The ultimate structure for capturing low light intensities is the **chlorosome** (Figure 13.7). Chlorosomes are present in the anoxygenic green sulfur bacteria (*Chlorobium*, Figure 13.1 and [Section 14.6](#)) and green nonsulfur bacteria (*Chloroflexus*, [Section 14.7](#)). Chlorosomes function as giant antenna systems, but unlike the antennae of purple bacteria or cyanobacteria, bacteriochlorophyll molecules in the chlorosome are not attached to proteins.

Pigment/Absorption maxima (in vivo)	R ₁	R ₂	R ₃	R ₄	R ₅	R ₆	R ₇

Bchl <i>g</i> (heliobacteria)/ 670, 788 nm	$H-C=CH_2$	$-CH_3^a$	$-C_2H_5$	$-CH_3$	$-C-O-CH_3$	F	$-H$

^aNo double bond between C₃ and C₄; additional H atoms are in positions C₃ and C₄.
^bP, Phytyl ester (C₂₀H₃₉O—); F, farnesyl ester (C₁₅H₂₅O—); Gg, geranylgeraniol ester (C₁₀H₁₇O—); S, stearyl alcohol (C₁₈H₃₇O—).

^cNo double bond between C₃ and C₄; an additional H atom is in position C₃.
^dBacteriochlorophylls *c*, *d*, and *e* consist of isomeric mixtures with the different substituents on R₃ as shown.

Figure 13.3 Structure of all known bacteriochlorophylls (Bchl). The different substituents present in the positions R₁ to R₇ in the structure at the right are listed. Absorption properties can be determined by suspending intact cells of a phototroph in a viscous liquid such as 60% sucrose (this reduces light scattering and smooths out spectra) and running absorption spectra as shown in Figure 13.2b. In vivo absorption maxima are the physiologically relevant absorption peaks. The spectrum of bacteriochlorophylls extracted from cells and dissolved in organic solvents is often quite different.

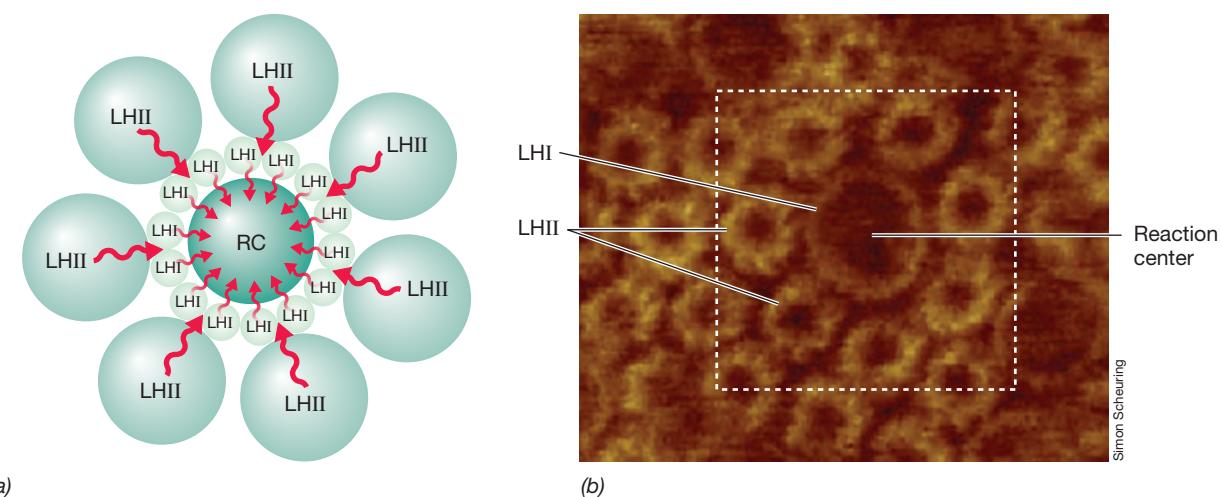

Figure 13.4 Arrangement of light-harvesting chlorophylls/bacteriochlorophylls and reaction centers within a photosynthetic membrane. (a) Light energy absorbed by light-harvesting (LH) molecules (light green) is transferred to the reaction centers (dark green, RC) where photosynthetic electron transport reactions begin. Pigment molecules are secured within the membrane by specific pigment-binding proteins. Compare this figure to Figures 13.11 and 13.12b. (b) Atomic force micrograph of photocentrals of the purple bacterium *Phaeospirillum molischianum*. This organism has two types of light-harvesting complexes, LHI and LHII. LHII complexes transfer energy to LHI complexes, and these transfer energy to the reaction center (see Figure 13.12b).

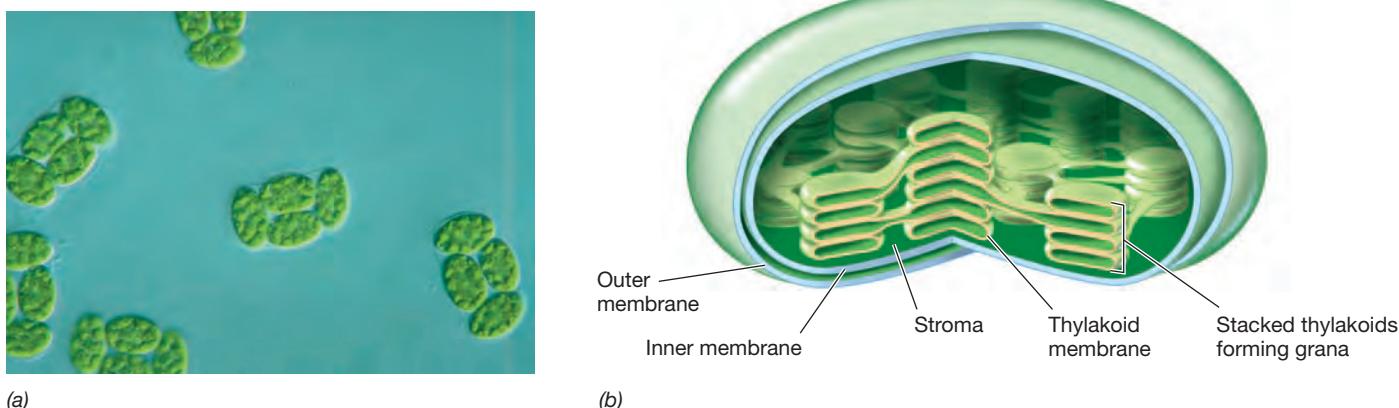

Figure 13.5 The chloroplast. (a) Photomicrograph of cells of the green alga *Makinoella*. Each of the four cells in a cluster contains several chloroplasts. (b) Details of chloroplast structure, showing how the convolutions of the thylakoid membranes define an inner space called the stroma and form membrane stacks called grana.

Chlorosomes contain bacteriochlorophyll *c*, *d*, or *e* (Figure 13.3) arranged in dense arrays running along the long axis of the structure. Light energy absorbed by these antenna pigments is transferred to bacteriochlorophyll *a* in the reaction center in the cytoplasmic membrane through a small protein called the *FMO protein* (Figure 13.7).

Green bacteria can grow at the lowest light intensities of all known phototrophs and are often found in the deepest waters of lakes, inland seas, and other anoxic aquatic habitats where light levels are too low to support other phototrophs. Green nonsulfur bacteria are major components of microbial mats, thick biofilms that form in hot springs and highly saline environments (☞ Section 19.5). Microbial mats experience a steep light gradient, with light levels even a few millimeters into the mat approaching darkness. Hence, chlorosomes allow green nonsulfur bacteria to grow phototrophically with only the minimal light intensities available.

MINIQUIZ

- What is the fundamental difference between an oxygenic and an anoxygenic phototroph?
- What is the difference between the relative numbers of antenna and reaction center chlorophyll/bacteriochlorophyll molecules in a photosynthetic complex, and why?
- Why can phototrophic green bacteria grow at light intensities that will not support purple bacteria?

13.2 Carotenoids and Phycobilins

Although chlorophyll/bacteriochlorophyll is required for photosynthesis, phototrophic organisms contain other pigments as well. These pigments include, in particular, the *carotenoids* and *phycobilins*.

Carotenoids

The most widespread accessory pigments in phototrophs are the **carotenoids**. Carotenoids are hydrophobic pigments that are firmly embedded in the photosynthetic membrane. Figure 13.8 shows the structure of a common carotenoid, β -carotene. Carotenoids are typically yellow, red, brown, or green and absorb light in the blue region of the spectrum (Figure 13.2).

The major carotenoids of anoxygenic phototrophs are shown in Figure 13.9. Because they tend to mask the color of bacteriochlorophylls, carotenoids are responsible for the brilliant colors of red, purple, pink, green, yellow, or brown that are observed in different species of anoxygenic phototrophs (☞ Figure 14.12).

Carotenoids are closely associated with chlorophyll or bacteriochlorophyll in photosynthetic complexes, and some of the energy absorbed by carotenoids can be transferred to the reaction center. However, carotenoids function primarily as photoprotective agents. Bright light can be harmful to cells because it can catalyze photooxidation reactions that can produce toxic forms of oxygen, such as singlet oxygen (${}^1\text{O}_2$). Like superoxide and other forms of toxic oxygen (☞ Section 5.16), singlet oxygen can spontaneously oxidize photocomplexes, rendering them nonfunctional. Carotenoids quench toxic oxygen species by absorbing much of this harmful light and in this way prevent these dangerous photooxidations. Because phototrophic organisms by their very nature must live in the light, the photoprotection conferred by carotenoids is clearly advantageous.

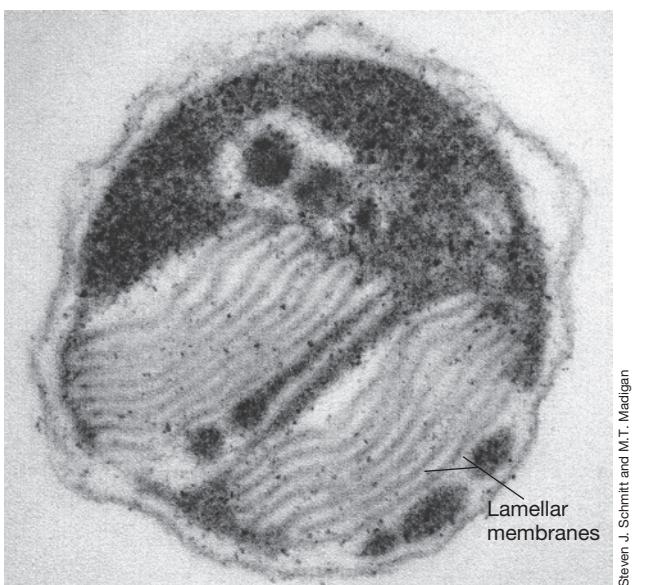

Phycobiliproteins and Phycobilisomes

Cyanobacteria and the chloroplasts of red algae (which are descendants of cyanobacteria, ☞ Section 17.1) contain pigments called **phycobiliproteins**, which are the main light-harvesting systems of these phototrophs. Phycobiliproteins consist of red or blue-green linear tetrapyrroles, called *bilins*, bound to proteins, and give cyanobacteria and red algae their characteristic colors (Figure 13.10). The red phycobiliprotein, called *phycoerythrin*, absorbs most strongly at wavelengths around 550 nm, whereas the blue phycobiliprotein, *phycocyanin* (Figure 13.10b), absorbs most strongly at 620 nm. A third phycobiliprotein, called *allophycocyanin*, absorbs at about 650 nm.

Phycobiliproteins assemble into aggregates called **phycobilisomes** that attach to cyanobacterial thylakoids (Figure 13.10c). Phycobilisomes are arranged such that the allophycocyanin molecules are in direct contact with the photosynthetic membrane. Allophycocyanin is surrounded by phycocyanin or phycoerythrin (or both, depending on the organism). Phycocyanin and phycoerythrin absorb light of shorter wavelengths (higher energy) and transfer some energy to allophycocyanin, which is positioned

Figure 13.6 Membranes in anoxygenic phototrophs. (a) Chromatophores. Section through a cell of the purple bacterium *Rhodobacter* showing vesicular photosynthetic membranes. The vesicles are continuous with and arise by invagination of the cytoplasmic membrane. A cell is about 1 μm wide. (b) Lamellar membranes in the purple bacterium *Ectothiorhodospira*. A cell is about 1.5 μm wide. These membranes are also continuous with and arise from invagination of the cytoplasmic membrane, but instead of forming vesicles, they form membrane stacks.

closest to the reaction center chlorophyll and transfers energy to it (Figure 13.10b). Thus, in a fashion similar to how antenna bacteriochlorophyll systems function in anoxygenic phototrophs (Figure 13.4), energy transfer proceeds “downhill” from phycobilisomes to the reaction center. Phycobilisomes facilitate energy transfer to cyanobacterial reaction centers, allowing cyanobacteria to grow at lower light intensities than would otherwise be possible.

- Phycocyanin is blue-green. What color of light does it absorb?

13.3 Anoxygenic Photosynthesis

In the photosynthetic light reactions, electrons traverse an electron transport chain arranged in a photosynthetic membrane in order of their increasingly more electropositive reduction potential (E'_0). This generates a proton motive force that drives ATP synthesis. Key parts of this process include photosynthetic reaction centers and photosynthetic membranes (Section 13.1).

Reaction centers of purple bacteria contain three polypeptides, designated L, M, and H. These proteins, along with a molecule of cytochrome *c*, are firmly embedded in the photosynthetic membrane (Figure 13.6) and wind through the membrane several times (Figure 13.11). The L, M, and H polypeptides bind two molecules of bacteriochlorophyll *a*, called the *special pair*, two additional bacteriochlorophyll *a* molecules that function in photosynthetic electron flow, two molecules of bacteriopheophytin (bacteriochlorophyll *a* minus its magnesium atom), two molecules of quinone (► Section 3.10), and one carotenoid (Figure 13.11). All reaction center components are integrated in such a way that they can interact in very fast electron transfer reactions in the early stages of photosynthetic energy conversion.

Electron Flow in Purple Bacteria

Photosynthetic light reactions begin when light energy absorbed by the antenna systems is transferred to the special pair of bacteriochlorophyll *a* molecules (Figure 13.11*a*). This excites the special pair, converting it from a relatively weak to a very strong electron donor (very electronegative E'_0 , ► Section 3.6). Once this strong donor has been produced, the remaining steps in photosynthetic electron flow are strongly reminiscent of those we have seen before in respiration (► Section 3.10 and Figure 3.20); that is, electrons flowing through a membrane from carriers of low E'_0 to those of high E'_0 , generating a proton motive force in the process (Figure 13.12).

Before excitation, the purple bacterial reaction center, which is called P870, has an E'_0 of about +0.5 V; after excitation, it has a potential of about −1.0 V (Figure 13.12*a*). An excited electron within P870 proceeds to reduce a molecule of bacteriochlorophyll *a* within the reaction center (Figures 13.11*a* and 13.12*a*). This transition takes place incredibly fast, taking only about three-trillionths (3×10^{-12}) of a second. Once reduced, bacteriochlorophyll *a* reduces bacteriopheophytin *a* and the latter reduces quinone molecules within the membrane. These transitions are also very fast, taking less than one-billionth of a second (Figure 13.12). From the quinone, electrons are transported more slowly (on a millisecond scale) through a series of iron–sulfur proteins and cytochromes (Figure 13.12), eventually returning to the reaction center.

Figure 13.12*b* shows electron flow within the actual context of the photosynthetic membrane. Key electron transport proteins include many that also participate in respiratory electron flow (► Figure 3.20)—cytochrome *bc*₁ and cytochrome *c*₂, in particular (Figure 13.12). Cytochrome *c*₂ is a periplasmic cytochrome (recall that the periplasm is the region between the cytoplasmic membrane and the outer membrane in gram-negative bacteria,

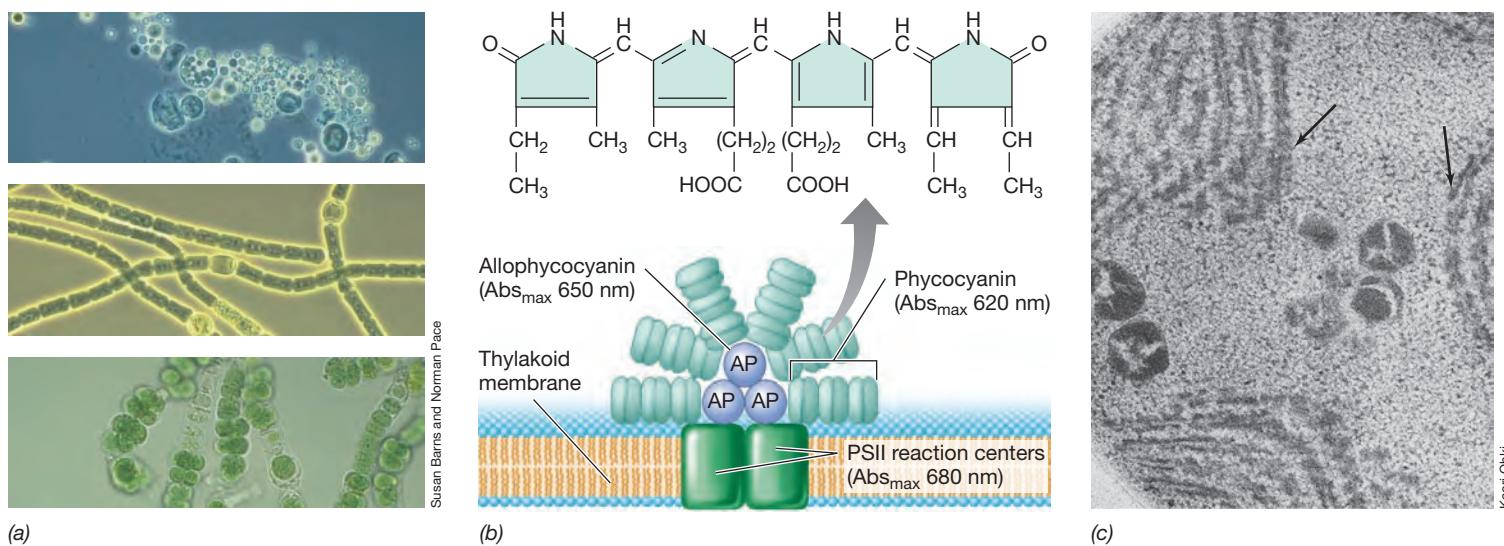

Figure 13.10 Phycobiliproteins and phycobilisomes. (a) Light photomicrographs of cells of the cyanobacteria (top to bottom) *Dermocarpa*, *Anabaena*, and *Fischerella*, showing the typical blue-green color of cells due to phycobiliproteins. (b) Structure of phycocyanin (top) and a phycobilisome. Phycocyanin absorbs at higher energies (shorter wavelengths) than allophycocyanin. Chlorophyll *a* absorbs at longer wavelengths (lower energies) than allophycocyanin. Energy flow is thus phycocyanin → allophycocyanin → chlorophyll *a* of PSII. (c) Electron micrograph of a thin section of the cyanobacterium *Synechocystis*. Note the darkly staining ball-like phycobilisomes (arrows) attached to the lamellar membranes.

Section 2.11) that functions as an electron shuttle between the membrane-bound *bc*₁ complex and the reaction center (Figure 13.12b). Electron flow is completed when cytochrome *c*₂ donates an electron to the special pair to return it to its original ground-state reduction potential. The reaction center can then absorb new light energy and repeat the process.

ATP is synthesized during photosynthetic electron flow from the activity of ATPase that couples the proton motive force to ATP synthesis (Section 3.11). This mechanism of ATP synthesis is called **photophosphorylation**, specifically *cyclic photophosphorylation*, because electrons move within a closed loop. Unlike respiration, where there is a net consumption of electrons,

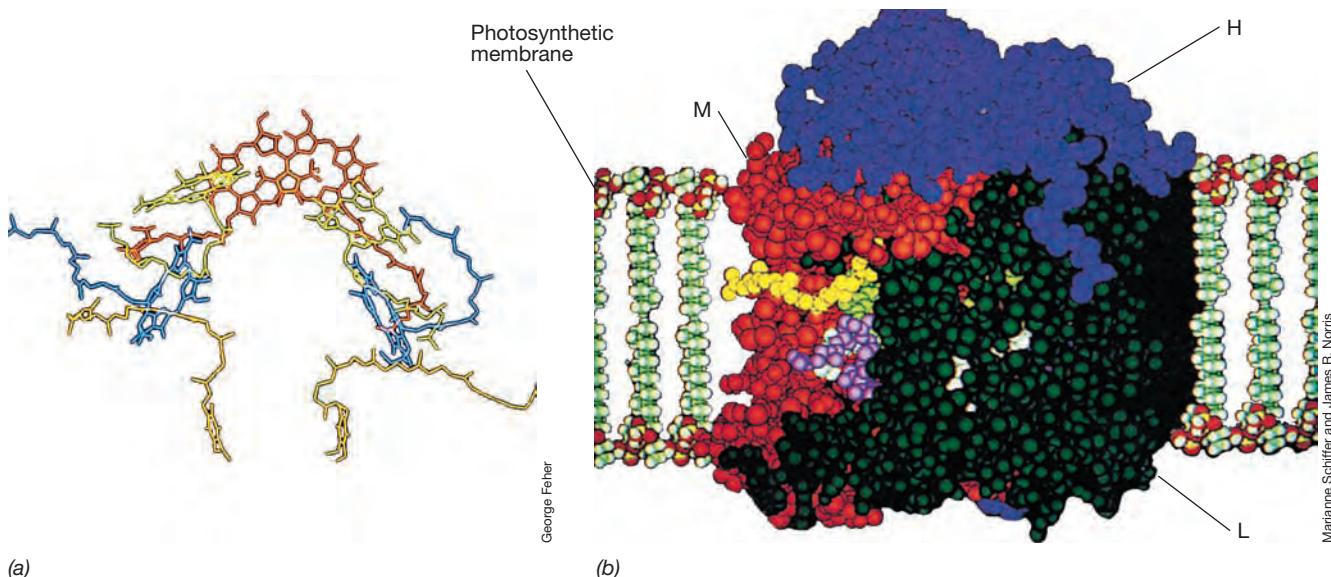

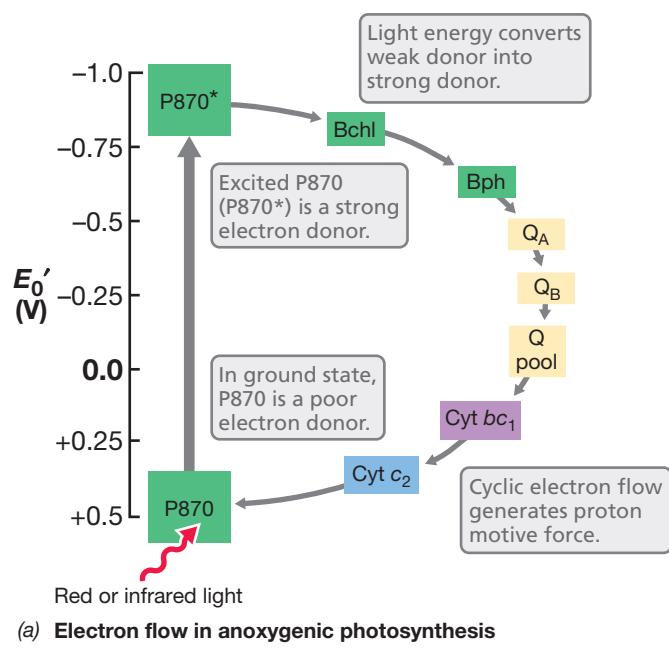

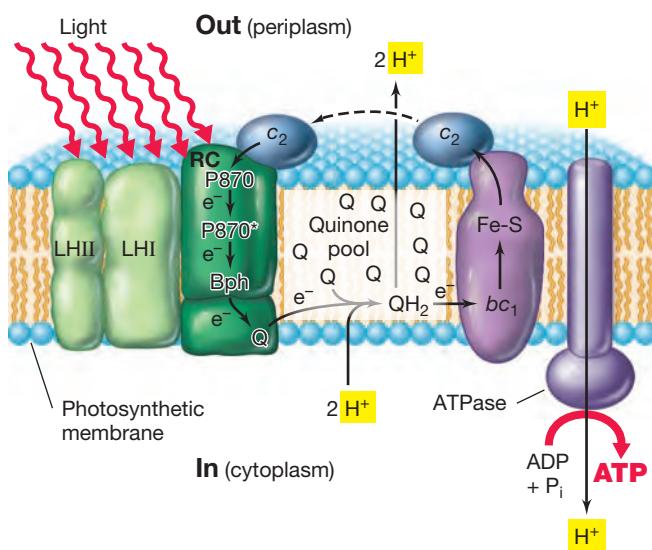

Figure 13.11 Structure of the reaction center of a purple phototrophic bacterium. (a) Arrangement of pigment molecules in the reaction center. The “special pair” of bacteriochlorophyll molecules overlap and are shown in orange at the top; quinones are in dark yellow and are at the bottom of the figure. The accessory bacteriochlorophylls are in lighter yellow near the special pair, and the bacteriopheophytin molecules are shown in blue. (b) Molecular model of the protein structure of the reaction center. The pigments described in part a are bound to membranes by protein H (blue), protein M (red), and protein L (green). The reaction center pigment–protein complex is integrated into the lipid bilayer.

For a description of ATPase function, see Section 3.11.

in cyclic photophosphorylation there is no net input or consumption of electrons; electrons simply travel a circuitous route, returning from whence they came (Figure 13.12).

Generation of Reducing Power

For a purple bacterium to grow as a photoautotroph (Section 13.1), the formation of ATP is not enough. Reducing power (NADH) is also necessary to reduce CO₂ to cell material. Reducing power for purple bacteria can come from many sources, in particular reduced sulfur compounds such as H₂S. When H₂S is the electron donor in purple sulfur bacteria, globules of S⁰ are stored inside the cells (Figure 13.1). When S⁰ is formed, electrons end up in the “quinone pool” (Figure 13.12). However, the E_0' of quinone (about 0 V) is insufficiently electronegative to reduce NAD⁺ (−0.32 V). Hence, electrons from the quinone pool must be forced backwards (against the electrochemical gradient) to reduce NAD⁺ to NADH (see Figure 13.13). This energy-requiring process, called **reverse electron transport**, is driven by the energy of the proton motive force. We will see later that reverse electron flow is also the mechanism by which chemolithotrophs obtain reducing power for CO₂ fixation; in many of these cases, the electrons come from electron donors of quite positive E_0' (Sections 13.6–13.10).

Photosynthetic Electron Flow in Other Anoxygenic Phototrophs

Thus far we have focused on electron flow in purple bacteria. Although analogous membrane-associated reactions drive

photophosphorylation in other anoxygenic phototrophs, there are significant differences in the details. The reaction centers of green nonsulfur bacteria and purple bacteria are structurally quite similar but differ from the reaction centers of green sulfur bacteria and heliobacteria, and this is reflected in differences in cyclic electron flow.

Figure 13.13 contrasts photosynthetic electron flow in purple and green bacteria and the heliobacteria. Note that in green sulfur bacteria and heliobacteria the excited state of the reaction center bacteriochlorophylls is significantly more electronegative than in purple bacteria and that actual chlorophyll *a* (green bacteria) or a structurally modified form of chlorophyll *a* (hydroxychlorophyll *a*) (heliobacteria) is present in the reaction center. Thus, unlike in purple bacteria, where the first stable acceptor molecule (quinone) has an E_0' of about 0 V (Figure 13.12a), the acceptors in green bacteria and heliobacteria are iron–sulfur proteins that have a much more electronegative E_0' than does NADH. Hence, reverse electron flow is unnecessary in green sulfur bacteria or heliobacteria. In green sulfur bacteria a protein called *ferredoxin* ($E_0' = -0.4V$) is the direct electron donor for CO₂ fixation (Section 13.5). When H₂S is the source of reducing power in green sulfur or purple sulfur bacteria, globules of S⁰ are produced from the oxidation of H₂S. In green bacteria the globules remain outside the cell but in purple sulfur bacteria they remain inside the cells (Figure 13.1). In both cases the S⁰ eventually disappears as it is oxidized to sulfate (SO₄²⁻) to generate additional reducing power for CO₂ fixation.

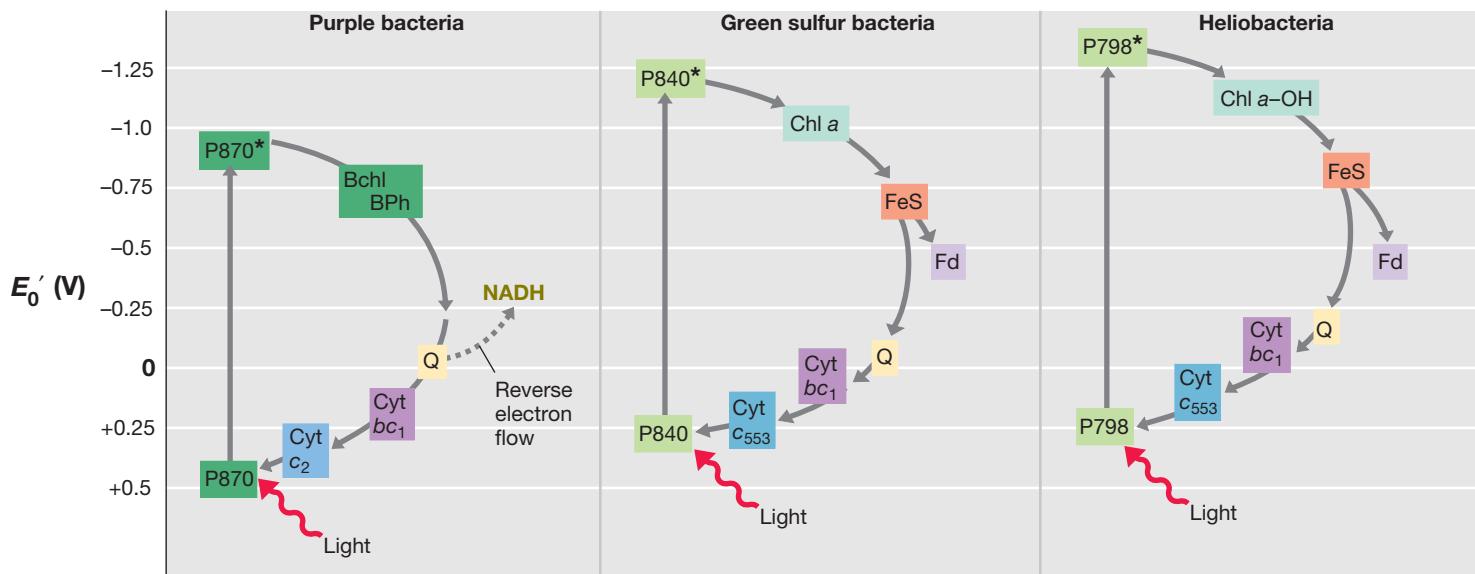

Figure 13.13 A comparison of electron flow in purple bacteria, green sulfur bacteria, and heliobacteria. Reverse electron flow in purple bacteria is necessary to produce NADH because the primary acceptor (quinone, Q) is more positive in potential than the NAD^+/NADH couple. In green and heliobacteria, ferredoxin (Fd), whose E_0' is more negative than that of NADH, is produced by light-driven reactions for reducing power needs. Bchl, bacteriochlorophyll; BPh, bacteriopheophytin. P870 and P840 are reaction centers of purple and green bacteria, respectively, and consist of Bchl a. The reaction center of heliobacteria (P798) contains Bchl g, and the reaction center of *Chloroflexus* is of the purple bacterial type. Note that forms of chlorophyll a are present in the reaction centers of green bacteria and heliobacteria.

MINIQUIZ

- What parallels exist in the processes of photophosphorylation and oxidative phosphorylation?
- What is reverse electron flow and why is it necessary? Which phototrophs need to use reverse electron flow?
- Chlorophyll a is not limited to oxygenic phototrophs. Explain.

13.4 Oxygenic Photosynthesis

In contrast to photosynthetic electron flow in *anoxygenic* phototrophs, in *oxygenic* phototrophs electrons flow through two distinct photosystems called *photosystem I* (PSI, or P700) and *photosystem II* (PSII, or P680). As in *anoxygenic* photosynthesis, the light reactions in oxygenic photosynthesis occur in photocomplexes embedded in membranes. In eukaryotic cells, the membranes are in the chloroplast (Figure 13.5), whereas in cyanobacteria, the membranes are arranged in stacks within the cytoplasm (Figure 13.10c).

Electron Flow and ATP Synthesis in Oxygenic Photosynthesis

PSI and PSII interact as shown in Figure 13.14 in the “Z scheme” of photosynthesis, so named because the pathway resembles the letter “Z” turned on its side. The reduction potential of the P680 chlorophyll a molecule in PSII is very electropositive, even more positive than that of the $\text{O}_2/\text{H}_2\text{O}$ couple. This is necessary to allow for the first step in electron flow, the splitting of water into oxygen and electrons (Figure 13.14). Light energy converts P680 into a strong reductant that reduces pheophytin a (chlorophyll a minus its magnesium atom), a molecule with an E_0' of about -0.5 V . An electron from H_2O is then donated to the oxidized

P680 molecule to return it to its ground-state reduction potential. From the pheophytin the electron travels through several membrane carriers of increasingly more positive E_0' including quinones, cytochromes, and a copper-containing protein called *plastocyanin*; the latter donates the electron to the PSI reaction center. The electron is accepted by P700 of PSI, which has previously absorbed light energy and donated an electron that will eventually lead to the reduction of NADP^+ . Electrons travel through several intermediates in PSI terminating with the reduction of NADP^+ to NADPH (Figure 13.14).

Besides the net synthesis of NADPH, other important events take place while electrons flow from PSII to PSI. Electron transport reactions generate a proton motive force from which ATP is produced by ATPase. This mechanism for ATP synthesis is called *noncyclic photophosphorylation* because electrons do not cycle back to reduce the oxidized P680, but instead are used in the reduction of NADP^+ . However, when reducing power is plentiful, ATP can also be produced in oxygenic phototrophs by *cyclic photophosphorylation*. This occurs when, instead of reducing NADP^+ , electrons from PSI that would normally reduce ferredoxin are returned to travel the electron transport chain that connects PSII to PSI. In so doing, these electrons also generate a proton motive force that supports additional ATP synthesis (dashed line in Figure 13.14).

Anoxygenic Photosynthesis in Oxygenic Phototrophs

Photosystems I and II normally function in tandem in oxygenic photosynthesis. However, if PSII activity is blocked, some oxygenic phototrophs can perform photosynthesis using only PSI. Under these conditions, cyclic but not noncyclic photophosphorylation (Figure 13.14) occurs, and reducing power for CO_2 reduction

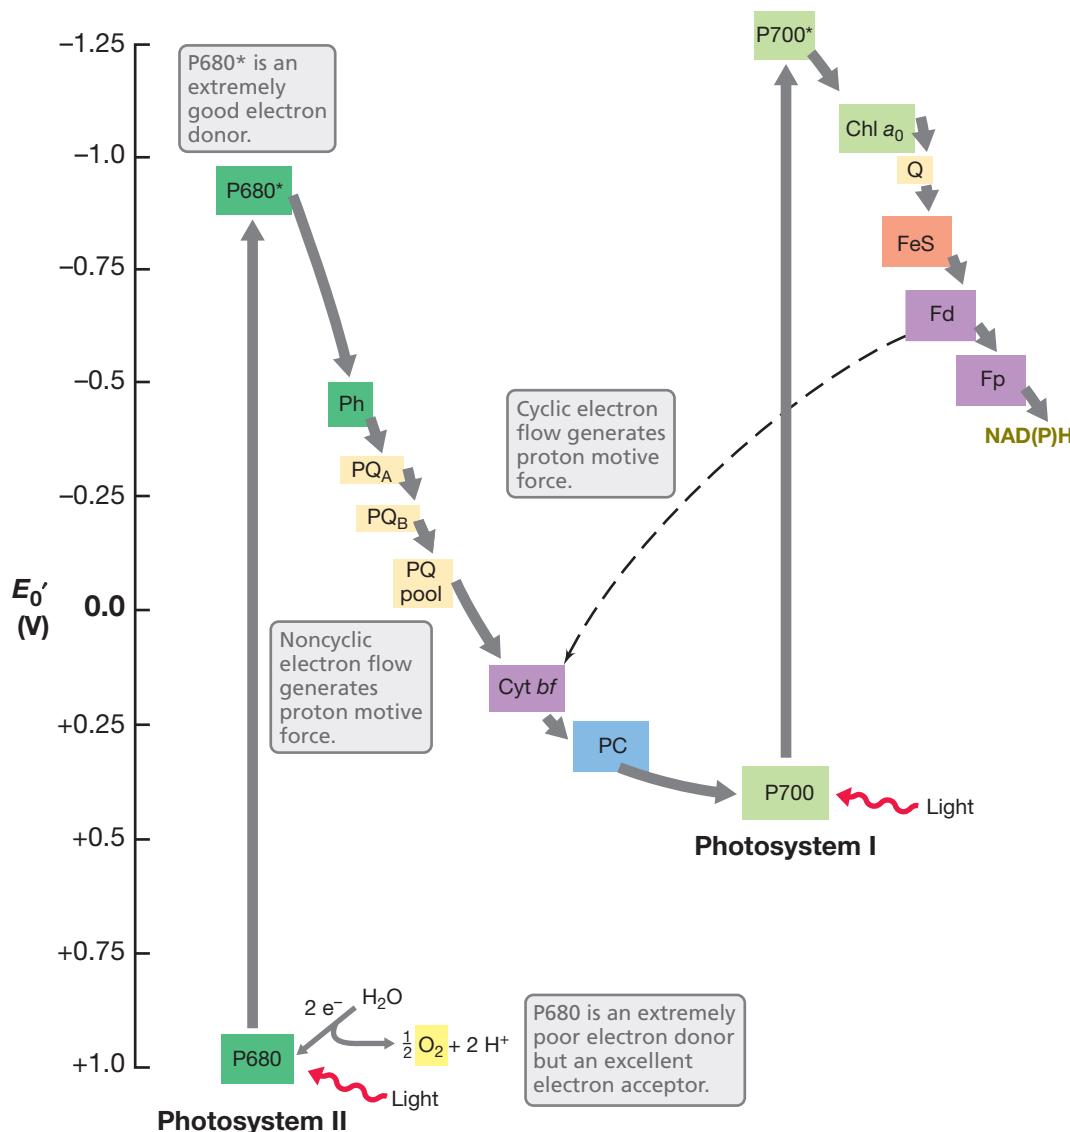

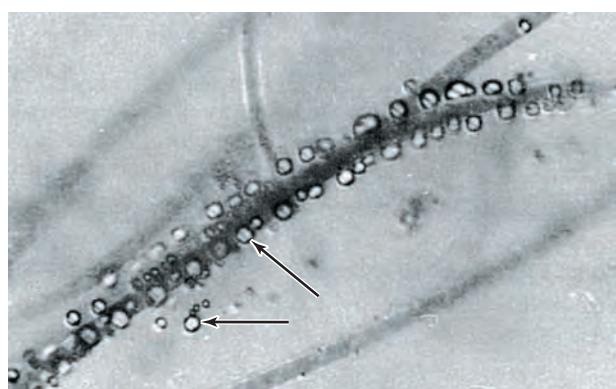

Figure 13.14 Electron flow in oxygenic photosynthesis, the “Z” scheme. Electrons flow through two photosystems, PSI and PSII. Ph, pheophytin; Q, quinone; Chl, chlorophyll; Cyt, cytochrome; PC, plastocyanin; FeS, nonheme iron–sulfur protein; Fd, ferredoxin; Fp, flavoprotein; P680 and P700 are the reaction center chlorophylls of PSII and PSI, respectively. Compare with Figure 13.12.

comes from sources other than water. In a nutshell, this is anoxygenic photosynthesis occurring in oxygenic phototrophs.

Many cyanobacteria can use H_2S as an electron donor under these conditions and many green algae can use H_2 . When H_2S is used, it is oxidized to elemental sulfur (S^0), and sulfur granules similar to those produced by green sulfur bacteria (Figure 13.1) are deposited outside the cyanobacterial cells. **Figure 13.15** shows this in the filamentous cyanobacterium *Oscillatoria limnetica*. This organism lives in anoxic salt ponds where it oxidizes sulfide and carries out anoxygenic photosynthesis along with green and purple bacteria.

From an evolutionary standpoint, the process of cyclic photophosphorylation in both oxygenic and anoxygenic phototrophs is one of many indications of their close relationship. Further evidence of evolutionary relationships among phototrophs can be found in the fact that the structure of the purple bacterial and green nonsulfur photosynthetic reaction center resembles that of PSII, whereas the structure of the reaction centers of green

Yehuda Cohen and Moshe Shilo

Figure 13.15 Oxidation of H_2S by *Oscillatoria limnetica*. Note the globules of S^0 (arrows), the oxidation product of H_2S , formed outside the cells. *O. limnetica* carries out oxygenic photosynthesis, but in the presence of H_2S , cells revert to the anoxygenic process.

sulfur bacteria and heliobacteria resembles that of PSI. Because the evidence is strong that purple and green bacteria preceded cyanobacteria on Earth by perhaps as many as 0.5 billion years (➡ Section 12.2), it is clear that anoxygenic photosynthesis was the first form of photosynthesis on Earth. The key evolutionary inventions of cyanobacteria were to connect the two forms of reaction centers (as PSI and PSII) and evolve the ability to use H_2O as a photosynthetic electron donor.

MINIQUIZ

- Differentiate between cyclic and noncyclic electron flow in oxygenic photosynthesis.
- What is the key role of light energy in the initial step of the photosynthetic light reactions?
- What evidence is there that anoxygenic and oxygenic photosynthesis are related processes?

13.5 Autotrophic Pathways

Autotrophy is the process by which an energy-poor and highly oxidized form of carbon— CO_2 —is reduced and assimilated into cell material. Many microorganisms are autotrophic, including

virtually all phototrophs and chemolithotrophs. We focus here on autotrophy in phototrophs, where the greatest metabolic diversity is on display.

The Calvin Cycle

Several autotrophic pathways are known, but the **Calvin cycle** is the most widely distributed in nature. The Calvin cycle is present in purple bacteria, cyanobacteria, algae, green plants, most chemolithotrophic *Bacteria*, and a few *Archaea*. The cycle requires CO_2 , a CO_2 -acceptor molecule, $NAD(P)H$, ATP, and two key enzymes, *ribulose bisphosphate carboxylase* and *phosphoribulokinase*.

The first step in the Calvin cycle is catalyzed by the enzyme ribulose bisphosphate carboxylase, **RubisCO** for short. RubisCO catalyzes the formation of two molecules of 3-phosphoglyceric acid (PGA) from ribulose bisphosphate and CO_2 as shown in **Figure 13.16**. The PGA is then phosphorylated and reduced to a key intermediate of glycolysis, glyceraldehyde 3-phosphate. From this, glucose can be formed by reversal of the early steps in glycolysis (➡ Figure 3.14).

Instead of focusing on the incorporation of a single molecule of CO_2 , it is easiest to consider Calvin cycle reactions based on the incorporation of 6 molecules of CO_2 , as this is what is required to make one hexose ($C_6H_{12}O_6$). For RubisCO to incorporate

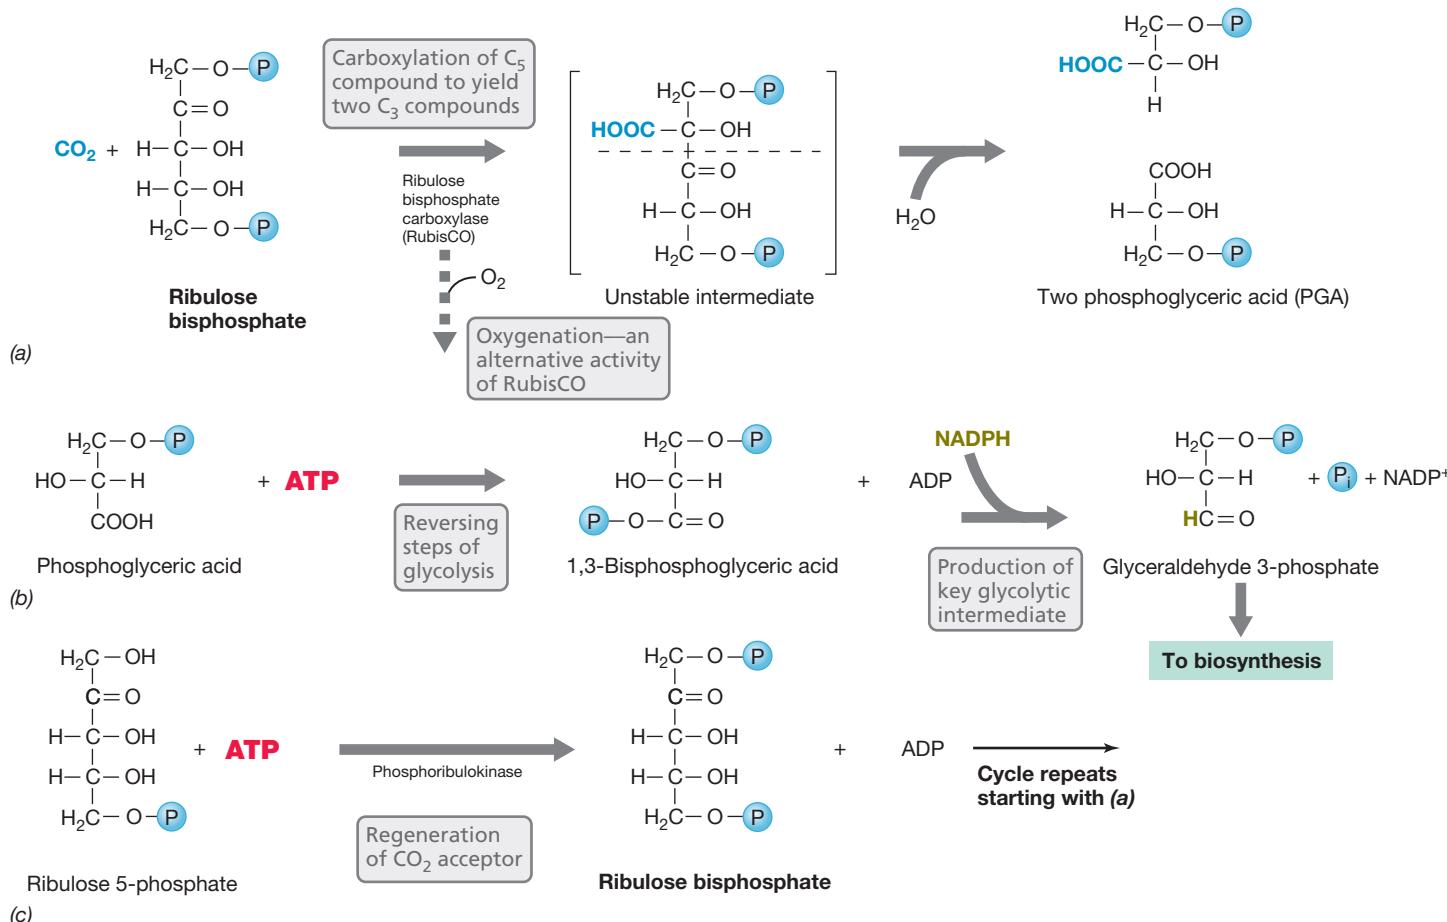

Figure 13.16 Key reactions of the Calvin cycle. (a) Reaction of the enzyme ribulose bisphosphate carboxylase. (b) Steps in the conversion of 3-phosphoglyceric acid (PGA) to glyceraldehyde 3-phosphate. Note that both ATP and NADPH are required. (c) Conversion of ribulose 5-phosphate to the CO_2 acceptor molecule ribulose 1,5-bisphosphate by the enzyme phosphoribulokinase.

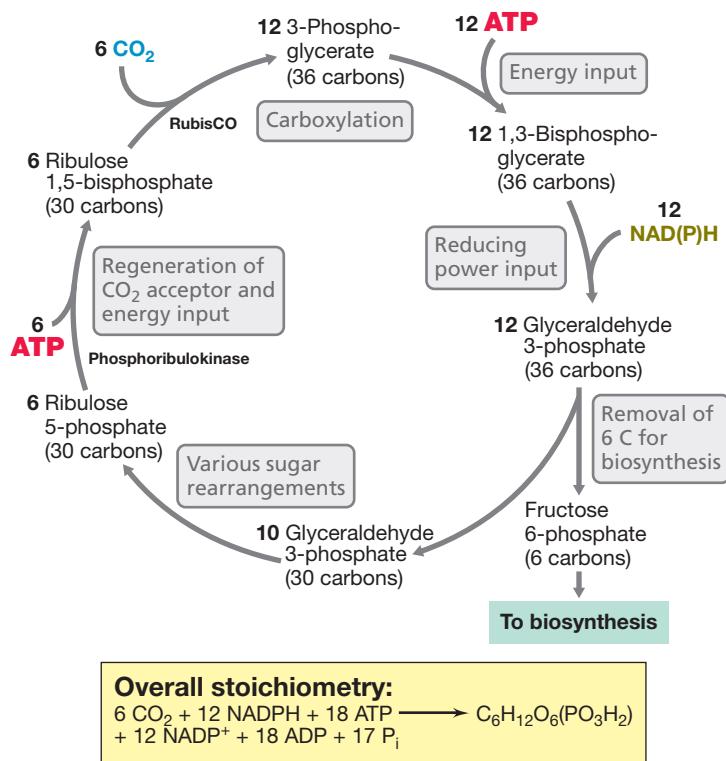

Figure 13.17 The Calvin cycle. Shown is the production of one hexose molecule from CO_2 . For each six molecules of CO_2 incorporated, one fructose 6-phosphate is produced. In phototrophs, ATP comes from photophosphorylation and NAD(P)H from light or reverse electron flow.

6 molecules of CO_2 , 6 molecules of ribulose bisphosphate (total, 30 carbons) are required; carboxylation of these yields 12 molecules of PGA (total, 36 carbon atoms) (Figure 13.17). These then form the carbon skeletons for the eventual synthesis of 6 molecules of ribulose bisphosphate (total, 30 carbons) plus one hexose (6 carbons) for cell biosynthesis. A series of biochemical rearrangements between various sugars follow, resulting in 6 molecules of ribulose 5-phosphate (30 carbons). The final step in the Calvin cycle is the phosphorylation of each of these by the enzyme phosphoribulokinase (Figures 13.16b and 13.17) to regenerate 6 molecules of the acceptor molecule, ribulose bisphosphate. All totaled, 12 NADPH and 18 ATP are required to synthesize one glucose from 6 CO_2 by the Calvin cycle.

Carboxysomes

Several Calvin cycle autotrophs produce polyhedral cell inclusions called **carboxysomes**. These inclusions, about 100 nm in diameter, are surrounded by a thin, protein membrane and consist of a crystalline array of RubisCO (Figure 13.18), with about 250 RubisCO molecules present per carboxysome.

Carboxysomes are a mechanism for concentrating CO_2 in the cell and making it readily available to RubisCO. Inorganic carbon incorporated into the cell as bicarbonate (HCO_3^-) enters the carboxysome as CO_2 through the activity of a second carboxysome enzyme, *carbonic anhydrase*. CO_2 (rather than HCO_3^-) is the actual substrate for RubisCO, and once inside the carboxysome, the CO_2 is trapped and ready for incorporation in the

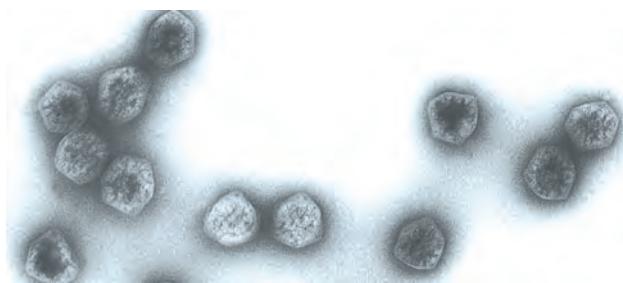

Figure 13.18 Crystalline Calvin cycle enzymes: Carboxysomes. Electron micrograph of carboxysomes purified from the chemolithotrophic sulfur oxidizer *Halothiobacillus neapolitanus*. The structures are about 100 nm in diameter. Carboxysomes are present in a wide variety of obligately autotrophic aerobic prokaryotes.

first step of the Calvin cycle. The carboxysome also functions to restrict access of RubisCO to O_2 , an alternative substrate for this enzyme, and this ensures that RubisCO carboxylates rather than oxygenates ribulose bisphosphate (Figure 13.16a). If ribulose 1,5-bisphosphate is oxygenated, more energy and reducing power are required to incorporate it into central metabolic pathways than if it is carboxylated.

Autotrophy in Green Bacteria

Although they are autotrophs, the Calvin cycle does not operate in green sulfur and green nonsulfur bacteria. Instead, two novel autotrophic pathways are present, one in each group. Green sulfur bacteria such as *Chlorobium* (Figure 13.1) fix CO_2 by a reversal of steps in the citric acid cycle, a pathway called the **reverse citric acid cycle** (Figure 13.19a). This pathway requires the activity of two ferredoxin-linked enzymes that catalyze the reductive fixation of CO_2 ; ferredoxin is produced in the light reactions of green sulfur bacteria (Figure 13.13).

Ferredoxin is an electron donor with a very electronegative E'_0 , about -0.4 V. The two ferredoxin-linked reactions catalyze (1) the carboxylation of succinyl-CoA to α -ketoglutarate, and (2) the carboxylation of acetyl-CoA to pyruvate (Figure 13.19a). Most of the remaining reactions of the reverse citric acid cycle are catalyzed by enzymes working in reverse of the normal oxidative direction of the cycle. One exception is *citrate lyase*, an ATP-dependent enzyme that cleaves citrate into acetyl-CoA and oxaloacetate (Figure 13.19a). In the oxidative direction of the cycle, citrate is produced by the enzyme *citrate synthase* (► Figure 3.22).

The reverse citric acid cycle operates in certain nonphotosynthetic autotrophs as well. For example, the hyperthermophilic *Thermoproteus* and *Sulfolobus* (Archaea; ► Section 16.10) and *Aquifex* (Bacteria; ► Section 15.19) use the reverse citric acid cycle, as do certain sulfur chemolithotrophic bacteria, such as *Thiomicrospira*. Thus, this pathway, originally discovered in green sulfur bacteria and thought to be unique to these phototrophs, is likely distributed among several groups of autotrophic prokaryotes.

Autotrophy in *Chloroflexus*

The green nonsulfur phototroph *Chloroflexus* (► Section 14.7) grows autotrophically with either H_2 or H_2S as electron donor.

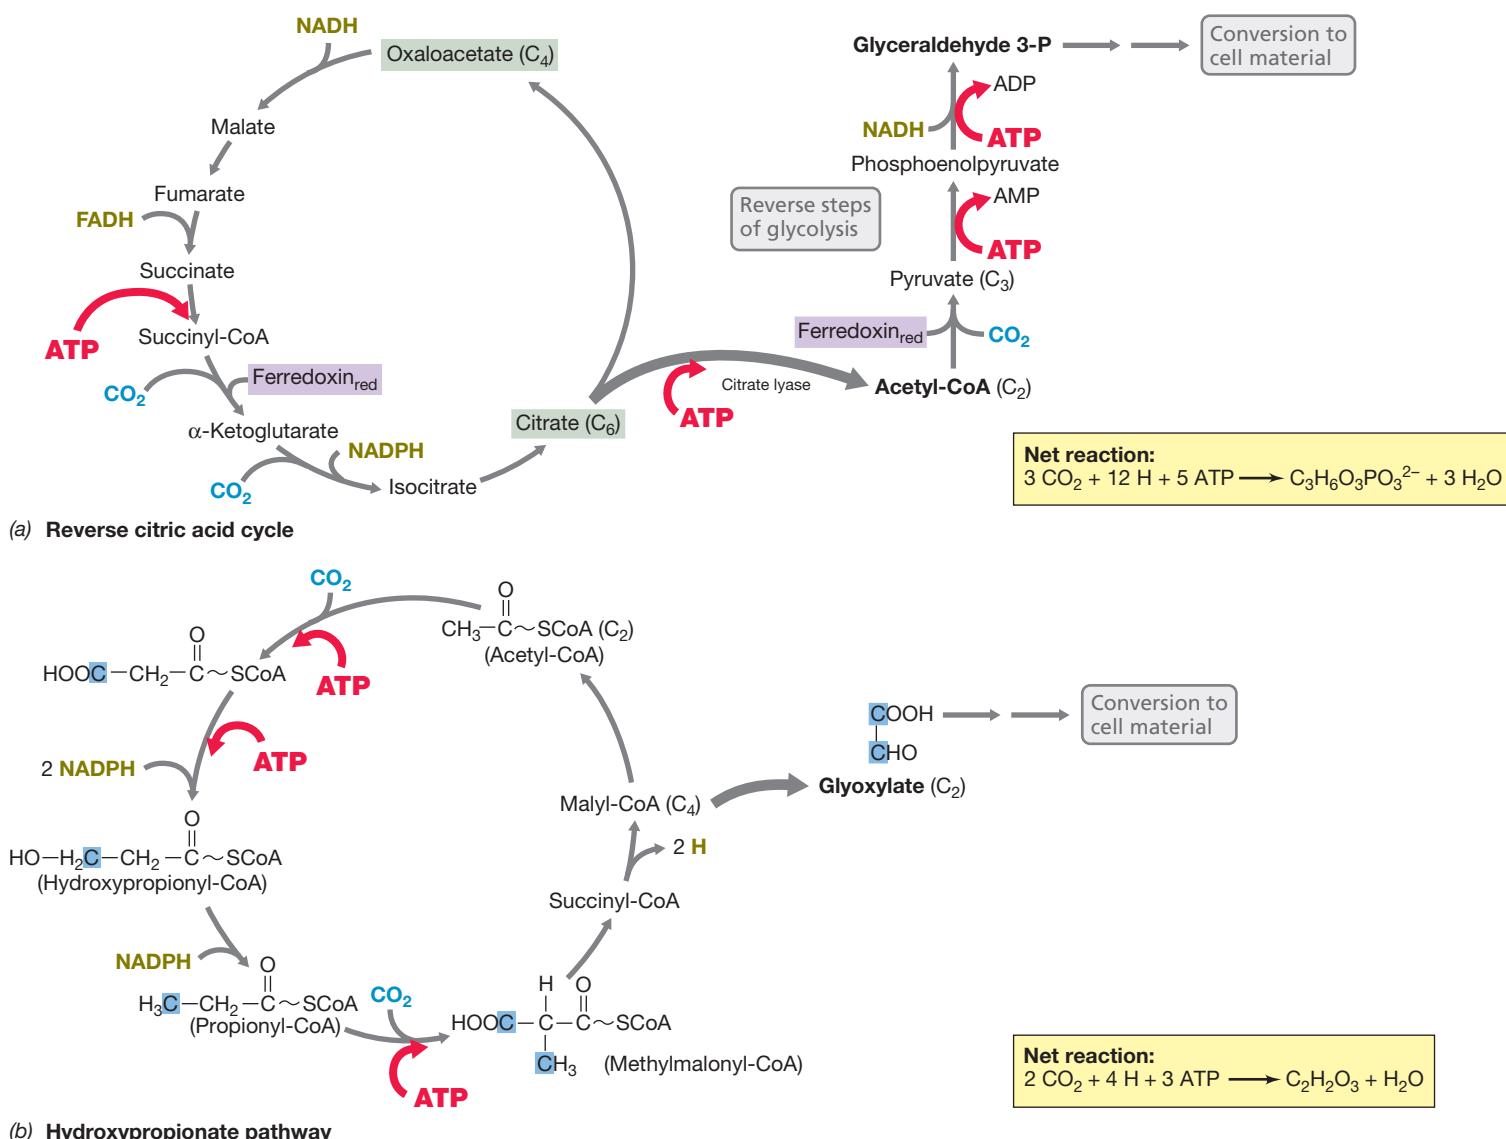

Figure 13.19 Unique autotrophic pathways in phototrophic green bacteria. (a) The reverse citric acid cycle is the mechanism of CO_2 fixation in green sulfur bacteria. Ferredoxin_{red} indicates carboxylation reactions requiring reduced ferredoxin (2 H each). Starting from oxaloacetate, each turn of the cycle results in three molecules of CO_2 being incorporated and pyruvate as the product. (b) The hydroxypropionate pathway is the autotrophic pathway in the green nonsulfur bacterium *Chloroflexus*. Acetyl-CoA is carboxylated twice to yield methylmalonyl-CoA. This intermediate is rearranged to yield a new acetyl-CoA acceptor molecule and a molecule of glyoxylate, which is converted to cell material.

However, neither the Calvin cycle nor the reverse citric acid cycle operates in this organism. Instead, two molecules of CO_2 are reduced to glyoxylate by the **hydroxypropionate pathway**. This pathway is so named because hydroxypropionate, a three-carbon compound, is a key intermediate (Figure 13.19b).

In phototrophic bacteria, the hydroxypropionate pathway is found in *Chloroflexus*, thought to be one of the earliest phototrophs on Earth. This suggests that the hydroxypropionate pathway may have been one of the earliest mechanisms, if not the earliest, for autotrophy in anoxygenic phototrophs. In addition to *Chloroflexus*, the hydroxypropionate pathway operates in several hyperthermophilic *Archaea*, including *Metallosphaera*, *Acidianus*, and *Sulfolobus*. These are all chemolithotrophs that lie

near the base of the phylogenetic tree of *Archaea* (Chapter 16). The evolutionary roots of the hydroxypropionate pathway may thus be very deep, and it is possible that this pathway was nature's first attempt at autotrophy.

MINIQUIZ

- What reaction(s) does the enzyme RubisCO carry out?
- How much NADPH and ATP is required to make one hexose molecule by the Calvin cycle?
- What is a carboxysome and what is its function?
- Contrast autotrophy in the following phototrophs: cyanobacteria; purple and green sulfur bacteria; *Chloroflexus*.

II • Chemolithotrophy

We now turn our attention from phototrophs to the chemolithotrophs, highlighting the strategies, problems, and advantages of a lifestyle dependent on inorganic chemicals as energy sources. From an evolutionary standpoint, chemolithotrophy may have been the first form of energy conservation to evolve on Earth, as it is widespread among lineages that lie near the base of the phylogenetic trees of both *Bacteria* and *Archaea* (► Figures 1.6b, 12.13, and 16.1).

13.6 Inorganic Compounds as Electron Donors

Organisms that conserve energy from the oxidation of inorganic compounds are called **chemolithotrophs**. Most chemolithotrophic bacteria are also autotrophs. As we have noted with the phototrophs, for growth on CO₂ as the sole carbon source an organism needs (1) ATP and (2) reducing power. Some chemolithotrophs grow as **mixotrophs**, meaning that although they can conserve energy from the oxidation of an inorganic compound, they require an organic compound as their carbon source (that is, they are *not* autotrophs).

Inorganic Donors and ATP Generation

Chemolithotrophs can tap into many natural sources of inorganic electron donors, including geological, biological, and anthropogenic (the result of human activities). Volcanic activity is a major source of reduced sulfur compounds, primarily H₂S and S⁰. Agricultural and mining operations add inorganic electron donors to the environment, especially reduced nitrogen and iron compounds, as does the burning of fossil fuels and the input of industrial wastes. Biological sources are also quite extensive, especially in the cases of H₂S, H₂, Fe²⁺, and NH₃. The ecological success and metabolic diversity of chemolithotrophs is a good indication that diverse and abundant sources of inorganic electron donors are

available in nature. The energy yield from the oxidation of these donors, however, varies considerably (Table 13.1).

In general terms, ATP generation in chemolithotrophs is similar to that in respiring chemoorganotrophs except that the electron donor is *inorganic* rather than *organic*. Just as for electrons from the oxidation of organic compounds, electrons from inorganic donors feed into electron transport chains and generate a proton motive force. Then, ATP synthesis occurs from the activity of ATPases (► Section 3.11). Reducing power in chemolithotrophs is obtained in either of two ways: directly from the inorganic compound (if it has a sufficiently negative reduction potential, such as H₂), or from reverse electron transport reactions (as discussed in Section 13.3 for phototrophic purple bacteria), if the inorganic electron donor is more electropositive than NADH. As we will see, with most chemolithotrophs, reverse electron transport is necessary since their electron donors are so electrochemically weak.

Energetics of Chemolithotrophy

A review of reduction potentials listed in Table 13.1 reveals that the oxidation of a number of inorganic electron donors can provide sufficient energy for ATP synthesis.

Recall from Chapter 3 that the farther apart two half reactions are in terms of the E_{0'} of their redox couples, the greater the amount of energy released (► Figure 3.9). For instance, the difference in reduction potential between the 2 H⁺/H₂ couple and the $\frac{1}{2}$ O₂/H₂O couple is 1.23 V, which is equivalent to a free-energy yield of -237 kJ/mol (Appendix 1 shows how free energy values are calculated). On the other hand, the potential difference between the 2 H⁺/H₂ couple and the NO₃⁻/NO₂⁻ couple is less, 0.84 V, equivalent to a free-energy yield of -163 kJ/mol. This is still sufficient for the production of ATP (the energy-rich phosphate bond of ATP has a free energy of -31.8 kJ/mol). Thus, various inorganic electron donors and terminal electron

Table 13.1 Energy yields from the oxidation of various inorganic electron donors^a

Electron donor	Chemolithotrophic reaction	Group of chemolithotrophs	E _{0'} of couple (V)	ΔG ^{0'} (kJ/reaction)	Number of electrons/reaction	ΔG ^{0'} (kJ/2 e ⁻)
Phosphite ^b	4 HPO ₃ ²⁻ + SO ₄ ²⁻ + H ⁺ + HS ⁻ → 4 HPO ₄ ²⁻	Phosphite bacteria	-0.69	-364	8	-91

^aData calculated from E_{0'} values in Appendix 1; values for Fe²⁺ are for pH 2, and others are for pH 7. At pH 7 the value for the Fe³⁺/Fe²⁺ couple is about +0.2 V.

^bExcept for phosphite, all reactions are shown coupled to O₂ as electron acceptor. The only known phosphite oxidizer couples to SO₄²⁻ as electron acceptor. H₂ and most sulfur compounds can be oxidized anaerobically using one or more electron acceptors, and Fe²⁺ can be oxidized at neutral pH with NO₃⁻ as electron acceptor. For other chemolithotrophic reactions of sulfur compounds, see Table 13.2.

^cAmmonium can also be oxidized with NO₂⁻ as electron acceptor (anammox, Section 13.10).

acceptors can be coupled in chemolithotrophic reactions (see Figure 13.39).

Energy calculations make it possible to predict the kinds of chemolithotrophs that should exist in nature. Because organisms must obey the laws of thermodynamics, only reactions that are exergonic are potential energy-conserving reactions for cells, and Table 13.1 lists all known classes of chemolithotrophs. We examine ecological aspects of chemolithotrophy in Chapter 20, where we will see that chemolithotrophic reactions form the heart of most nutrient cycles.

From Table 13.1 it should be clear that of the organisms listed, hydrogen bacteria obtain the most energy per two electrons oxidized while iron bacteria obtain the least. Put another way, the hydrogen bacteria oxidize a very strong electron donor while the iron bacteria oxidize a very weak donor. These differences come into play not only in terms of how much ATP can be produced per two electrons oxidized, but also in the energetic costs of making NADH for autotrophic growth. For hydrogen bacteria, this cost can be zero, while for the iron bacteria the expense is a major one, as we will see in Section 13.9.

MINIQUIZ

- For what two purposes are inorganic compounds oxidized by chemolithotrophs?
- Why does the oxidation of H₂ yield more energy with O₂ as electron acceptor than with SO₄²⁻ as electron acceptor?

13.7 Hydrogen (H₂) Oxidation

Hydrogen (H₂) is a common product of microbial metabolism, especially of some fermentations (Sections 13.12–13.15), and a number of *aerobic* chemolithotrophs are able to use H₂ as an electron donor in energy metabolism. These are the classical “hydrogen bacteria.” In addition, many *anaerobic* H₂-oxidizing *Bacteria* and *Archaea* are known, which differ in the electron acceptor they use (for example, nitrate, sulfate, ferric iron, CO₂); these organisms are discussed in Unit IV of this chapter. Here we focus on the aerobic H₂-oxidizing bacteria, organisms that couple the oxidation of H₂ to the reduction of O₂, forming water.

Energetics of H₂ Oxidation

Synthesis of ATP during H₂ oxidation by O₂ is the result of electron transport reactions that generate a proton motive force. The overall reaction

is highly exergonic and can be coupled to the synthesis of ATP. In this reaction, which is catalyzed by the enzyme **hydrogenase**, the electrons from H₂ are initially transferred to a quinone acceptor. From there electrons travel through a series of cytochromes to generate a proton motive force and eventually reduce O₂ to water (Figure 13.20).

Some hydrogen bacteria synthesize two distinct hydrogenases, one cytoplasmic and one membrane-integrated. The latter enzyme participates in energetics, whereas the soluble hydrogenase has a different function. Instead of binding H₂ for use as

an electron donor in energy metabolism, the cytoplasmic hydrogenase binds H₂ and catalyzes the reduction of NAD⁺ to NADH (the reduction potential of H₂ is sufficiently electronegative that reverse electron flow reactions are unnecessary). The organism *Ralstonia eutropha* has been a model for studying aerobic H₂ oxidation by species that make two hydrogenases, and we discuss some of the properties of this organism in Section 14.16. Species that synthesize only one hydrogenase make only the membrane-integrated enzyme, and it functions in both energy conservation and autotrophy in the cell.

Autotrophy in H₂ Bacteria

Although most hydrogen bacteria can also grow as chemoorganotrophs, when growing chemolithotrophically, they fix CO₂ by the Calvin cycle (Section 13.5). However, when readily usable organic compounds such as glucose are present, synthesis of Calvin cycle and hydrogenase enzymes by H₂ bacteria is repressed. Thus, H₂ bacteria are *facultative* chemolithotrophs. This undoubtedly has ecological value. In nature, H₂ levels in oxic environments are transient and low at best for at least two reasons: (1) most biological H₂ production is the result of fermentations, which are anoxic processes, and (2) H₂ can be utilized by several different anaerobic prokaryotes and thus totally consumed before it reaches oxic regions of a habitat. Hence, aerobic hydrogen bacteria must have a backup metabolism to H₂ oxidation, and in nature they likely shift between chemoorganotrophic and chemolithotrophic lifestyles as nutrients allow in their habitats. Moreover, many aerobic H₂ bacteria grow best microaerobically and are probably most competitive as H₂ bacteria in oxic–anoxic interfaces where H₂ may be in greater and more continuous supply than in fully oxic habitats.

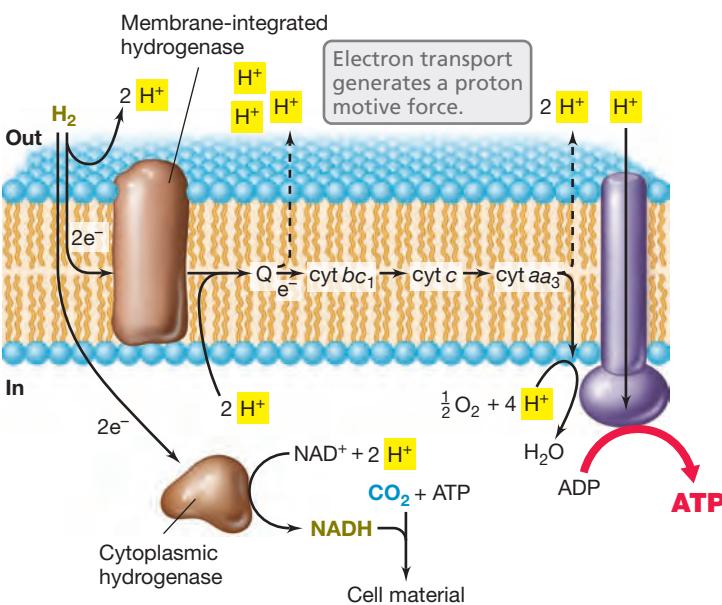

Figure 13.20 Bioenergetics and function of the two hydrogenases of aerobic hydrogen bacteria. In *Ralstonia eutropha* two hydrogenases are present; the membrane-bound hydrogenase participates in energetics, whereas the cytoplasmic hydrogenase makes NADH for the Calvin cycle. Some hydrogen bacteria have only the membrane-bound hydrogenase, and in these organisms reducing power is synthesized by reverse electron flow from Q back to NAD⁺ to form NADH. Cyt, cytochrome; Q, quinone.

MINIQUIZ

- What enzyme is required for hydrogen bacteria to grow as H₂ chemolithotrophs?
- Why is reverse electron flow unnecessary in H₂ bacteria that contain two hydrogenases?

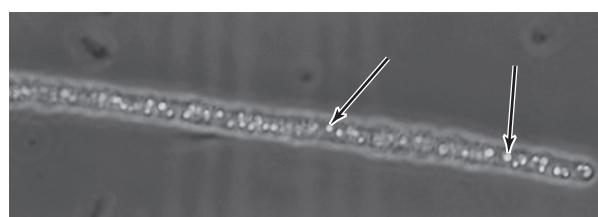

13.8 Oxidation of Reduced Sulfur Compounds

Many reduced sulfur compounds can be electron donors for the colorless sulfur bacteria, called *colorless* to distinguish them from the pigmented green and purple sulfur bacteria discussed earlier in this chapter (Figure 13.1 and Section 13.3). Historically, the very concept of chemolithotrophy emerged in the late nineteenth century from studies of the sulfur bacteria by the Russian microbiologist Sergei Winogradsky (Section 1.9). This was a major new concept in microbiology at the time, and as our understanding of prokaryotic diversity has improved, it has become clear that chemolithotrophy is a major metabolic lifestyle of many *Bacteria* and *Archaea*.

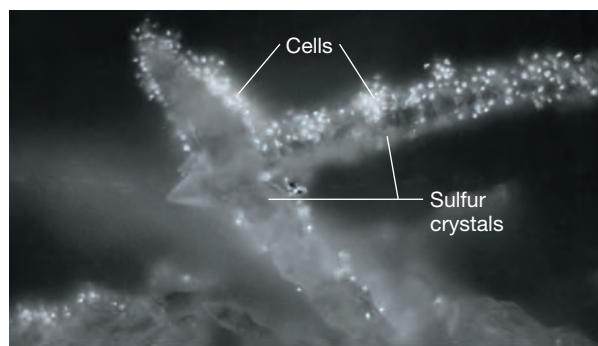

Energetics of Sulfur Oxidation

The most common sulfur compounds used as electron donors are hydrogen sulfide (H₂S), elemental sulfur (S⁰), and thiosulfate (S₂O₃²⁻); sulfite (SO₃²⁻) can also be oxidized (Table 13.1 and Table 13.2). In most cases, the final oxidation product is sulfate (SO₄²⁻). Sulfide oxidation occurs in stages, with the first oxidation step yielding elemental sulfur, S⁰. Some sulfide-oxidizing bacteria, such as *Beggiatoa*, deposit this elemental sulfur inside the cell (Figure 13.21a), where the sulfur exists as a potential energy (electron) reserve. When the supply of sulfide has been depleted, additional energy can then be conserved from the oxidation of sulfur to sulfate. When S⁰ is present externally, the organism must attach itself to the sulfur particle because elemental sulfur is rather insoluble (Figure 13.21b). By adhering to the particle, the organism can remove sulfur atoms for oxidation to sulfate. This occurs by way of membrane or periplasmic proteins that solubilize S⁰ by reducing it to HS⁻; the latter is then transported into the cell and enters chemolithotrophic metabolism (see Figure 13.22).

One product of the oxidation of reduced sulfur compounds is protons (Tables 13.1 and 13.2). Consequently, one result of sulfur chemolithotrophy is acidification of the environment. Because of this, many sulfur bacteria have evolved to be acid-tolerant or even acidophilic. *Acidithiobacillus thiooxidans*, for example, grows best at a pH between 2 and 3.

(a)

(b)

Figure 13.21 **Sulfur bacteria.** (a) Internal sulfur granules in *Beggiatoa* (arrows). (b) Attachment of cells of the sulfur-oxidizing archaeon *Sulfolobus acidocaldarius* to a crystal of elemental sulfur. Cells are visualized by fluorescence microscopy after being stained with the dye acridine orange. The sulfur crystal does not fluoresce.

Biochemistry of Sulfur Oxidation

The biochemical steps in the oxidation of sulfur compounds are summarized in Figure 13.22. At least three pathways for sulfur oxidation are known. In two of the systems, the starting substrate, HS⁻, S₂O₃²⁻, or S⁰, is first oxidized to sulfite (SO₃²⁻); starting from sulfide this releases six electrons. The sulfite is then oxidized to sulfate plus two electrons, and this can occur in either of two ways. The most widespread system employs the enzyme *sulfite oxidase*. This enzyme oxidizes sulfite and transfers the electrons directly to cytochrome c; ATP is made during subsequent electron transport reactions coupled to formation of a proton motive force (Figure 13.22b). By contrast, some sulfur chemolithotrophs oxidize SO₃²⁻ to SO₄²⁻ via a reversal of the activity of the enzyme *adenosine phosphosulfate reductase*, an enzyme essential for the metabolism of sulfate-reducing bacteria (Section 13.18 and see Figure 13.42). This reaction, run in the direction of SO₄²⁻ production by sulfur chemolithotrophs, yields one energy-rich phosphate bond when AMP is converted to ADP (Figure 13.22a). When thiosulfate is the electron donor for sulfur chemolithotrophs (Table 13.2), it is first split into S⁰ and SO₃²⁻, both of which are eventually oxidized to SO₄²⁻.

Table 13.2 Comparison of the energetics of oxidation of some common reduced sulfur compounds

Chemolithotrophic reaction	Electrons	Stoichiometry ^a	Energetics (kJ/electron) ^a
Sulfide to sulfate	8	H ₂ S + 2 O ₂ → SO ₄ ²⁻ + 2 H ⁺	ΔG ^{0'} = -798.2 kJ/reaction (-99.75 kJ/e ⁻)
Sulfite to sulfate	2	SO ₃ ²⁻ + ½ O ₂ → SO ₄ ²⁻	ΔG ^{0'} = -258 kJ/reaction (-129 kJ/e ⁻)
Thiosulfate to sulfate	8	S ₂ O ₃ ²⁻ + H ₂ O + 2 O ₂ → 2 SO ₄ ²⁻ + 2 H ⁺	ΔG ^{0'} = -818.3 kJ/reaction (-102 kJ/e ⁻)

^aAll reactions are balanced, both atomically and electrically. See Appendix 1 for details of calculations. For the reaction and energetics of the oxidation of sulfide to sulfur and sulfate, see Table 13.1.

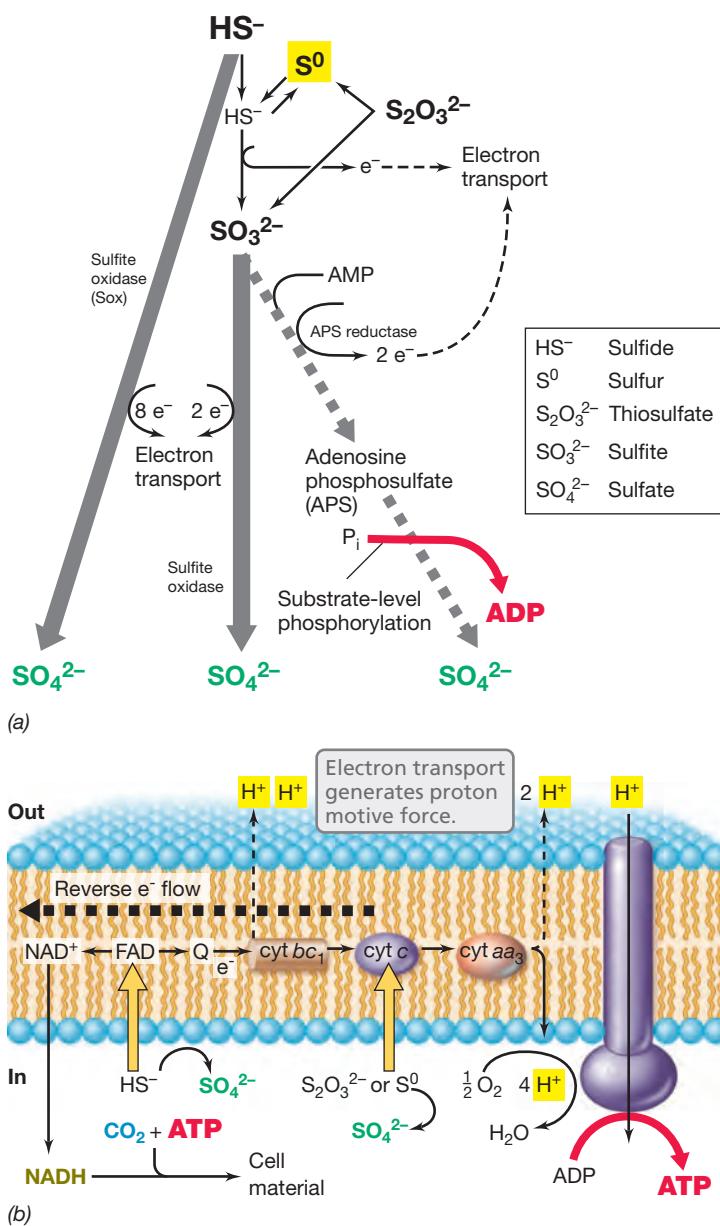

Figure 13.22 Oxidation of reduced sulfur compounds by sulfur chemolithotrophs. (a) Steps in the oxidation of different reduced sulfur compounds. Three different pathways are known. (b) Electrons from sulfur compounds feed into the electron transport chain to drive a proton motive force; electrons from S₂O₃²⁻ and S⁰ enter at the level of cytochrome c. NADH is made by reverse electron flow. Cyt, cytochrome; FAD, flavoprotein; Q, quinone. For the structure of APS, see Figure 13.42a.

A functionally distinct sulfide and thiosulfate oxidation system is present in *Paracoccus pantotrophus* and many other sulfur bacteria. This system, called the *Sox* (for sulfur oxidation) system, oxidizes reduced sulfur compounds directly to sulfate without the intermediate formation of sulfite (Figure 13.22a). The *Sox* system contains over 15 genes encoding various cytochromes and other proteins necessary for the oxidation of reduced sulfur compounds directly to sulfate. The *Sox* system is present in several sulfur chemolithotrophs and also in some phototrophic sulfur bacteria that oxidize sulfide to obtain reducing power for CO₂ fixation rather than for energy conservation. The fact that

this biochemical system is distributed among prokaryotes that oxidize sulfide for very different reasons is a good indication that the genes that encode *Sox* have been transferred between species by horizontal gene flow (Section 6.12 and Chapter 10).

Other Aspects of Chemolithotrophic Sulfur Oxidation

Electrons from the oxidation of reduced sulfur compounds eventually reach the electron transport chain as shown in Figure 13.22b. Depending on the E_{0'} of the electron donor couple, electrons enter at the flavoprotein (E_{0'} = -0.2 V), quinone (E_{0'} = 0 V), or cytochrome c (E_{0'} = +0.3 V) levels and are transported through the chain to O₂, generating a proton motive force that forms ATP by ATPase. Electrons for autotrophic CO₂ fixation come from reverse electron flow (Section 13.3), eventually yielding NADH. Autotrophy is driven by reactions of the Calvin cycle or some other autotrophic pathway (Section 13.5). Although the sulfur chemolithotrophs are primarily an aerobic group, some species can grow anaerobically using nitrate as an electron acceptor. The sulfur bacterium *Thiobacillus denitrificans* is a classic example, reducing nitrate to dinitrogen gas (the process of denitrification, Section 13.17).

MINIQUIZ

- How many electrons are available from the oxidation of H₂S if S⁰ or SO₄²⁻ is the final product?
- In terms of intermediates, how does the *Sox* system differ from other sulfide-oxidizing systems?

13.9 Iron (Fe²⁺) Oxidation

The aerobic oxidation of ferrous iron (Fe²⁺) to ferric iron (Fe³⁺) supports growth of the chemolithotrophic “iron bacteria” (Section 14.15). At acidic pH, only a small amount of energy is available from this reaction (Table 13.1), and for this reason the iron bacteria must couple the oxidation of large amounts of iron in order to produce only tiny amounts of cell material. The ferric iron produced spontaneously forms insoluble ferric hydroxide (Fe³⁺ + 3 H₂O → Fe(OH)₃ + 3 H⁺) and other iron precipitates in aquatic environments, and this drives down the pH (Figure 13.23). This inevitable chemical reaction probably explains why many iron-oxidizing bacteria have evolved to be strongly acidophilic.

Iron-Oxidizing Bacteria

The best-known iron bacteria, *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans*, can both grow autotrophically using ferrous iron (Figure 13.23) as electron donor at pH values as low as 1; growth is optimal at pH 2–3. These bacteria are common in acid-polluted environments such as coal-mining runoff waters (Figure 13.23a). *Ferroplasma*, a species of *Archaea*, is an extremely acidophilic iron oxidizer and can grow at pH values below 0 (Section 16.3). We discuss the role of all of these organisms in acid-mine pollution and mineral oxidation in Sections 20.5, 21.1, and 21.2.

At neutral pH, Fe²⁺ spontaneously oxidizes to Fe³⁺, so opportunities for the iron bacteria are restricted to locations where Fe²⁺ is transitioning from anoxic to oxic conditions. For example, anoxic groundwater often contains Fe²⁺, and when it is released, as in iron-rich springwater, it becomes exposed to O₂. At such

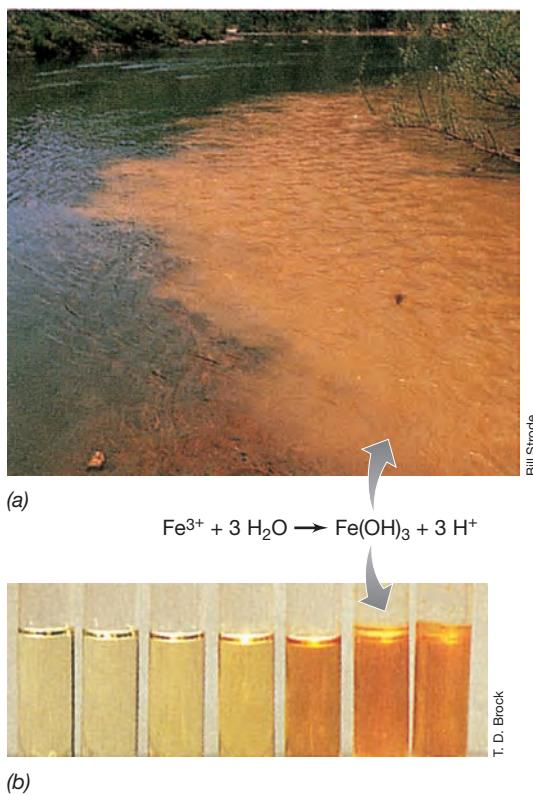

Figure 13.23 Iron-oxidizing bacteria. (a) Acid mine drainage, showing the confluence of a normal river and a creek draining a coal-mining area. At low pH values, Fe^{2+} does not oxidize spontaneously in air, but *Acidithiobacillus ferrooxidans* carries out the oxidation; insoluble Fe(OH)_3 and complex ferric salts precipitate. (b) Cultures of *A. ferrooxidans*. Shown is a dilution series, with no growth in the tube on the left and increasing amounts of growth from left to right. Growth is evident from the production of Fe(OH)_3 .

interfaces, iron bacteria oxidize Fe^{2+} to Fe^{3+} before it oxidizes spontaneously. *Gallionella ferruginea*, *Sphaerotilus natans*, and *Leptothrix discophora* are examples of bacteria that live at these interfaces. They are typically seen mixed in with the characteristic ferric iron deposits they form (► Figures 14.36 and 21.22).

Energy from Iron Oxidation

The bioenergetics of ferrous iron oxidation by *Acidithiobacillus ferrooxidans* and other acidophilic iron oxidizers are of considerable interest because of the very electropositive reduction potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple at acidic pH ($E'_0 = +0.77$ V at pH 2). The respiratory chain of *A. ferrooxidans* contains cytochromes of the *c* and *aa₃* types and a periplasmic copper-containing protein called *rusticyanin* (Figure 13.24). There is also an iron-oxidizing protein located in the outer membrane of the cell.

Because the reduction potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is so high, steps in electron transport to oxygen ($\frac{1}{2}\text{O}_2/\text{H}_2\text{O}, E'_0 = +0.82$ V) can obviously be few. Iron oxidation begins in the outer membrane where the organism contacts either soluble Fe^{2+} or insoluble ferrous iron minerals. Fe^{2+} is oxidized to Fe^{3+} , a one-electron transition (Table 13.1), by an outer membrane cytochrome *c* that transfers electrons into the periplasm where rusticyanin ($E'_0 = +0.68$ V) is the electron acceptor. This thermodynamically slightly unfavorable reaction is thought to be pulled forward by

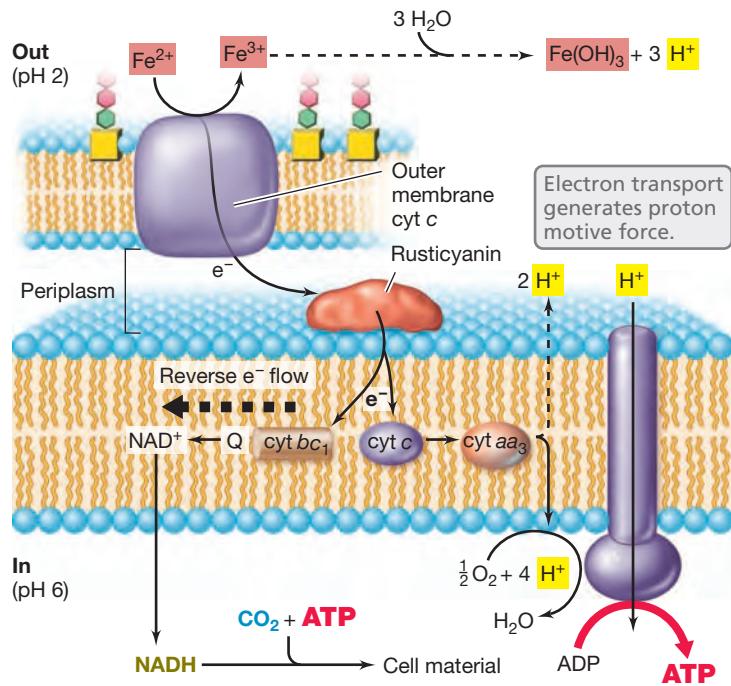

Figure 13.24 Electron flow during Fe^{2+} oxidation by the acidophile *Acidithiobacillus ferrooxidans*. The periplasmic copper-containing protein rusticyanin receives electrons from Fe^{2+} oxidized by a *c*-type cytochrome located in the outer membrane. From here, electrons travel a short electron transport chain, resulting in the reduction of O_2 to H_2O . Reducing power comes from reverse electron flow. Note the steep pH gradient across the membrane.

the immediate consumption of Fe^{3+} in Fe(OH)_3 formation (Figure 13.24). Rusticyanin then reduces a periplasmic cytochrome *c*, which transfers electrons to cytochrome *aa₃*, and it is the latter protein that reduces O_2 to H_2O ; ATP is synthesized by ATPase in the usual fashion (Figure 13.24).

The nature of the proton motive force in *A. ferrooxidans* is of interest. In a highly acidic environment, a large gradient of protons already exists across the *A. ferrooxidans* membrane (the cell periplasm is pH 1–2, whereas the cytoplasm is pH 5.5–6, Figure 13.24). Although this situation might make one think that *A. ferrooxidans* can make ATP at no energetic cost, this is not the case, as the organism cannot make ATP from this natural proton motive force in the absence of an electron donor. This is because H^+ ions that enter the cytoplasm via ATPase must be consumed in order to maintain the internal pH within acceptable limits. Proton consumption occurs during the reduction of O_2 in the electron transport chain and this reaction requires electrons; the latter come from the oxidation of Fe^{2+} to Fe^{3+} (Figure 13.24).

Autotrophy in *A. ferrooxidans* is supported by the Calvin cycle (Section 13.5), and because of the high potential of the electron donor, much energy must be consumed in reverse electron flow reactions to obtain the reducing power (NADH) necessary to drive CO_2 fixation. NADH is formed by reduction of NAD^+ by electrons obtained from Fe^{2+} that are forced backwards through cytochrome *bc₁* and the quinone pool at the expense of the proton motive force (Figure 13.24).

The relatively poor energetic yield from ferrous iron oxidation coupled with the large energetic demands of the Calvin cycle

(Figure 13.17) means that *A. ferrooxidans* must oxidize large amounts of Fe^{2+} to produce even a very small amount of cell material. Thus, in environments where acidophilic iron-oxidizing bacteria thrive, their presence is signaled not by the formation of high cell numbers but by the presence of the large amounts of ferric iron precipitates they have generated (Figure 13.23). We consider the ecology of iron bacteria in Sections 20.5, 21.1, and 21.2.

Ferrous Iron Oxidation under Anoxic Conditions

Ferrous iron can be oxidized under *anoxic* conditions by certain chemolithotrophs and anoxygenic phototrophic bacteria (Figure 13.25). In these cases, Fe^{2+} is used as either an electron donor in energy metabolism (chemolithotrophs) and/or as a reductant for CO_2 fixation (phototrophs). An important point to consider here is that at neutral pH where these organisms thrive, the E_0' of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is significantly more electronegative than at acidic pH (+0.2 V versus +0.77 V, respectively). Hence, electrons from Fe^{2+} can reduce cytochrome *c* to initiate electron transport reactions. For chemolithotrophs, the electron acceptor is nitrate (NO_3^-), with either nitrite (NO_2^-) or dinitrogen gas (N_2) being the final product of this anaerobic respiration. For Fe^{2+} -oxidizing purple and green bacteria, either soluble Fe^{2+} or iron sulfide (FeS) can be used as electron donor. With FeS , both Fe^{2+} and S^{2-} are oxidized, Fe^{2+} to Fe^{3+} (one electron) and HS^- to SO_4^{2-} (eight electrons).

MINIQUIZ

- Why is only a very small amount of energy available from the oxidation of Fe^{2+} to Fe^{3+} at acidic pH?
- What is the function of rusticyanin and where is it found in the cell?
- How can Fe^{2+} be oxidized under anoxic conditions?

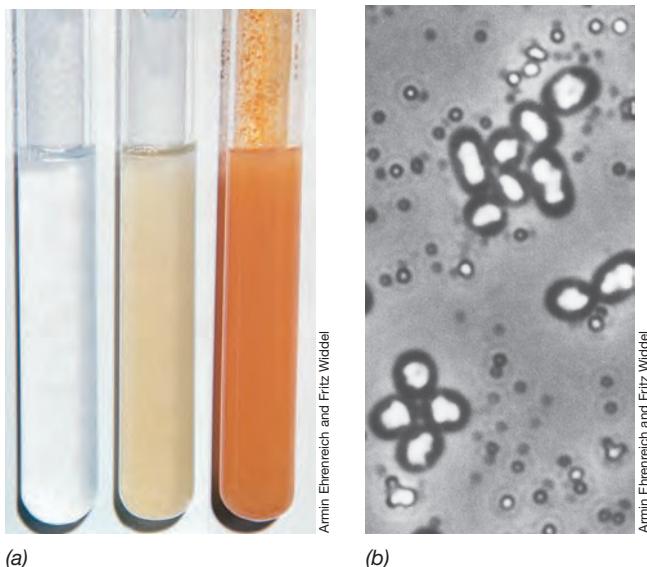

Figure 13.25 Fe^{2+} oxidation by anoxygenic phototrophic bacteria.

(b) Phase-contrast photomicrograph of an Fe^{2+} -oxidizing purple bacterium. The bright refractile areas within cells are gas vesicles. The granules outside the cells are iron precipitates. This organism is phylogenetically related to the purple sulfur bacterium *Chromatium*.

13.10 Nitrification and Anammox

The reduced inorganic nitrogen compounds ammonia (NH_3) and nitrite (NO_2^-) are oxidized aerobically by the chemolithotrophic *nitrifying bacteria* in the process of **nitrification** (➡ Section 14.13). Under anoxic conditions, ammonia is also oxidized by a unique group of bacteria in the process called **anammox**.

Nitrifying and anammox bacteria are widely distributed in soils, water, wastewaters, and the oceans. Aerobically, nitrifying *Bacteria* and *Archaea* oxidize NH_3 but only to nitrite, while a distinct group of *Bacteria* oxidizes the NO_2^- to NO_3^- . The complete oxidation of NH_3 to NO_3^- , an eight-electron transfer, is thus carried out by the cooperative activities of two physiological groups of organisms—the *ammonia oxidizers* and the *nitrite oxidizers*.

Bioenergetics and Enzymology of Ammonia and Nitrite Oxidation

The bioenergetics of nitrification is based on the same principles that govern other chemolithotrophic reactions: electrons from reduced inorganic substrates (in this case, reduced nitrogen compounds) enter an electron transport chain, and electron transport reactions establish a proton motive force that drives ATP synthesis. The electron donors for the nitrifying bacteria are not particularly strong. The E_0' of the $\text{NO}_2^-/\text{NH}_3$ couple (the first step in the oxidation of NH_3) is +0.34 V, and the E_0' of the $\text{NO}_3^-/\text{NO}_2^-$ couple is even more positive, about +0.43 V. By necessity, these reduction potentials force the nitrifying bacteria to donate electrons to rather high-potential electron acceptors, and this of course limits the amount of energy that can be conserved.

Several key enzymes participate in the oxidation of reduced nitrogen compounds. In ammonia-oxidizing bacteria such as *Nitrosomonas*, NH_3 is oxidized by *ammonia monooxygenase* (monooxygenases are discussed in Section 13.22), producing hydroxylamine (NH_2OH) and H_2O (Figure 13.26). A second key enzyme, *hydroxylamine oxidoreductase*, then oxidizes NH_2OH to NO_2^- , removing four electrons in the process. Ammonia monooxygenase is an integral membrane protein, whereas hydroxylamine oxidoreductase is periplasmic (Figure 13.26). In the reaction carried out by ammonia monooxygenase

two electrons and protons are needed to reduce one atom of (O_2) to H_2O . These electrons originate from the oxidation of hydroxylamine and are supplied to ammonia monooxygenase from hydroxylamine oxidoreductase via cytochrome *c* and ubiquinone (Figure 13.26). Thus, for every four electrons generated from the oxidation of NH_3 to NO_2^- , only two actually reach cytochrome aa_3 , the terminal oxidase that interacts with O_2 to form H_2O (Figure 13.26).

Nitrite-oxidizing bacteria such as *Nitrobacter* oxidize NO_2^- to NO_3^- by the enzyme *nitrite oxidoreductase*, with electrons traveling a very short electron transport chain (because of the high potential of the $\text{NO}_3^-/\text{NO}_2^-$ couple) to the terminal oxidase (Figure 13.27). Cytochromes of the *a* and *c* types are present in the electron transport chain of nitrite oxidizers, and the activity of cytochrome aa_3 generates a proton motive force (Figure 13.27). As is the case with the iron bacteria (Section 13.9), only small

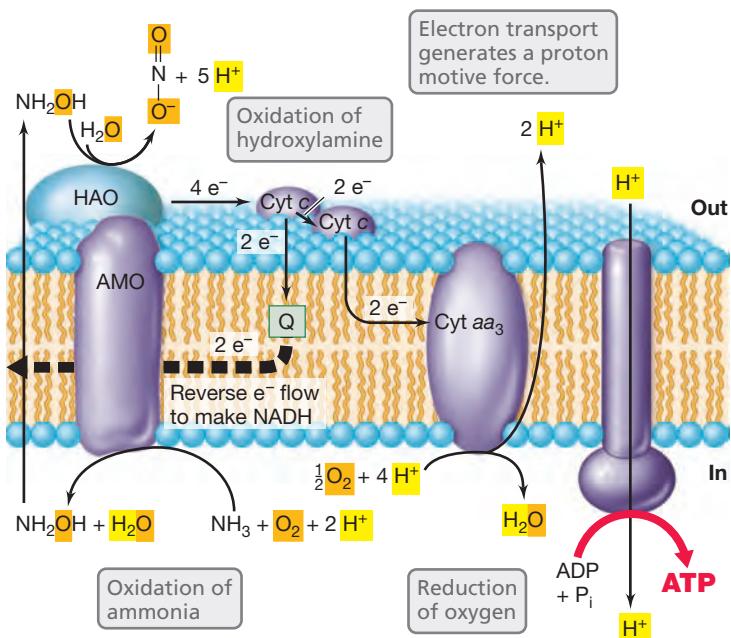

Figure 13.26 Oxidation of NH_3 and electron flow in ammonia-oxidizing bacteria. The reactants and the products of this reaction series are highlighted. The cytochrome c (Cyt c) in the periplasm is a different form of Cyt c than that in the membrane. AMO, ammonia monooxygenase; HAO, hydroxylamine oxidoreductase; Q, ubiquinone.

amounts of energy are available from nitrite oxidation. Hence, minimal amounts of cell material are obtained even though large amounts of nitrite may be oxidized.

Ammonia-Oxidizing Archaea

From a phylogenetic standpoint, *Nitrosomonas* and *Nitrobacter* are *Bacteria*. However, some *Archaea* are also ammonia oxidizers. For example, *Nitrosopumilus* is a marine ammonia-oxidizing

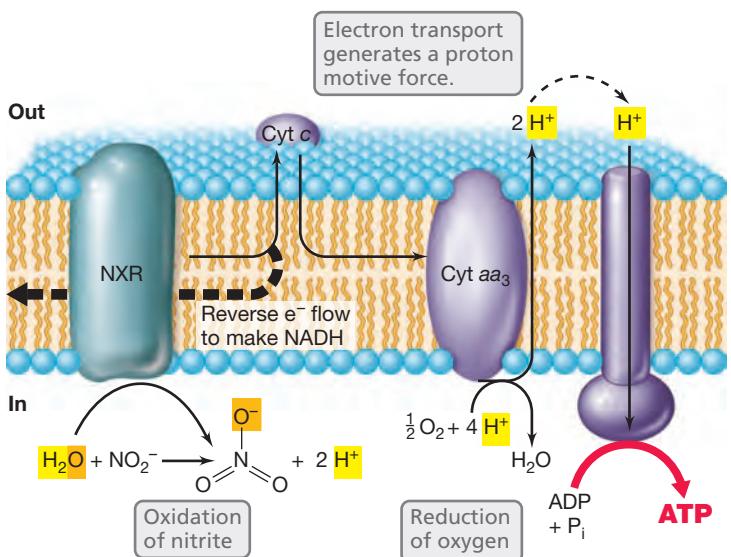

Figure 13.27 Oxidation of NO_2^- to NO_3^- by nitrifying bacteria. The reactants and products of this reaction series are highlighted to show the reaction clearly. NXR, nitrite oxidoreductase.

chemolithotroph of the archaeal phylum *Thaumarchaeota* (► Section 16.6 and chapter opening page of Chapter 6). Genes in *Nitrosopumilus* that encode ammonia monooxygenase are similar to those in *Nitrosomonas*, and thus the biochemistry of ammonia oxidation is likely to have a common mechanism in both domains. One major difference, however, is that unlike ammonia-oxidizing *Bacteria*, ammonia-oxidizing *Archaea* can oxidize ammonia in the vanishingly small levels found in the open oceans. Thus, archaeal nitrifiers may dominate marine nitrification and may also play significant roles in other habitats that contain only low levels of ammonia. In this connection, the nitrifying archaeon *Nitrososphaera* inhabits soils instead of the oceans and may be a major ammonia oxidizer in terrestrial habitats. Thus far, nitrite-oxidizing *Archaea* are unknown.

Carbon Metabolism and Ecology of Nitrifying Bacteria

Like sulfur- and iron-oxidizing chemolithotrophs, aerobic nitrifying *Bacteria* employ the Calvin cycle for CO_2 fixation. The ATP and reducing power requirements of the Calvin cycle place additional burdens on an energy-generating system that already has a relatively low yield (NADH to drive the Calvin cycle in nitrifiers is formed by reverse electron flow, Figures 13.26 and 13.27). The energetic constraints are particularly severe for NO_2^- oxidizers, and it is perhaps for this reason that most NO_2^- oxidizers have alternative energy-conserving mechanisms, being able to grow chemoorganotrophically on glucose and a few other organic substrates. By contrast, species of ammonia-oxidizing bacteria are either obligate chemolithotrophs or mixotrophs. Autotrophy in ammonia-oxidizing *Archaea* is supported by a variation of the hydroxypropionate cycle (Section 13.5).

Nitrifying prokaryotes play key ecological roles in the nitrogen cycle, converting ammonia into nitrate, a key plant nutrient. Nitrifiers are also important in sewage and wastewater treatment, removing toxic amines and ammonia and releasing less toxic nitrogen compounds (► Section 21.6). Nitrifiers play a similar role in the water column of lakes, where ammonia produced in the sediments from the decomposition of organic nitrogenous compounds is oxidized to nitrate, a more favorable nitrogen source for algae and cyanobacteria.

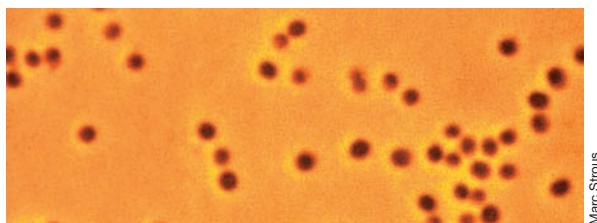

Anammox

Although the ammonia-oxidizing prokaryotes just discussed are strict *aerobes*, NH_3 can also be oxidized under anoxic conditions. This process is called *anammox* (for *anoxic ammonia oxidation*) and is catalyzed by an unusual group of obligately anaerobic *Bacteria*.

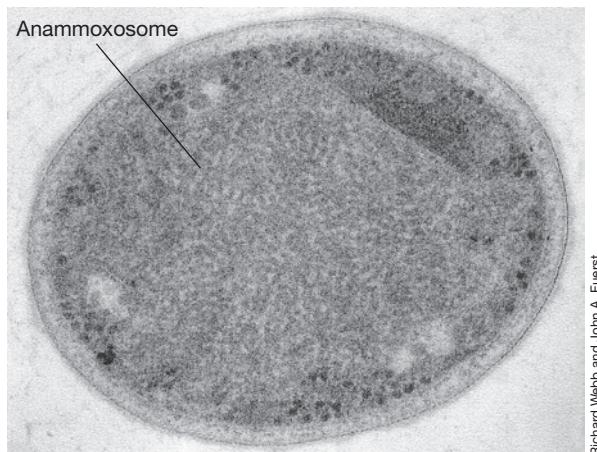

Ammonia is oxidized in the anammox reaction using NO_2^- as the electron acceptor to yield N_2 :

A major anammox organism, *Brocadia anammoxidans*, is a species of the *Planctomycetes* phylum of *Bacteria* (► Section 15.16). *Planctomycetes* are unusual *Bacteria* in that they lack peptidoglycan and their cytoplasm contains membrane-enclosed compartments of various types (Figure 13.28). In cells of *B. anammoxidans* this compartment is the *anammoxosome*, and it is within this structure that the anammox reaction occurs (Figure 13.28c). In addition to

(b)

(c)

Figure 13.28 Anammox. (a) Phase-contrast photomicrograph of cells of *Brocadia anammoxidans*. A single cell is about 1 μm in diameter. (b) Transmission electron micrograph of a cell; note the membrane-enclosed compartments including the large fibrillar anammoxosome. (c) Reactions in the anammoxosome. NiR, nitrite reductase; HH, hydrazine hydrolase; HZO, hydrazine dehydrogenase.

Brocadia, several other genera of anammox bacteria are known, including *Kuenenia*, *Anammoxoglobus*, *Jettenia*, and *Scalindua*, all of which are related to *Brocadia* and also contain anammoxosomes. Like aerobic ammonia oxidizers, anammox bacteria are also autotrophs, but they do not fix CO_2 using the pathways employed by aerobic ammonia oxidizers. Instead, anammox bacteria fix CO_2 by way of the acetyl-CoA pathway, an autotrophic pathway widespread among some obligately anaerobic autotrophic *Bacteria* and *Archaea* (Section 13.19).

The anammoxosome is a unit membrane-enclosed structure (Figure 13.28b) and in this respect is technically an organelle in the eukaryotic sense of the term. Lipids that form the

anammoxosome membrane are not the typical lipids of *Bacteria* but instead consist of fatty acids constructed of multiple cyclobutane (C_4) rings bonded to glycerol by both ester and ether bonds. These *ladderane lipids*, as they are called, aggregate in the membrane to form an unusually dense membrane structure that prevents diffusion of substances from the anammoxosome into the cytoplasm.

The strong anammoxosome membrane is required to protect the cell from toxic intermediates produced during anammox reactions. These include, in particular, the compound *hydrazine* (N_2H_4), a very strong reductant. In the anammox reaction, NO_2^- is first reduced to nitric oxide (NO) by nitrite reductase, and then NO reacts with ammonium (NH_4^+) to yield N_2H_4 by activity of the enzyme hydrazine hydrolase (Figure 13.28c). N_2H_4 is then oxidized to N_2 plus electrons by the enzyme hydrazine dehydrogenase. Some of the electrons generated at this step enter the anammoxosome electron transport chain, and electron transport reactions yield a proton motive force; other electrons feed back into the system to drive earlier anammox reactions (Figure 13.28c). ATP is formed from the proton motive force by ATPases in the anammoxosome membrane (Figure 13.28c).

Ecology of Anammox

In nature the source of NO_2^- for the anammox reaction is presumably aerobic ammonia-oxidizing *Bacteria* and *Archaea*. These organisms coexist with anammox bacteria in ammonia-rich habitats such as sewage and other wastewaters. The suspended particles that form in these habitats contain both oxic and anoxic zones in which ammonia oxidizers of different physiologies can coexist in close association. In mixed laboratory cultures, high levels of oxygen inhibit anammox and favor classic nitrification, and thus it is likely that in nature, the fraction of ammonia oxidation catalyzed by anammox bacteria is governed by the concentration of O_2 in the habitat.

From an environmental standpoint, anammox is a very beneficial process in the treatment of wastewaters. The anoxic removal of NH_3 and amines by the formation of N_2 (Figure 13.28c) helps reduce the input of fixed nitrogen from wastewater treatment facilities into rivers and streams, thereby maintaining higher water quality than would otherwise be possible. The activities of marine anammox organisms likely account for the significant fraction (>50%) of NH_3 known to disappear from marine sediments, a process which has previously been unexplained. At least some ammonia-rich freshwater lake sediments also support anammox, and thus it appears that anammox can occur in any anoxic environment in which NH_3 and NO_2^- coexist.

MINIQUIZ

- What are the substrates for the enzyme ammonia monooxygenase?
- Why must anammox reactions be carried out in a special structure within the cell?
- What is the carbon source for nitrifying and anammox organisms?

III • Fermentations

We have thus far considered phototrophy and chemolithotrophy, strategies for energy conservation that do not require organic compounds as electron donors. In the next three units we focus on organic compounds as electron donors and the many ways in which chemoorganotrophs conserve energy. We begin with fermentations, major forms of anaerobic energy conservation.

13.11 Energetic and Redox Considerations

Many microbial habitats are *anoxic* (oxygen-free), and in such environments, decomposition of organic material occurs anaerobically. If sulfate (SO_4^{2-}), nitrate (NO_3^-), ferric iron (Fe^{3+}), and other electron acceptors are absent from these habitats, organic compounds are catabolized by **fermentation**. Recall from Chapter 3 that we emphasized how redox balance is achieved in fermentations by having the substrate serve as *both* electron donor and electron acceptor and that ATP is synthesized by *substrate-level phosphorylation*. We pick up on these two essential features of fermentation here (Figure 13.29).

Energy-Rich Compounds and Substrate-Level Phosphorylation

Energy can be conserved by substrate-level phosphorylation from many different compounds. However, central to an understanding of substrate-level phosphorylation is the concept of *energy-rich compounds*. These are organic compounds that contain an energy-rich phosphate bond or a molecule of coenzyme A. The bond is “energy-rich” because its hydrolysis is highly exergonic. Table 13.3 lists some energy-rich compounds formed during metabolism; the hydrolysis of most of these yields sufficient free energy to be coupled to ATP synthesis ($\Delta G^0' = -31.8 \text{ kJ/mol}$). If an organism can form one of these compounds during fermentative metabolism, it can likely make ATP by substrate-level phosphorylation.

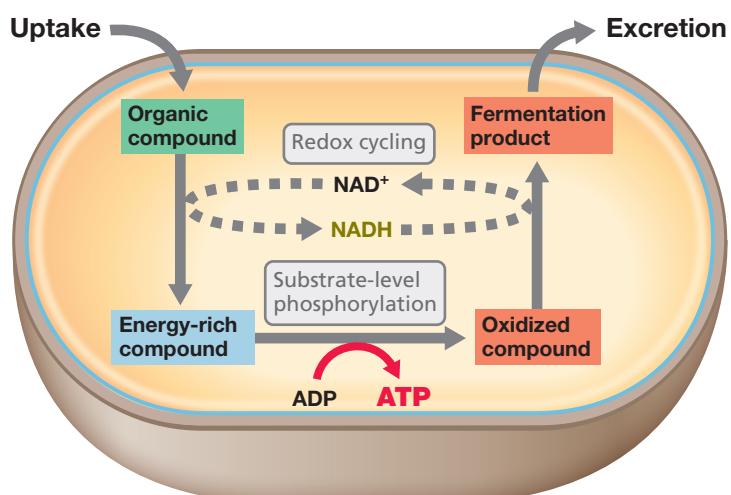

Figure 13.29 The essentials of fermentation. The fermentation product is excreted from the cell, and only a relatively small amount of the original organic compound is used for biosynthesis.

Table 13.3 Energy-rich compounds that can couple to substrate-level phosphorylation^a

Compound	Free energy of hydrolysis, $\Delta G^0'$ (kJ/mol) ^b
Acetyl-CoA	-35.7
Propionyl-CoA	-35.6
Butyryl-CoA	-35.6
Caproyl-CoA	-35.6
Succinyl-CoA	-35.1
Acetyl phosphate	-44.8
Butyryl phosphate	-44.8
1,3-Bisphosphoglycerate	-51.9
Carbamyl phosphate	-39.3
Phosphoenolpyruvate	-51.6
Adenosine phosphosulfate (APS)	-88
N ¹⁰ -Formyltetrahydrofolate	-23.4
Energy of hydrolysis of ATP (ATP → ADP + Pi)	-31.8

^aData from Thauer, R.K., K. Jungermann, and K. Decker. 1977. Energy conservation in chemotrophic anaerobic bacteria. *Bacteriol. Rev.* 41: 100–180.

^bThe $\Delta G^0'$ values shown here are for “standard conditions,” which are not necessarily those of cells. Including heat loss, the energy costs of making an ATP are more like 60 kJ than 32 kJ, and the energy of hydrolysis of the energy-rich compounds shown here is thus likely higher. But for simplicity and comparative purposes, the values in this table will be taken as the actual energy released per reaction.

Redox Balance and H₂ and Acetate Production

In any fermentation there must be atomic and redox balance. That is, the total number of each type of atom and electrons in the products of the reaction must balance those in the reactants (the substrates). Redox balance is achieved in fermentations by the excretion from the cell of *fermentation products*, reduced substances such as acids or alcohols that are produced as end products of the catabolism of the original fermentable substance (Figure 13.29). In several fermentations, redox balance is facilitated by the production of molecular hydrogen (H₂). The production of H₂ is associated with the activity of the iron–sulfur protein *ferredoxin*, a very low-potential electron carrier, and is catalyzed by the enzyme *hydrogenase*. H₂ can also be produced from the C₁ fatty acid formate (Figure 13.30). Although the H₂ can no longer be used by the fermenter and is thus excreted, H₂ is a very powerful electron donor and can be oxidized by various respiratory prokaryotes. Indeed, with its very electronegative E_0' (making it suitable as an electron donor for any form of respiration), H₂ is never wasted in microbial ecosystems.

Many anaerobic bacteria produce acetate or other fatty acids as a major or minor fermentation product. The production of these is energy conserving because it offers the organism the opportunity to make ATP by substrate-level phosphorylation. The key intermediate generated is the coenzyme-A derivative of each fatty acid, since these are energy-rich compounds (Table 13.3). For example, acetyl-CoA can be converted to acetyl phosphate (Figure 13.30) and the phosphate group subsequently transferred

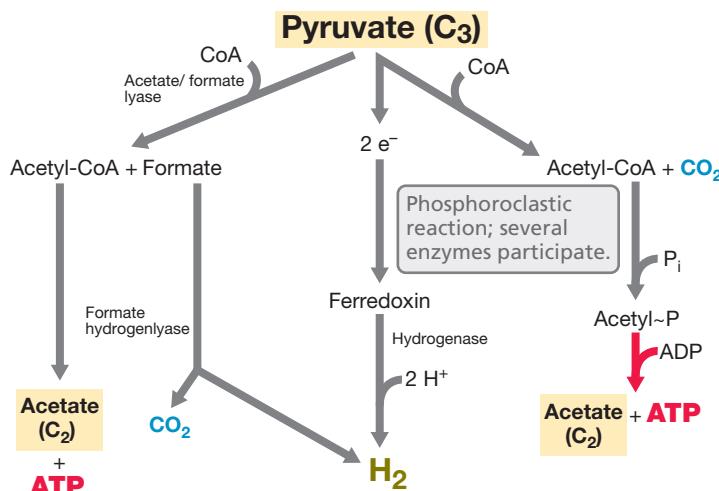

Figure 13.30 Production of H₂ and acetate from pyruvate. At least two mechanisms are known, one that produces H₂ directly and the other that makes formate as an intermediate. When acetate is produced, ATP synthesis is possible (see Table 13.3).

to ADP, yielding ATP. Fatty acid production is common in fermentations and if the fatty acid is metabolized through a Co-A intermediate, the potential for ATP synthesis by substrate-level phosphorylation is a possibility.

MINIQUIZ

- What is substrate-level phosphorylation?
- Why is acetate formation in fermentation energetically beneficial to the cell?

13.12 Lactic and Mixed-Acid Fermentations

Fermentations are classified by either the substrate fermented or the products formed. **Table 13.4** lists some major fermentations classified on the basis of products formed. Note some of the broad categories, such as alcohol, lactic acid, propionic acid, mixed acid,

Table 13.5 Some unusual bacterial fermentations

Type	Reaction	Organisms
Acetylene	2 C ₂ H ₂ + 3 H ₂ O → ethanol + acetate ⁻ + H ⁺	<i>Pelobacter acetylenicus</i>
Glycerol	4 Glycerol + 2 HCO ₃ ⁻ → 7 acetate ⁻ + 5 H ⁺ + 4 H ₂ O	<i>Acetobacterium</i> spp.
Resorcinol (aromatic)	2 C ₆ H ₄ (OH) ₂ + 6 H ₂ O → 4 acetate ⁻ + butyrate ⁻ + 5 H ⁺	<i>Clostridium</i> spp.
Phloroglucinol (aromatic)	C ₆ H ₆ O ₃ + 3 H ₂ O → 3 acetate ⁻ + 3 H ⁺	<i>Pelobacter massiliensis</i> <i>Pelobacter acidigallici</i>
Putrescine	10 C ₄ H ₁₂ N ₂ + 26 H ₂ O → 6 acetate ⁻ + 7 butyrate ⁻ + 20 NH ₄ ⁺ + 16 H ₂ + 13 H ⁺	Unclassified gram-positive nonsporulating anaerobes
Citrate	Citrate ³⁻ + 2 H ₂ O → formate ⁻ + 2 acetate ⁻ + HCO ₃ ⁻ + H ⁺	<i>Bacteroides</i> spp.
Aconitate	Aconitate ³⁻ + H ⁺ + 2 H ₂ O → 2 CO ₂ + 2 acetate ⁻ + H ₂	<i>Acidaminococcus fermentans</i>
Glyoxylate	4 Glyoxylate ⁻ + 3 H ⁺ + 3 H ₂ O → 6 CO ₂ + 5 H ₂ + glycolate ⁻	Unclassified gram-negative bacterium
Benzoate	2 Benzoate ⁻ → cyclohexane carboxylate ⁻ + 3 acetate ⁻ + HCO ₃ ⁻ + 3 H ⁺	<i>Syntrophus aciditrophicus</i>

butyric acid, and acetogenic. Other fermentations are classified by the substrate fermented rather than the fermentation product; for instance, amino acid, purine/pyrimidine, or the succinate/oxalate fermentations. Some anaerobes even ferment aromatic compounds and other unusual substrates (**Table 13.5**). Clearly, a wide variety of organic compounds can be fermented, and in a few cases, only a very restricted group of anaerobes can carry out the fermentation. Many of these are metabolic specialists, having evolved the capacity to ferment a substrate not catabolized by other bacteria.

Table 13.4 Common fermentations and their energetics and example organisms

Type	Reaction	Energy yield ($\Delta G^{\circ\prime}$, kJ/mol)	Organisms
Alcoholic	Hexose → 2 ethanol + 2 CO ₂	-239	Yeast, <i>Zymomonas</i>
Homolactic	Hexose → 2 lactate ⁻ + 2 H ⁺	-196	<i>Streptococcus</i> , some <i>Lactobacillus</i>
Heterolactic	Hexose → lactate ⁻ + ethanol + CO ₂ + H ⁺	-216	<i>Leuconostoc</i> , some <i>Lactobacillus</i>
Propionic acid	3 Lactate ⁻ → 2 propionate ⁻ + acetate ⁻ + CO ₂ + H ₂ O	-170	<i>Propionibacterium</i> , <i>Clostridium propionicum</i>
Mixed acid ^{a,b}	Hexose → ethanol + 2,3-butanediol + succinate ²⁻ + lactate ⁻ + acetate ⁻ + formate ⁻ + H ₂ + CO ₂	—	Enteric bacteria including <i>Escherichia</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Klebsiella</i> , <i>Enterobacter</i>
Butyric acid ^b	Hexose → butyrate ⁻ + 2 H ₂ + 2 CO ₂ + H ⁺	-264	<i>Clostridium butyricum</i>
Butanol ^b	2 Hexose → butanol + acetone + 5 CO ₂ + 4 H ₂	-468	<i>Clostridium acetobutylicum</i>
Caproate/Butyrate	6 Ethanol + 3 acetate ⁻ → 3 butyrate ⁻ + caproate ⁻ + 2 H ₂ + 4 H ₂ O + H ⁺	-183	<i>Clostridium kluyveri</i>
Acetogenic	Fructose → 3 acetate ⁻ + 3 H ⁺	-276	<i>Clostridium aceticum</i>

^aNot all organisms produce all products. In particular, butanediol production is limited to only certain enteric bacteria. Reaction not balanced.

^bStoichiometry shows major products. Other products include some acetate and a small amount of ethanol (butanol fermentation only).

We begin with two very common fermentations of sugars in which lactic acid is the sole or major product.

Lactic Acid Fermentation

Lactic acid bacteria are gram-positive nonsporulating bacteria that produce lactic acid as a major or sole fermentation product from the fermentation of sugars (► Section 15.6). Two fermentative patterns are observed. One, called **homofermentative**, yields a single fermentation product, lactic acid. The other, called **heterofermentative**, yields products in addition to lactate, mainly ethanol plus CO₂.

Figure 13.31 summarizes pathways for the fermentation of glucose by homofermentative and heterofermentative lactic acid bacteria. The differences observed can be traced to the presence or absence of the enzyme *aldolase*, a key enzyme of glycolysis (► Figure 3.14). Homofermentative lactic acid bacteria contain aldolase and produce *two* molecules of lactate from glucose by

the glycolytic pathway (Figure 13.31a). Heterofermenters lack aldolase and thus cannot break down fructose bisphosphate to triose phosphate. Instead, they oxidize glucose 6-phosphate to 6-phosphogluconate and then decarboxylate this to pentose phosphate. The latter compound is then converted to triose phosphate and acetyl phosphate by the key enzyme *phosphoketolase* (Figure 13.31b). The early steps in catabolism by heterofermentative lactic acid bacteria are those of the pentose phosphate pathway (► Figure 3.26).

In heterofermenters, triose phosphate is converted to lactic acid with the production of ATP (Figure 13.31b). However, to achieve redox balance the acetyl phosphate produced is used as an electron acceptor and is reduced by NADH (generated during the production of pentose phosphate) to ethanol. This occurs without ATP synthesis because the energy-rich CoA bond is lost during ethanol formation. Because of this, heterofermenters produce only *one* ATP/glucose instead of the *two* ATP/glucose produced

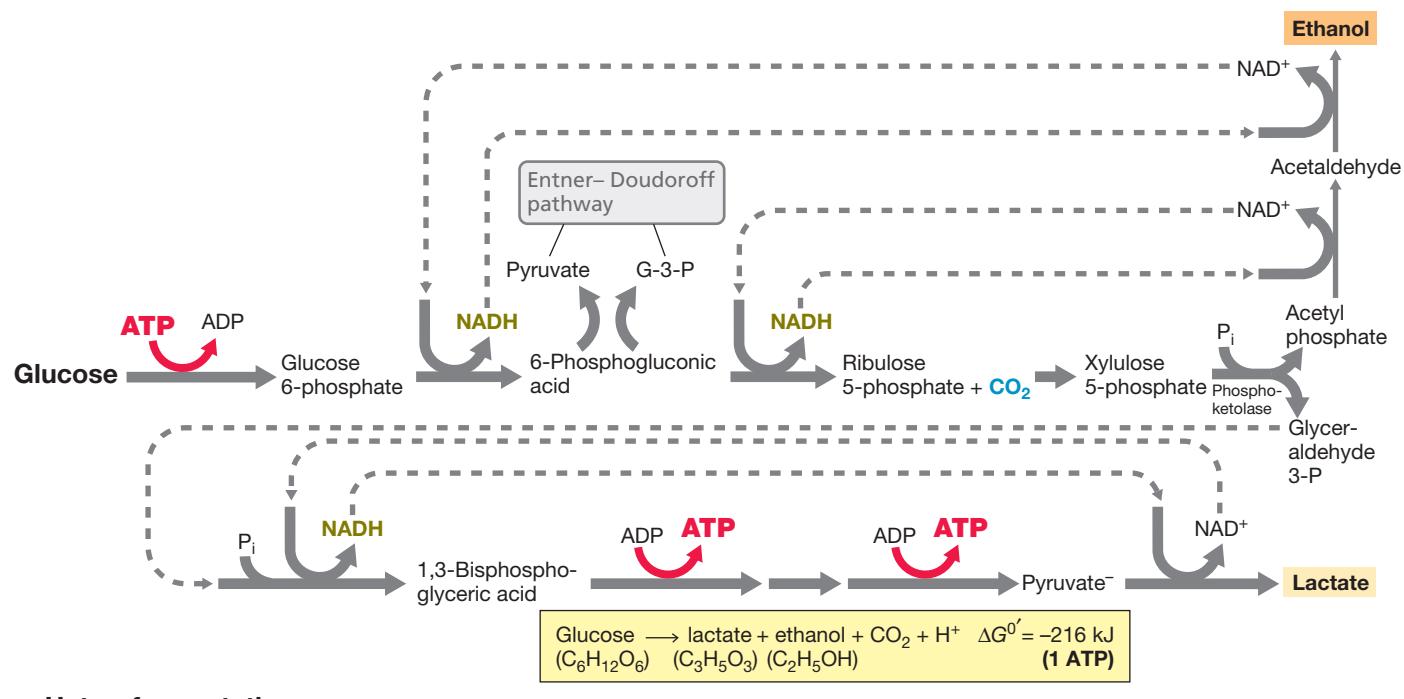

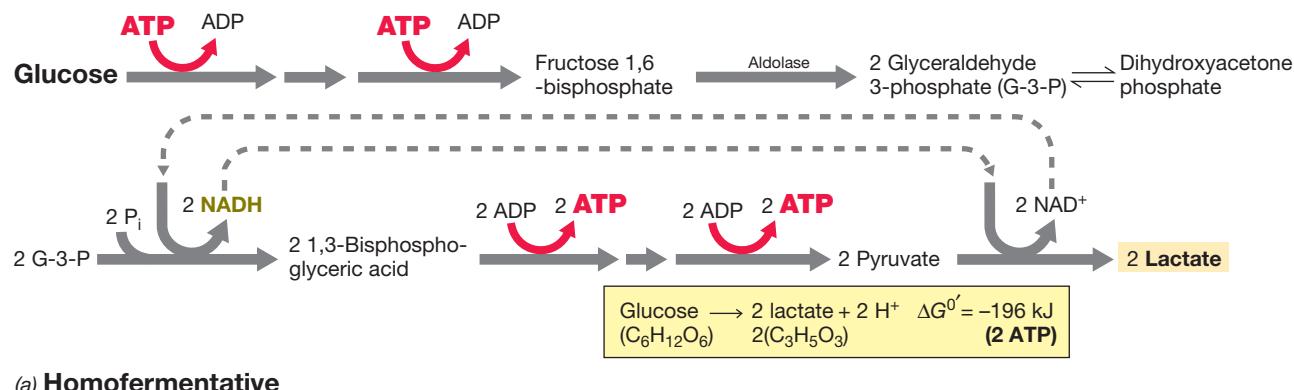

Figure 13.31 The fermentation of glucose in (a) homofermentative and (b) heterofermentative lactic acid bacteria.

Note that no ATP is made in reactions leading to ethanol formation in heterofermentative organisms.

by homofermenters. In addition, because heterofermenters decarboxylate 6-phosphogluconate, they produce CO_2 as a fermentation product; homofermenters do not produce CO_2 . Thus an easy way to differentiate a homofermenter from a heterofermenter is to observe for the production of CO_2 in laboratory cultures.

Entner–Doudoroff Pathway

A variant of the glycolytic pathway, called the *Entner–Doudoroff pathway*, is widely distributed in bacteria, especially among species of the pseudomonad group. In this pathway glucose 6-phosphate is oxidized to 6-phosphogluconic acid and NADPH; the 6-phosphogluconic acid is dehydrated and split into pyruvate and glyceraldehyde 3-phosphate (G-3-P), a key intermediate of the glycolytic pathway. G-3-P is then catabolized as in glycolysis, generating NADH and two ATP, and used as an electron acceptor to balance redox reactions (Figure 13.31a).

Because pyruvate is formed directly in the Entner–Doudoroff pathway and cannot yield ATP as can G-3-P (Figure 13.31), the Entner–Doudoroff pathway yields only half the ATP of the glycolytic pathway. Organisms using the Entner–Doudoroff pathway therefore share this physiological characteristic with heterofermentative lactic acid bacteria (Figure 13.31b). *Zymomonas*, an obligately fermentative pseudomonad, and *Pseudomonas*, a strictly respiratory bacterium (☞ Section 15.4), are major genera that employ the Entner–Doudoroff pathway for glucose catabolism.

Mixed-Acid Fermentations

In *mixed-acid fermentations* (Table 13.4), characteristic of enteric bacteria (☞ Section 15.3), three different acids—*acetic*, *lactic*, and *succinic*—are formed from the fermentation of glucose or other sugars that can be converted into glucose. Ethanol, CO_2 , and H_2 are also typically formed as fermentation products. Glycolysis is the pathway used by mixed-acid fermenters, such as *Escherichia coli*, and we outlined the steps in that pathway in Figure 3.14.

Some enteric bacteria produce acidic products in lower amounts than *E. coli* and balance redox in their fermentations by

producing larger amounts of neutral products. One key neutral product is the four-carbon alcohol *butanediol*. In this variation of the mixed-acid fermentation, butanediol, ethanol, CO_2 , and H_2 are the main products observed (Figure 13.32). In the mixed-acid fermentation of *E. coli*, equal amounts of CO_2 and H_2 are produced, whereas in a butanediol fermentation, considerably more CO_2 than H_2 is produced. This is because mixed-acid fermenters produce CO_2 only from formic acid by means of the enzyme *formate hydrogenlyase* (Figure 13.32):

By contrast, butanediol producers, such as *Enterobacter aerogenes*, produce CO_2 and H_2 from formic acid but also produce two additional molecules of CO_2 during the formation of each molecule of butanediol (Figure 13.32). However, because butanediol production consumes only half of the NADH generated in glycolysis (Figure 13.32), more ethanol is produced by these organisms than by non-butanediol fermenters in order to achieve redox balance.

MINIQUIZ

- How can homo- and heterofermentative metabolism be differentiated in pure cultures of lactic acid bacteria?
- Butanediol production leads to greater ethanol production than in the mixed-acid fermentation of *Escherichia coli*. Why?

13.13 Clostridial and Propionate Fermentations

Species of the genus *Clostridium* are obligately fermentative anaerobes (☞ Section 15.7). Different clostridia ferment sugars, amino acids, purines and pyrimidines, and a few other compounds. In all cases ATP synthesis is linked to substrate-level phosphorylations either in the glycolytic pathway or from the hydrolysis of a CoA intermediate (Table 13.3). We begin with sugar-fermenting, or *saccharolytic*, clostridia.

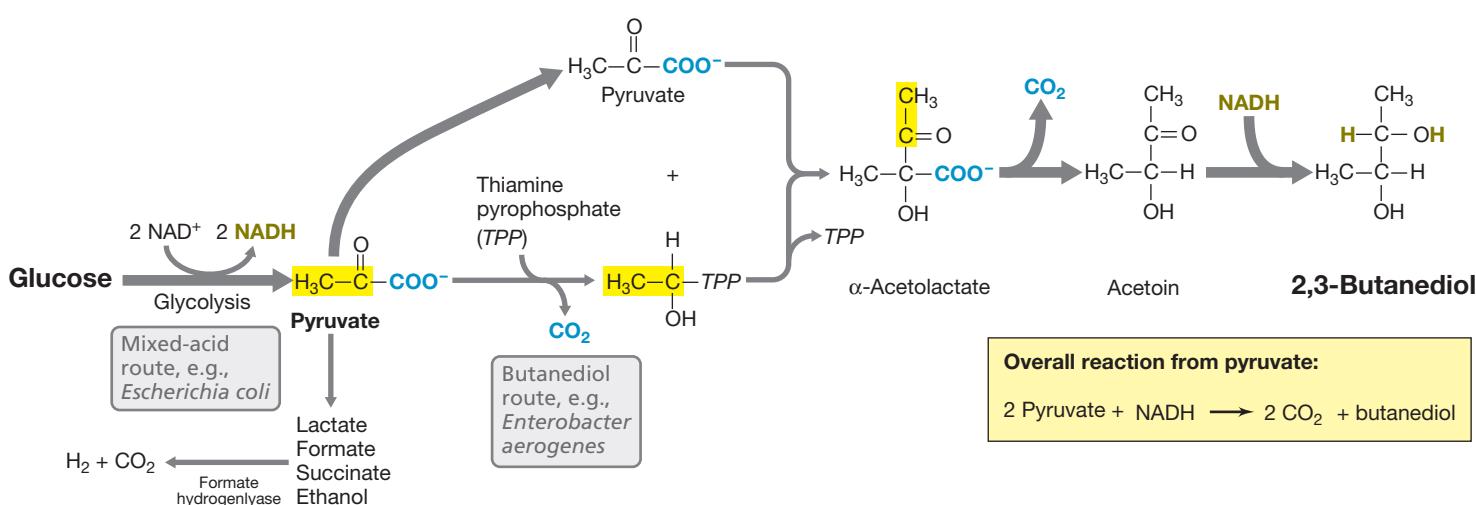

Figure 13.32 Butanediol production and mixed-acid fermentations. Note how only one NADH, but two molecules of pyruvate, are used to make one butanediol. This leads to redox imbalance and the production of more ethanol by butanediol producers than by mixed-acid fermenters.

Sugar Fermentation by *Clostridium* Species

A number of clostridia ferment sugars, producing *butyric acid* as a major fermentation product. Some species also produce the neutral products acetone and butanol; *Clostridium acetobutylicum* is a classic example of this pattern. The biochemical steps in the formation of butyric acid and neutral products from sugars are shown in **Figure 13.33**.

In saccharolytic clostridia, glucose is converted to pyruvate and NADH via the glycolytic pathway, and pyruvate is split to yield acetyl-CoA, CO₂, and H₂ (through ferredoxin) by the phosphoroclastic reaction (Figure 13.30). Most of the acetyl-CoA is then reduced to butyrate or other fermentation products using NADH derived from glycolytic reactions as electron donor. The actual products observed are influenced by the duration and the conditions of the fermentation. During the early stages of the butyric

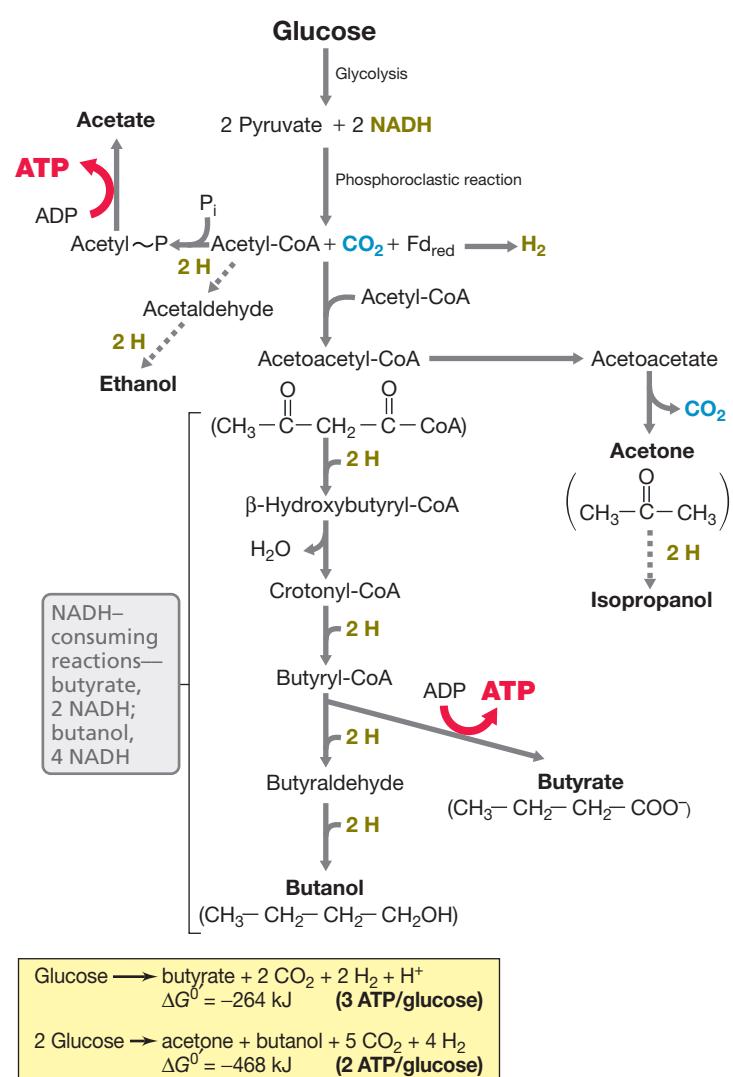

Figure 13.33 The butyric acid and butanol/acetone fermentation. All fermentation products from glucose are shown in bold (dashed lines indicate minor products). Note how the production of acetate and butyrate lead to additional ATP by substrate-level phosphorylation. By contrast, formation of butanol and acetone reduces the ATP yield because the butyryl-CoA to butyrate step is bypassed. 2 H, NADH; Fd_{red}, reduced ferredoxin.

fermentation, butyrate and a small amount of acetate and ethanol are produced. But as the pH of the medium drops, acid production decreases and acetone and butanol begin to appear. If the pH of the medium is kept neutral by buffering, there is very little formation of acetone and butanol; instead, butyric acid production continues, and this is for a good reason.

When *C. acetobutylicum* synthesizes butyrate, extra ATP is produced (Figure 13.33 and Table 13.3) and the organism will continue to make butyrate unless conditions become overly acidic. However, the organism is acid-sensitive, and if the pH drops below about pH 5, genes encoding enzymes that make neutral products are derepressed and the fermentation shifts to solvent production. Interestingly, the production of butanol is in part a consequence of the production of acetone. For each acetone that is made, two NADH produced during glycolysis are not reoxidized as they would be if butyrate were produced. To achieve redox balance, the cell then uses butyrate as an electron acceptor with butanol being the final fermentation product (Figure 13.33). Previously excreted butyrate can also be reincorporated by the cell and reduced to butanol and then excreted again. Although neutral product formation helps *C. acetobutylicum* keep its environment from becoming too acidic, there is an energetic price to pay for this. In producing butanol, the cell loses the opportunity to convert butyryl-CoA to butyrate and gain ATP (Figure 13.33 and Table 13.3).

Amino Acid Fermentation by *Clostridium* Species and the Stickland Reaction

Some *Clostridium* species ferment amino acids. These are the *proteolytic* clostridia, organisms that degrade proteins released from dead organisms. Some of these, such as the animal pathogen *Clostridium tetani* (tetanus), are strictly proteolytic, while other species are both saccharolytic and proteolytic.

Depending on the species, some proteolytic clostridia ferment individual amino acids, typically glutamate, glycine, alanine, cysteine, histidine, serine, or threonine. The biochemistry behind these fermentations is quite complex, but the metabolic strategy is simple. In virtually all cases, the amino acids are catabolized in such a way as to eventually yield a fatty acid–CoA derivative, typically acetyl (C₂), butyryl (C₄), or caproyl (C₆). From these, ATP is produced by substrate-level phosphorylation (Table 13.3). Other typical products of amino acid fermentation include ammonia (NH₃) and CO₂.

Some clostridia ferment only an amino acid pair. In this situation one amino acid functions as the electron donor and is oxidized, whereas the other amino acid is the electron acceptor and is reduced. This *coupled* amino acid fermentation is called a **Stickland reaction**, named for the scientist who discovered it. For example, *Clostridium sporogenes* ferments glycine and alanine, and in this reaction, alanine is the electron donor and glycine is the electron acceptor (Figure 13.34). The products of the Stickland reaction are invariably NH₃, CO₂, and a carboxylic acid with one fewer carbons than the amino acid that was oxidized (Figure 13.34).

Many of the products of amino acid fermentation by clostridia are foul-smelling substances, and the odor that results from putrefaction is mainly a result of clostridial activity. In addition

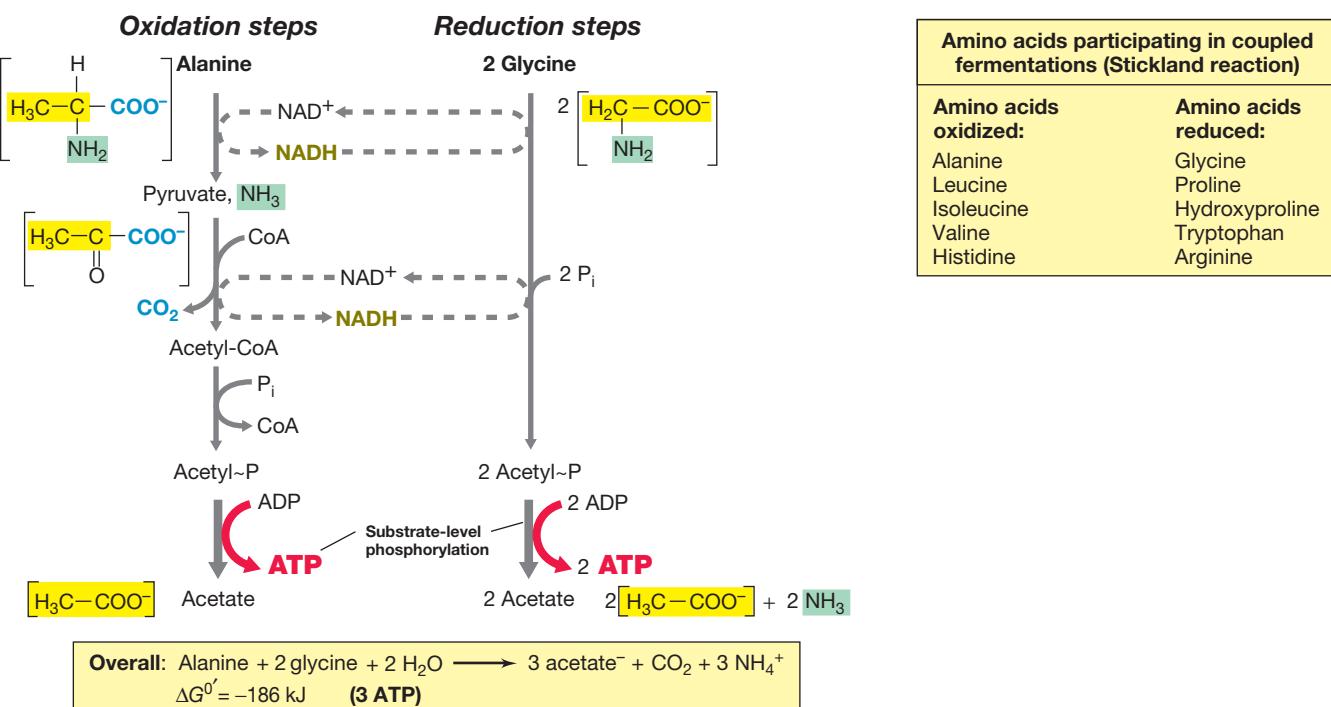

Figure 13.34 The Stickland reaction. This example shows the catabolism of the amino acids alanine and glycine. The structures of key substrates, intermediates, and products are shown in brackets to allow the chemistry of the reaction to be followed. Note how in the reaction shown, alanine is the electron donor and glycine is the electron acceptor.

to fatty acids, other odiferous compounds produced include hydrogen sulfide (H₂S), methylmercaptan (CH₃SH, derived from sulfur-containing amino acids), cadaverine (from lysine), putrescine (from ornithine), and NH₃. Purines and pyrimidines, released from the degradation of nucleic acids, lead to many of the same fermentation products and yield ATP by substrate-level phosphorylation from the hydrolysis of fatty acid–CoA derivatives (Table 13.3) produced in their respective fermentative pathways.

Clostridium kluyveri Fermentation

Another species of *Clostridium* also ferments a mixture of substrates in which one is the donor and one is the acceptor, as in the Stickland reaction. However, this organism, *C. kluyveri*, ferments not amino acids but instead *ethanol plus acetate*. In this fermentation, ethanol is the electron donor and acetate is the electron acceptor. The overall reaction is shown in Table 13.4.

The ATP yield in the caproate/butyrate fermentation is low, 1 ATP/6 ethanol fermented. However, *C. kluyveri* has a selective advantage over all other fermenters in its apparently unique ability to oxidize a highly reduced fermentation product of other anaerobes (ethanol) and couple it to the reduction of another common fermentation product (acetate), reducing the latter to longer-chain fatty acids, reactions that consume NADH (see Figure 13.33). The single ATP produced per 6 ethanol oxidized comes from substrate-level phosphorylation during conversion of a fatty acid–CoA derivative formed during the fermentation. The fermentation of *C. kluyveri* is an example of a **secondary fermentation**, which can be viewed as a fermentation of fermentation products. We see another example of this next.

Propionic Acid Fermentation

The gram-positive bacterium *Propionibacterium* and some related bacteria produce *propionic acid* as a major fermentation product from either glucose or lactate. Lactate, a fermentation product of the lactic acid bacteria, is probably the major substrate for propionic acid bacteria in nature, where these two groups live in close association. *Propionibacterium* is an important agent in the ripening of Swiss (Emmentaler) cheese, which gets its unique bitter and nutty taste from the propionic and acetic acids produced, and the CO₂ produced during the fermentation forms bubbles that leave the characteristic holes (eyes) in the cheese.

Figure 13.35 shows the reactions leading from lactate to propionate. When glucose is the starting substrate, it is first catabolized to pyruvate by the glycolytic pathway. Then pyruvate, produced either from glucose or from the oxidation of lactate, is converted to acetate plus CO₂ or carboxylated to form methylmalonyl-CoA; the latter is converted into oxaloacetate and, eventually, propionyl-CoA (Figure 13.35). Propionyl-CoA reacts with succinate in a step catalyzed by the enzyme CoA transferase, producing succinyl-CoA and propionate. This results in a lost opportunity for ATP production from propionyl-CoA (Table 13.3) but avoids the energetic costs of having to activate succinate with ATP to form succinyl-CoA. The succinyl-CoA is then isomerized to methylmalonyl-CoA and the cycle is complete; propionate is formed and CO₂ regenerated (Figure 13.35).

NADH is oxidized in the steps between oxaloacetate and succinate. The reduction of fumarate to succinate (Figure 13.35) is linked to electron transport reactions and the formation of a proton motive force; this yields one ATP by oxidative phosphorylation

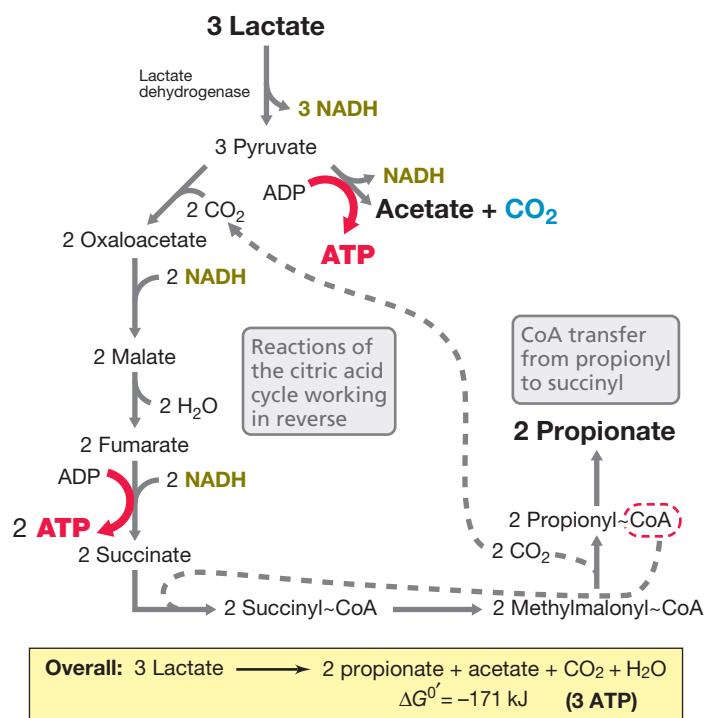

Figure 13.35 The propionic acid fermentation of *Propionibacterium*.

Products are shown in bold. The four NADH made from the oxidation of three lactate are reoxidized in the reduction of oxaloacetate and fumarate, and the CoA group from propionyl-CoA is exchanged with succinate during the formation of propionate.

(Section 13.21). The propionate pathway also converts some lactate to acetate plus CO₂, which allows for additional ATP to be made by substrate-level phosphorylation (Figure 13.35). Thus, in the propionate fermentation, both substrate-level *and* oxidative phosphorylation occur.

Propionate is also formed in the fermentation of succinate by the bacterium *Propionigenium*, but by a completely different mechanism than that described here for *Propionibacterium*. *Propionigenium*, to be considered next, is phylogenetically and ecologically unrelated to *Propionibacterium*, but aspects of its energy metabolism are of considerable interest from the standpoint of metabolic diversity and the energetic limits to life.

MINIQUIZ

- Compare the mechanisms for energy conservation in *Clostridium acetobutylicum* and *Propionibacterium*.
- What type of substrates are fermented by saccharolytic clostridia? By proteolytic clostridia?
- What are the substrates for the *Clostridium kluyveri* fermentation? In nature, where do these come from?

13.14 Fermentations without Substrate-Level Phosphorylation

Certain fermentations yield insufficient energy to synthesize ATP by substrate-level phosphorylation (that is, less than -32 kJ, Table 13.3), yet still support anaerobic growth without added electron

acceptors. In these cases, catabolism of the compound is linked to ion pumps that establish a proton motive force or sodium motive force across the cytoplasmic membrane. Examples of these include the fermentation of succinate by *Propionigenium modestum* and the fermentation of oxalate by *Oxalobacter formigenes*.

Propionigenium modestum

Propionigenium modestum was first isolated in anoxic enrichment cultures lacking electron acceptors and fed succinate as an electron donor. *Propionigenium* inhabits marine and freshwater sediments and can also be isolated from the human oral cavity. The organism is a gram-negative short rod and, phylogenetically, is a species of *Fusobacteria* (➡ Section 15.21). During studies of the physiology of *P. modestum*, it was shown to require sodium chloride (NaCl) for growth and to catabolize succinate under strictly anoxic conditions:

This decarboxylation releases insufficient free energy to support ATP synthesis by substrate-level phosphorylation (Table 13.3) but sufficient free energy to pump a sodium ion (Na⁺) from the cytoplasm to the periplasm across the cytoplasmic membrane. Energy conservation in *Propionigenium* is then linked to the resulting *sodium motive force*; a sodium-translocating (instead of proton-translocating) ATPase exists in the membrane of this organism that uses the sodium motive force to drive ATP synthesis (Figure 13.36a).

In a related decarboxylation reaction, the bacterium *Malonomonas* decarboxylates the C₃ dicarboxylic acid malonate, forming acetate plus CO₂. As for *Propionigenium*, energy metabolism in *Malonomonas* is linked to Na⁺ and a sodium-driven ATPase. But the free energy available from malonate fermentation by *Malonomonas* (-17.4 kJ) is even less than that of succinate fermentation by *P. modestum*. *Sporomusa*, an endospore-forming bacterium and also an acetogen (Section 13.19), is also capable of fermenting malonate, as are a few other *Bacteria*.

Oxalobacter formigenes

Oxalobacter formigenes is a bacterium present in the intestinal tract of animals, including humans. It catabolizes the C₂ dicarboxylic acid oxalate, producing formate plus CO₂. Oxalate degradation by *O. formigenes* is thought to be important in the human colon for preventing the accumulation of oxalate, a substance that can form calcium oxalate kidney stones. *O. formigenes* is a gram-negative strict anaerobe that carries out the following reaction:

As in the catabolism of succinate by *P. modestum*, insufficient energy is available from this reaction to drive ATP synthesis by substrate-level phosphorylation (Table 13.3). However, the reaction supports growth of the organism because the decarboxylation of oxalate is exergonic and forms formate, which is excreted from the cell. This is because the internal consumption of protons during the oxidation of oxalate and production of formate is, in effect, a proton pump; a divalent molecule (oxalate) enters the cell while a univalent molecule (formate) is excreted. The continued exchange of oxalate for formate establishes a proton motive

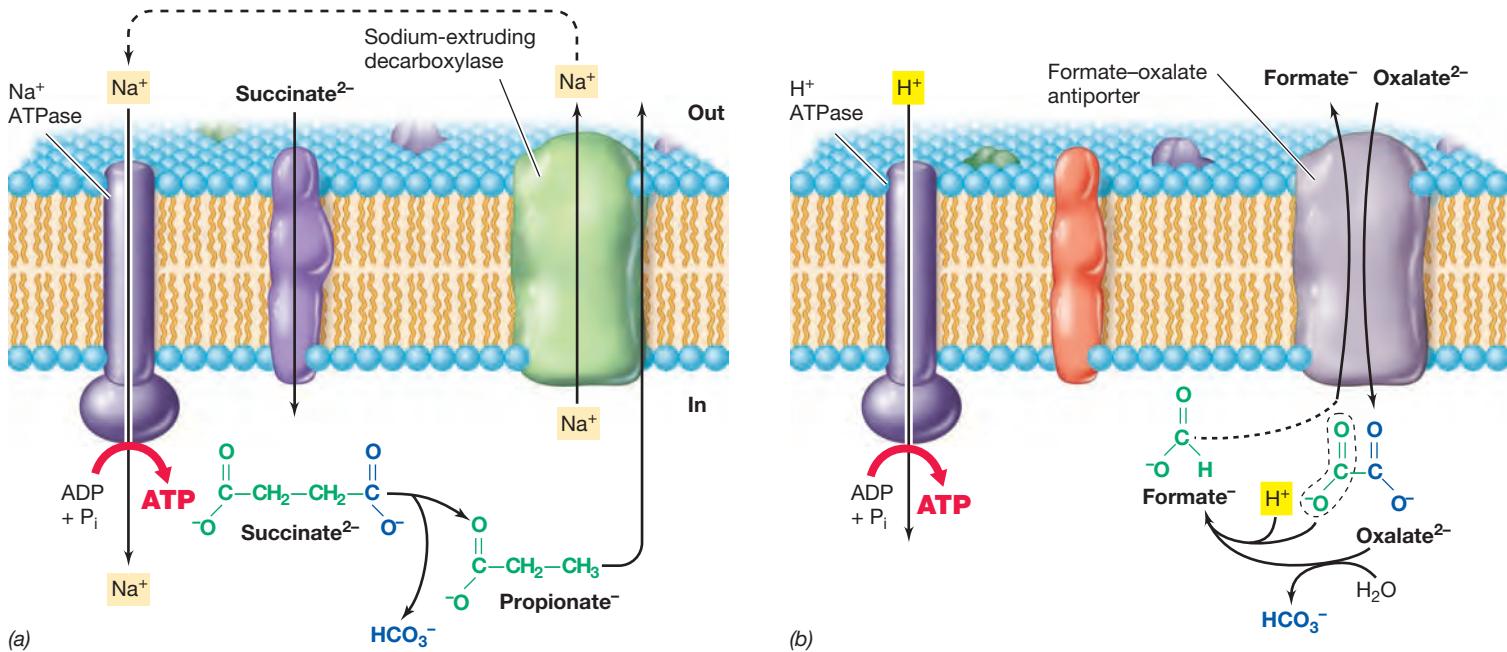

Figure 13.36 The unique fermentations of succinate and oxalate. (a) Succinate fermentation by *Propionigenium modestum*.

Sodium export is linked to the energy released by succinate decarboxylation, and a sodium-translocating ATPase produces ATP.

(b) Oxalate fermentation by *Oxalobacter formigenes*. Oxalate import and formate export by a formate–oxalate antiporter

(Figure 2.21) consume cytoplasmic protons. ATP synthesis is linked to a proton-driven ATPase. All substrates and products are shown in bold.

force that is coupled to ATP synthesis by the proton-translocating ATPase in the membrane (Figure 13.36b).

What Can Be Learned from Decarboxylating-Type Fermentations?

The unique aspect of all of these “decarboxylation-type” fermentations is that ATP is made without substrate-level phosphorylation or oxidative phosphorylation driven by electron transport reactions. Instead, ATP synthesis is driven by ion pumps coupled to the small amount of energy released from the decarboxylation reaction. Organisms such as *Propionigenium*, *Malonomonas*, or *Oxalobacter* thus offer an important lesson in microbial bioenergetics: ATP synthesis from reactions that yield less than -32 kJ is still possible if the reaction is coupled to an ion pump.

At a minimum, then, an energy-conserving reaction must yield sufficient free energy to pump at least one ion. This energy requirement is estimated to be near -12 kJ . Reactions that release less free energy than this should not be able to drive ion pumps and should therefore not be potential energy-conserving reactions. However, as we will see in the next section, bacteria are known that push this theoretical limit even lower and whose energetics, consequently, are still incompletely understood. These are the syntrophs, bacteria living on the energetic margin of existence.

MINIQUIZ

- Why does *Propionigenium modestum* require sodium for growth?
- Of what benefit is the organism *Oxalobacter* to human health?
- How can a fermentation that yields insufficient free energy to make an ATP still support growth?

13.15 Syntropy

There are many examples in microbiology of **syntropy**, a situation in which two different organisms cooperate to degrade a substance that neither can degrade alone. Most syntrophic reactions are secondary fermentations in which organisms ferment the fermentation products of other anaerobes. We will see in Chapter 20 how syntropy is often a key step in the anoxic catabolism that leads to the production of methane (CH_4) in nature. Here we consider the microbiology and energetic aspects of syntropy.

Table 13.6 lists some major groups of syntrophs and the compounds they degrade. Many organic compounds can be degraded syntrophically, including even aromatic and aliphatic hydrocarbons. But the major compounds of interest in syntrophic environments are fatty acids and alcohols.

H₂ Consumption in Syntropy: The Metabolic Link

The heart of syntrophic reactions is *interspecies H₂ transfer*—H₂ *production* by one partner, the syntroph, linked to H₂ *consumption* by the other. The H₂ consumer can be any one of a number of physiologically distinct organisms: denitrifying bacteria, ferric iron-reducing bacteria, sulfate-reducing bacteria, acetogens, or methanogens, groups we will consider in the next unit of this chapter. Consider ethanol fermentation to acetate plus H₂ by the syntroph *Pelotomaculum* coupled to the production of methane (Figure 13.37). As can be seen, the syntroph carries out a reaction whose standard free-energy change ($\Delta G^{\circ\prime}$) is positive. Hence, in pure culture, the organism will not grow. However, the H₂ produced by *Pelotomaculum* can be used as an electron donor by a methanogen to produce methane, an exergonic reaction. When the two reactions are summed, the overall reaction is exergonic

Table 13.6 Properties of major syntrophic bacteria^a

Genus	Number of known species	Phylogeny ^b	Substrates fermented in coculture ^c
<i>Syntrophobacter</i>	4	<i>Deltaproteobacteria</i>	Propionate (C ₃), lactate; some alcohols
<i>Syntrophomonas</i>	9	<i>Firmicutes</i>	C ₄ –C ₁₈ saturated/unsaturated fatty acids; some alcohols
<i>Pelotomaculum</i>	2	<i>Firmicutes</i>	Propionate, lactate, several alcohols; some aromatic compounds
<i>Syntrophus</i>	3	<i>Deltaproteobacteria</i>	Benzoate and several related aromatic compounds; some fatty acids and alcohols

^aAll syntrophs are obligate anaerobes.^bSee Chapters 14 and 15.^cNot all species can use all substrates listed.

(Figure 13.37), and when *Pelotomaculum* and a methanogen are cultured together (cocultured), both organisms grow luxuriously.

A second example of syntropy is the oxidation of a fatty acid such as butyrate to acetate plus H₂ by the fatty acid-oxidizing bacterium *Syntrophomonas* (Figure 13.38):

The free-energy change of this reaction is even more unfavorable than that of ethanol oxidation (Figure 13.37), and in pure culture *Syntrophomonas* will obviously not grow on butyrate. However, as with ethanol fermentation by *Pelotomaculum*, if the H₂ produced by *Syntrophomonas* is consumed by a partner organism, *Syntrophomonas* will grow on butyrate in coculture with the H₂-consuming partner. How does this occur?

Energetics of H₂ Transfer

In a syntrophic relationship, the removal of H₂ by a partner organism shifts the equilibrium of the entire reaction and pulls it in the direction of product formation; this can greatly affect the energetics of the reaction. A review of the principles of free energy given in Appendix 1 indicates that the concentration of reactants and products in a reaction can have a major effect on energetics. This is usually not the case for most fermentation products because they are not consumed to extremely low levels. H₂, by contrast, can be consumed to nearly undetectable levels, and at these tiny concentrations, the energetics of reactions can be dramatically affected.

For convenience, the $\Delta G^{0'}$ of a reaction is calculated on the basis of *standard conditions*—one molar concentration of products and reactants (➡ Section 3.4). By contrast, the related term ΔG is calculated on the basis of the *actual concentrations* of products and reactants present (Appendix 1 explains how to calculate

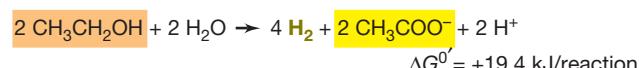

ΔG). At very low levels of H₂, the energetics of the oxidation of ethanol or fatty acids to acetate plus H₂, reactions that are endergonic under standard conditions, become exergonic. For example, if the concentration of H₂ is kept extremely low from consumption by the partner organism, ΔG for the oxidation of butyrate by *Syntrophomonas* yields −18 kJ (Figure 13.38a). As we learned in Section 13.14, this relatively low energy yield can still support growth of a bacterium.

Energetics in Syntrops

Energy conservation in syntrops is grounded in both substrate-level and oxidative phosphorylations. From biochemical studies of syntrophic butyrate catabolism, substrate-level phosphorylation has been shown to occur during the conversion of acetyl-CoA to acetate (Figure 13.38a) although the −18 kJ of energy released (ΔG) is in theory insufficient for this. However, the energy released is sufficient to produce *a fraction* of an ATP, so it is possible that in some way *Syntrophomonas* can couple two or more rounds of butyrate oxidation to the synthesis of one ATP by substrate-level phosphorylation.

Besides a syntrophic lifestyle, many syntrops can also carry out anaerobic respirations (Section 13.16) in pure culture by the disproportionation of unsaturated fatty acids (disproportionation is a process in which one molecule of a substrate is oxidized while another is reduced). For example, crotonate, an intermediate in syntrophic butyrate metabolism (Figure 13.38a), supports growth of pure cultures of *Syntrophomonas*. Under these conditions some of the crotonate is oxidized to acetate and

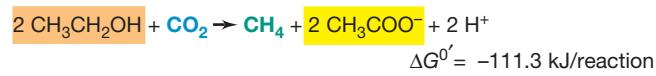

Ethanol fermentation:

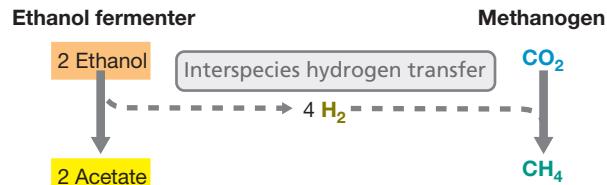

Methanogenesis:

Coupled reaction:

(b) Syntrophic transfer of H2

Figure 13.37 Syntropy: Interspecies H₂ transfer. Shown is the fermentation of ethanol to methane and acetate by syntrophic association of an ethanol-oxidizing syntroph and a H₂-consuming partner (in this case, a methanogen). (a) Reactions involved. The two organisms share the energy released in the coupled reaction. (b) Nature of the syntrophic transfer of H₂.

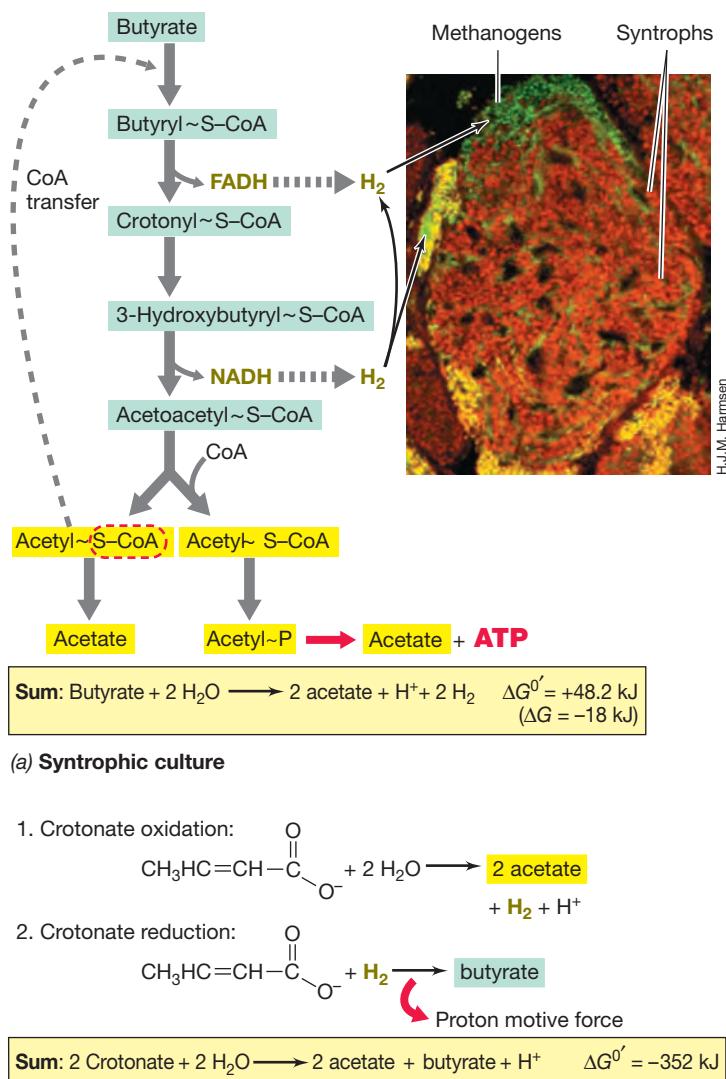

Figure 13.38 Energetics of growth of *Syntrophomonas* in syntrophic culture and in pure culture. (a) In syntrophic culture, growth requires a H_2 -consuming organism, such as a methanogen. H_2 production is driven by reverse electron flow because the E_0' values of the FADH and NADH couples are more electropositive than that of $2 \text{H}^+/\text{H}_2$. (b) In pure culture, energy conservation is linked to anaerobic respiration with crotonate reduction to butyrate. Inset: photomicrograph of cells of a fatty acid-degrading syntrophic bacterium (red) in association with a methanogen (green-yellow).

some is reduced to butyrate (Figure 13.38b). Because crotonate reduction by *Syntrophomonas* is coupled to the formation of a proton motive force, as occurs in other anaerobic respirations that employ organic electron acceptors (such as fumarate

reduction to succinate, Section 13.21), it is possible that some step(s) in syntrophic metabolism generate a proton motive force as well. Pumping protons or some other ion would almost certainly be required for benzoate- and propionate-fermenting syntrophs, whose free energy yield (ΔG) is vanishingly low, only about -5 kJ per reaction.

Regardless of how ATP is made during syntrophic growth, an additional energetic problem burdens syntrophs. During syntrophic metabolism, syntrophs produce H_2 ($E_0' = -0.42 \text{ V}$) from more electropositive electron donors such as FADH ($E_0' = -0.22 \text{ V}$) and NADH ($E_0' = -0.32 \text{ V}$), generated during fatty acid oxidation reactions (Figure 13.38a); it is unlikely that this occurs without an energy input. Thus, some fraction of the meager ATP generated by *Syntrophomonas* during syntrophic growth is probably consumed to drive reverse electron flow reactions (Section 13.3) to produce H_2 . Combining this energy drain with the inherently poor energetic yields of syntrophic reactions, it should be obvious that syntrophic bacteria thrive on a very marginal energy economy.

Ecology of Syntrophs

Ecologically, syntrophic bacteria are key links in the anoxic steps of the carbon cycle (Section 20.2). Syntrophs consume highly reduced fermentation products and release a key product, H_2 , for anaerobic respirations. Without syntrophs, a bottleneck would develop in anoxic environments in which electron acceptors (other than CO_2) were limiting. By contrast, when conditions are oxic or alternative electron acceptors are abundant, syntrophic relationships are unnecessary. For example, if O_2 or NO_3^- is available as an electron acceptor, the energetics of the respiration of a fatty acid or an alcohol is so favorable that syntrophic relationships are unnecessary. Thus, syntropy is characteristic of anoxic catabolism in which primarily methanogenesis or acetogenesis are the terminal processes in the ecosystem. Methanogenesis is a major process in anoxic wastewater biodegradation, and microbiological studies of sludge granules that form in such systems have shown the close physical relationship that develops between H_2 producer and H_2 consumer in such habitats (Figure 13.38a inset).

MINIQUIZ

- Give an example of interspecies H_2 transfer. Why can it be said that both organisms benefit from this process?
- Why can a pure culture of *Syntrophomonas* grow on crotonate but not butyrate?

IV • Anaerobic Respirations

We examined the process of aerobic respiration in Chapter 3. As we noted there, O_2 functions as a *terminal electron acceptor*, accepting electrons that have traversed an electron transport chain. However, we also noted that other electron acceptors can be used instead of O_2 , in which case the process is called **anaerobic respiration**. Here we consider these reactions in more detail.

13.16 Principles of Anaerobic Respiration

Bacteria that carry out anaerobic respiration have electron transport chains containing the typical electron transport proteins that we have seen in aerobic respiration, photosynthesis, and chemolithotrophy—cytochromes, quinones, iron–sulfur proteins, and the like. In some organisms, such as the denitrifying bacteria,

anaerobic respiration competes with aerobic respiration. In such cases, if O_2 is present, the organism will preferentially respire aerobically. Many other organisms that conserve energy through anaerobic respiration are obligate anaerobes, which are unable to respire O_2 and may even be killed by it.

Alternative Electron Acceptors and the Redox Tower

The energy released from the oxidation of an electron donor using O_2 as electron acceptor is greater than if the same compound is oxidized with an alternate electron acceptor (Figure 3.9). These energy differences are clearly apparent from the reduction potentials of each acceptor (Figure 13.39). Because the O_2/H_2O

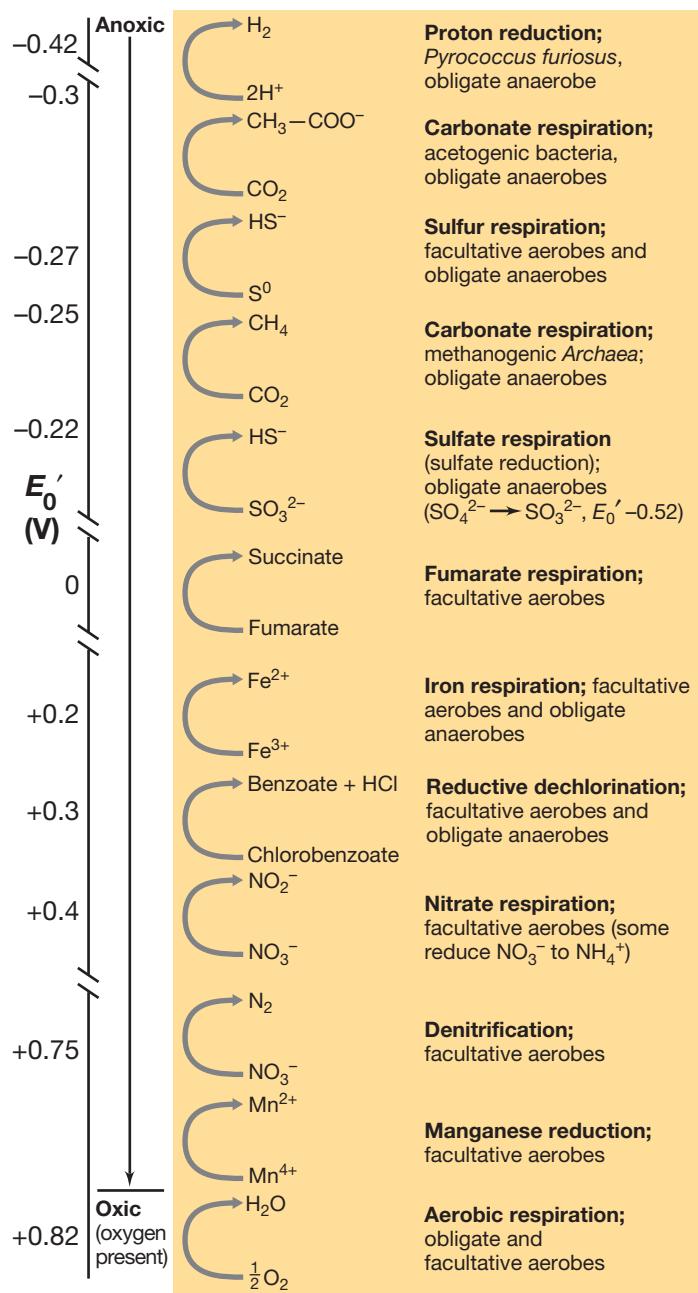

Figure 13.39 Major forms of anaerobic respiration. The redox couples are arranged in order from most electronegative E_0' (top) to most electropositive E_0' (bottom). See Figure 3.9 to compare how the energy yields of these anaerobic respirations vary.

couple is most electropositive, more energy is available when O_2 is used as a terminal electron acceptor than when any other acceptor is used. This is why aerobic respiration is the dominant process and occurs to the exclusion of anaerobic respiration in an organism in which both processes are possible. Other electron acceptors that are fairly near the O_2/H_2O couple are manganic ion (Mn^{4+}), ferric iron (Fe^{3+}), nitrate (NO_3^-), and nitrite (NO_2^-). Examples of more electronegative acceptors are sulfate (SO_4^{2-}), elemental sulfur (S^0), and carbon dioxide (CO_2); organisms that use these acceptors are typically not facultative aerobes and are thus locked into an anaerobic lifestyle. A summary of the most common types of anaerobic respiration is given in Figure 13.39.

Assimilative and Dissimilative Reductions

Inorganic compounds such as NO_3^- , SO_4^{2-} , and CO_2 are reduced by many organisms as sources of cellular nitrogen, sulfur, and carbon, respectively. The end products of such reductions are the amino groups ($-NH_2$) of amino acids and other nitrogenous substances, the sulfhydryl groups ($-SH$) of several sulfur-containing compounds in the cell, and the organic carbon found in all cell constituents, respectively. When NO_3^- , SO_4^{2-} , or CO_2 is reduced for these purposes, it is said to be *assimilated*, and the reduction process is called *assimilative* reduction. Assimilative metabolism is conceptually and physiologically quite different from the reduction of NO_3^- , SO_4^{2-} , and CO_2 during energy conservation in anaerobic metabolism. To distinguish these two kinds of reductions, use of these compounds as electron acceptors for energy purposes is called *dissimilative* reduction.

Assimilative and dissimilative metabolisms differ markedly. In assimilative metabolism, only enough of the compound (NO_3^- , SO_4^{2-} , or CO_2) is reduced to satisfy the needs for biosynthesis, and the products are eventually converted to cell material in the form of macromolecules and other biomolecules. By contrast, in dissimilative metabolism, a large amount of the electron acceptor is reduced, and the reduced product remains a small molecule (N_2 , H_2S , or CH_4 , for example) and is excreted from the cell.

Most organisms carry out an assortment of assimilative metabolisms, whereas a more restricted group catalyze dissimilative metabolisms. As for electron donors, virtually any organic compound that can be degraded aerobically can also be degraded under anoxic conditions by one or more forms of anaerobic respiration. Moreover, several inorganic substances can also be electron donors as long as the E_0' of their redox couple is more electronegative than that of the acceptor couple in the anaerobic respiration (Figure 13.39).

MINIQUIZ

- How does aerobic respiration differ from anaerobic respiration and why does aerobic respiration repress anaerobic respiration?
- With H_2 as an electron donor, why is the reduction of NO_3^- a more favorable reaction than the reduction of S^0 ?

13.17 Nitrate Reduction and Denitrification

Inorganic nitrogen compounds are some of the most common electron acceptors in anaerobic respiration. Table 13.7 summarizes the relevant forms of inorganic nitrogen with their oxidation states.

Table 13.7 Oxidation states of key nitrogen compounds

Compound	Oxidation state of N atom
Organic N ($-NH_2$)	-3
Ammonia (NH_3)	-3
Nitrogen gas (N_2)	0
Nitrous oxide (N_2O)	+1 (average per N)
Nitric oxide (NO)	+2
Nitrite (NO_2^-)	+3
Nitrogen dioxide (NO_2)	+4
Nitrate (NO_3^-)	+5

One of the most common alternative electron acceptors for dissimilative purposes is nitrate (NO_3^-), which can be reduced with two electrons to nitrite (NO_2^-), or reduced further to nitric oxide (NO), nitrous oxide (N_2O), and dinitrogen (N_2). Because NO, N_2O , and N_2 are all gases, they can be lost from the environment, and their biological production is called **denitrification** (Figure 13.40). For agricultural purposes denitrification is a detrimental process,

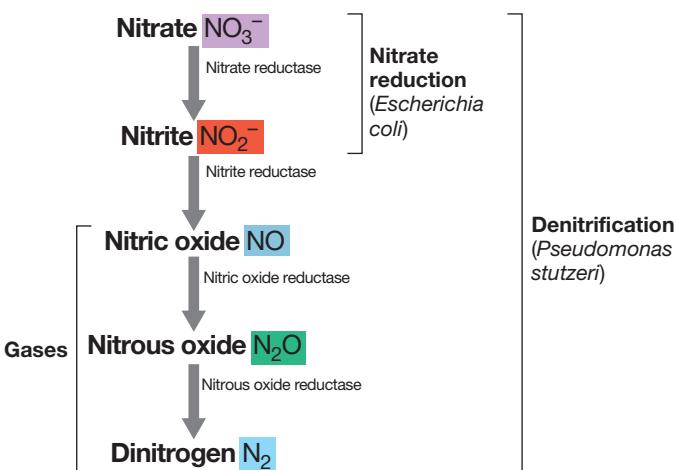

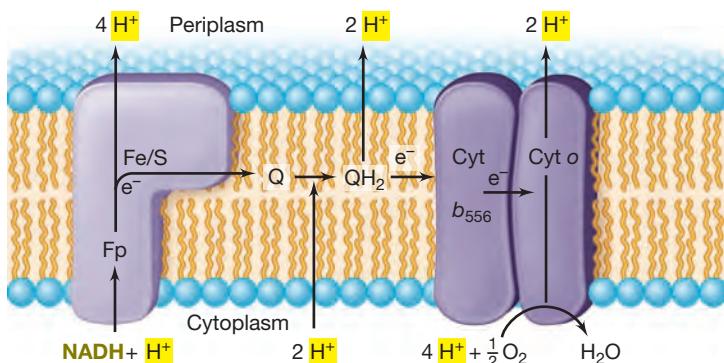

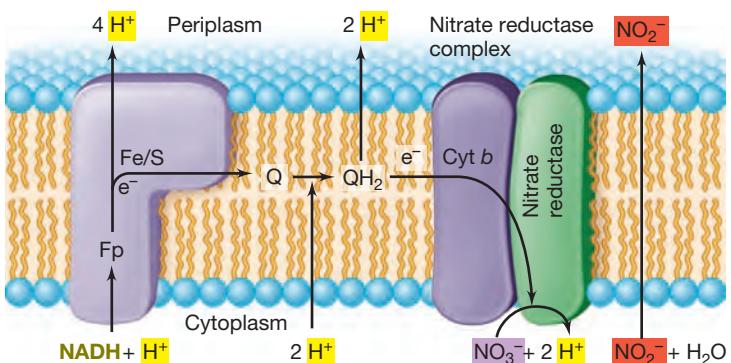

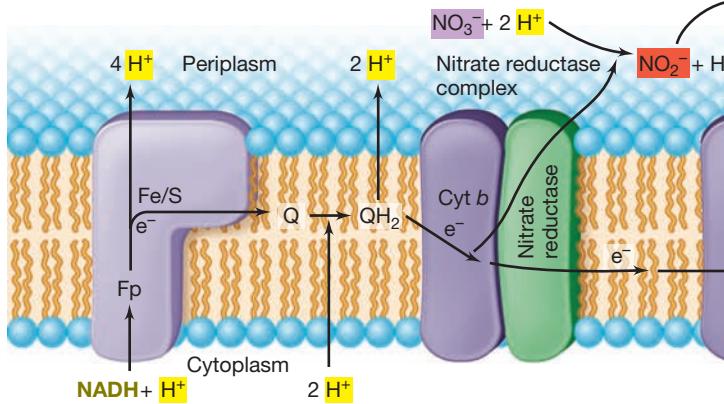

Figure 13.40 Steps in the dissimilative reduction of nitrate. Some organisms can carry out only the first step. All enzymes involved are derepressed by anoxic conditions. Also, some prokaryotes are known that can reduce NO_3^- to NH_4^+ in dissimilative metabolism. Note that colors used here match those used in Figure 13.41.

(a) Aerobic respiration

(b) Nitrate reduction

(c) Denitrification

Figure 13.41 Respiration and nitrate-based anaerobic respiration. Electron transport processes in the membrane of *Escherichia coli* when (a) O_2 or (b) NO_3^- is used as an electron acceptor and NADH is the electron donor. Fp, flavoprotein; Q, ubiquinone. Under high-oxygen conditions, the sequence of carriers is

cyt b_{556} cyt o O_2 . However, under low-oxygen conditions (not shown), the sequence is cyt b_{568} cyt d O_2 . Note how more protons are translocated per two electrons oxidized aerobically during electron transport reactions than anaerobically with NO_3^- as electron acceptor, because the aerobic terminal

oxidase (cyt o) pumps two protons. (c) Scheme for electron transport in membranes of *Pseudomonas stutzeri* during denitrification. Nitrate and nitric oxide reductases are integral membrane proteins, whereas nitrite and nitrous oxide reductases are periplasmic enzymes.

as it removes nitrate—often added in fertilizers—from the soil. However, for a process like sewage treatment, denitrification is beneficial because it removes fixed nitrogen, a major trigger of algal growth in rivers or lakes, from the sewage effluent (Sections 19.8, 21.6, and 21.7).

Denitrifying Microorganisms

Most denitrifying *Bacteria* are phylogenetically *Proteobacteria* and are facultative aerobes physiologically. Aerobic respiration occurs when O_2 is present, even if NO_3^- is also present in the medium. Many denitrifying bacteria also reduce other electron acceptors anaerobically, such as Fe^{3+} and certain organic electron acceptors (Section 13.21), and some denitrifiers can even ferment. Thus, denitrifying bacteria are metabolically diverse in terms of alternative energy-generating mechanisms. Some species of *Archaea* can grow anaerobically by nitrate reduction to nitrite, and several can also denitrify. Interestingly, at least one eukaryote has also been shown to be a denitrifier. The protist *Globulimina pseudospinescens*, a shelled amoeba (a foraminiferan, Section 17.7), can denitrify and likely employs this form of metabolism in its habitat, anoxic marine sediments.

Biochemistry of Dissimilative Nitrate Reduction

The electron transport pathways of aerobic respiration, nitrate respiration, and denitrification are compared in Figure 13.41. The enzyme that catalyzes the first step of dissimilative nitrate reduction is *nitrate reductase*, a molybdenum-containing membrane-integrated enzyme whose synthesis is repressed by O_2 . All subsequent enzymes of the pathway are coordinately regulated and thus also repressed by O_2 . But, in addition to anoxic conditions, nitrate must also be present before these enzymes are fully expressed.

The first product of nitrate reduction is NO_2^- , and the enzyme nitrite reductase reduces this to NO (Figure 13.41c). Some organisms can reduce NO_2^- to ammonia (NH_3) in a dissimilative process, but the production of gaseous products—*denitrification*—is of greatest global significance. This is because some products of denitrification, in particular N_2O and NO, are of environmental significance. N_2O can be converted to NO by sunlight, and NO reacts with and consumes ozone (O_3) in the upper atmosphere to form NO_2^- . When it rains, NO_2^- returns to Earth as nitrous acid (HNO_2) in *acid rain*.

The biochemistry of dissimilative nitrate reduction has been studied in detail in *Escherichia coli*, in which NO_3^- is reduced only to NO_2^- , and *Paracoccus denitrificans* and *Pseudomonas stutzeri*, in which denitrification occurs. The *E. coli* nitrate reductase accepts electrons from a *b*-type cytochrome, and a comparison of the electron transport chains in aerobic versus nitrate-respiring cells of *E. coli* is shown in Figure 13.41a, b. Because of the reduction potential of the NO_3^-/NO_2^- couple (+0.43 V), fewer protons are pumped during nitrate reduction than in aerobic respiration (O_2/H_2O , +0.82 V). In *P. denitrificans* and *P. stutzeri*, nitrogen oxides are formed from NO_2^- by the enzymes nitrite reductase, nitric oxide reductase, and nitrous oxide reductase. During these electron transport reactions, a proton motive force is established, and ATPase couples this to the synthesis of ATP (Figure 13.41c).

MINIQUIZ

- For *Escherichia coli*, why is more energy released in aerobic respiration than during NO_3^- reduction?
- How do the products of NO_3^- reduction differ between *E. coli* and *Pseudomonas*?
- Where is the dissimilative nitrate reductase found in the cell? What unusual metal does it contain?

13.18 Sulfate and Sulfur Reduction

Several inorganic sulfur compounds are important electron acceptors in anaerobic respiration. A summary of the oxidation states of key sulfur compounds is given in Table 13.8. Sulfate (SO_4^{2-}), the most oxidized form of sulfur, is reduced by the *sulfate-reducing bacteria*, a highly diverse group of obligately anaerobic bacteria widely distributed in nature. The end product of sulfate reduction is hydrogen sulfide, H_2S , an important natural product that participates in many biogeochemical processes (Sections 20.4 and 21.10). Species in the genus *Desulfovibrio*, in particular *D. desulfuricans*, have been widely studied, and the general properties of sulfate-reducing bacteria are discussed in Section 14.9.

As with nitrate (Section 13.17), it is necessary to distinguish between assimilative and dissimilative sulfate metabolism. Many organisms, including plants, algae, fungi, and most prokaryotes, incorporate sulfate for biosynthetic sulfur needs; this is assimilative metabolism. By contrast, the ability to use sulfate as an electron acceptor for energy conservation requires its large-scale reduction and is restricted to the sulfate-reducing bacteria. H_2S is produced on a very large scale by these organisms and is excreted from the cell, free to be oxidized by air, used by other organisms, or combined with metals to form metal sulfides.

Table 13.8 Sulfur compounds and electron donors for sulfate reduction

Compound	Oxidation state of S atom
<i>Oxidation states of key sulfur compounds</i>	
Organic S (R—SH)	-2
Sulfide (H_2S)	-2
Elemental sulfur (S^0)	0
Thiosulfate ($-S-SO_3^{2-}$)	-2/+6
Sulfur dioxide (SO_2)	+4
Sulfite (SO_3^{2-})	+4
Sulfate (SO_4^{2-})	+6
<i>Some electron donors used for sulfate reduction</i>	
H_2	Acetate
Lactate	Propionate
Pyruvate	Butyrate
Ethanol and other alcohols	Long-chain fatty acids
Fumarate	Benzoate
Malate	Indole
Choline	Various hydrocarbons

Biochemistry and Energetics of Sulfate Reduction

As the reduction potentials in Table A1.2 and Figure 13.39 show, SO_4^{2-} is a much less favorable electron acceptor than is O_2 or NO_3^- . However, sufficient free energy to make ATP is available from sulfate reduction when an electron donor is oxidized that yields NADH or FADH. Table 13.8 lists some of the electron donors used by sulfate-reducing bacteria. Hydrogen (H_2) is used by virtually all species, whereas the use of other donors is more restricted. For example, lactate and pyruvate are widely used by species found in freshwater anoxic environments, while acetate and longer-chain fatty acids are widely used by marine sulfate-reducing bacteria. Many morphological and physiological types of sulfate reducing bacteria are known, and with the exception of *Archaeoglobus* (► Section 16.5), a genus of *Archaea*, all known sulfate reducers are *Bacteria* (► Section 14.9).

The reduction of SO_4^{2-} to H_2S requires eight electrons and proceeds through a number of intermediate stages. The reduction of SO_4^{2-} requires that it first be *activated* in a reaction requiring ATP. The enzyme ATP sulfurylase catalyzes the attachment of SO_4^{2-} to a phosphate of ATP, forming *adenosine phosphosulfate* (APS) as shown in Figure 13.42a. Activation raises the extremely electronegative E_0' of the $\text{SO}_4^{2-}/\text{SO}_3^{2-}$ couple (-0.52 V) to near 0 V, making reduction of the sulfate moiety possible with electron donors such as NADH (-0.32 V).

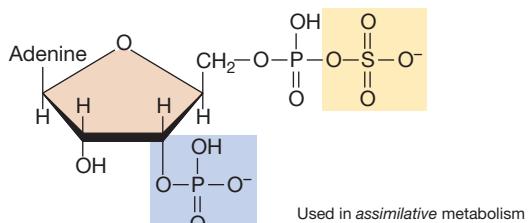

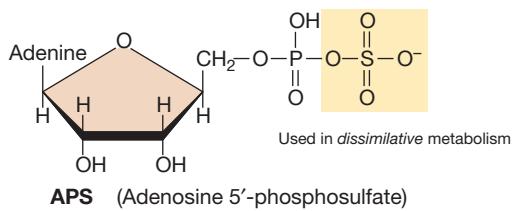

In dissimilative sulfate reduction, the SO_4^{2-} in APS is reduced directly to sulfite (SO_3^{2-}) by the enzyme APS reductase with the release of AMP. In assimilative reduction, another phosphate is added to APS to form *phosphoadenosine phosphosulfate* (PAPS) (Figure 13.42a), and only then is the SO_4^{2-} reduced. However, in both cases the product of sulfate reduction is sulfite (SO_3^{2-}). Once SO_3^{2-} is formed, it is reduced to H_2S by the activity of the enzyme sulfite reductase (Figures 13.42 and 13.43).

During dissimilative sulfate reduction, electron transport reactions lead to a proton motive force and this drives ATP synthesis by ATPase. A major electron carrier in this process is *cytochrome c₃*, a periplasmic low-potential cytochrome (Figure 13.43). Cytochrome *c₃* accepts electrons from a periplasmic hydrogenase and transfers these electrons to a membrane-associated protein complex. This complex, called *Hmc*, carries the electrons across the cytoplasmic membrane and transfers them to APS reductase and sulfite reductase, cytoplasmic enzymes that generate sulfite and sulfide, respectively (Figure 13.43).

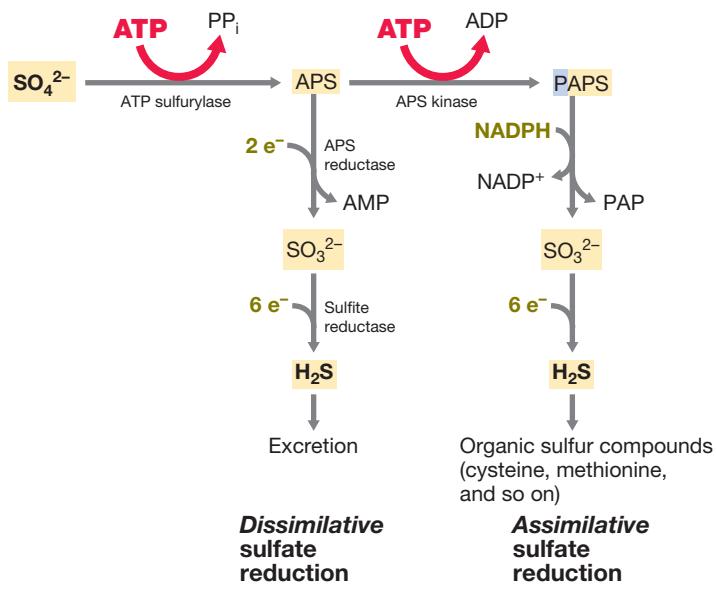

The enzyme hydrogenase plays a central role in sulfate reduction whether *Desulfovibrio* is growing on H_2 , *per se*, or on an organic compound such as lactate. This is because lactate is converted through pyruvate to acetate (much of the latter is either excreted or assimilated into cell material because *Desulfovibrio* cannot oxidize acetate to CO_2) with the production of H_2 . This H_2 crosses the cytoplasmic membrane and is oxidized by the periplasmic hydrogenase to electrons, which are fed back into the system, and protons, which establish the proton motive force (Figure 13.43). A net of one ATP is produced for each SO_4^{2-} reduced to HS^- by H_2 , and the reaction is

When lactate or pyruvate is the electron donor, ATP is produced not only from the proton motive force, but also by substrate-level

(a)

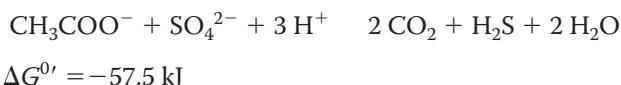

(b)

Figure 13.42 Biochemistry of sulfate reduction: Activated sulfate. (a) Two forms of active sulfate can be made, adenosine 5'-phosphosulfate (APS) and phosphoadenosine 5'-phosphosulfate (PAPS). Both are derivatives of adenosine diphosphate (ADP), with the second phosphate of ADP being replaced by SO_4^{2-} . (b) Schemes of assimilative and dissimilative sulfate reduction.

phosphorylation during the oxidation of pyruvate (via acetyl-CoA and acetyl phosphate, Table 13.3) to acetate plus CO_2 (Figure 13.43).

Marine but not freshwater species of sulfate-reducing bacteria can couple the oxidation of acetate and longer-chain fatty acids to CO_2 and sulfate reduction:

The mechanism for acetate oxidation in most of these species is the *acetyl-CoA pathway*, a series of reversible reactions used by many anaerobes for acetate synthesis or acetate oxidation

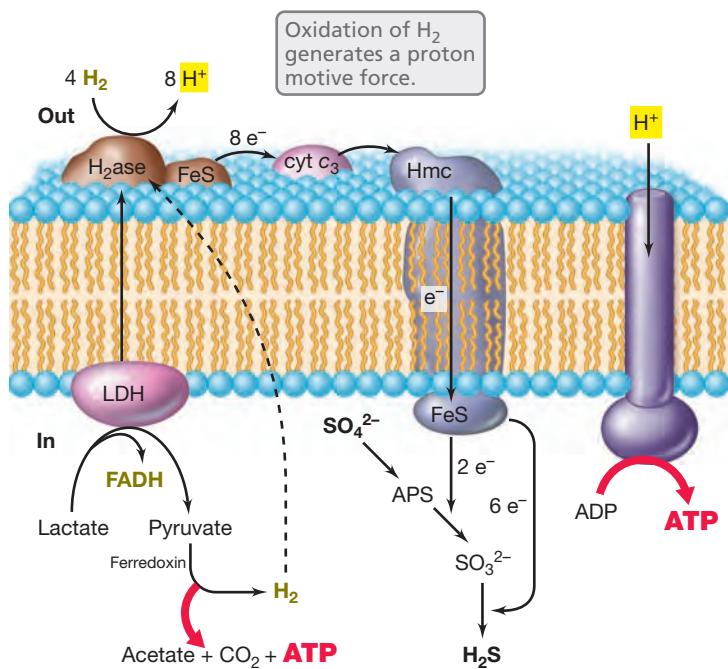

Figure 13.43 Electron transport and energy conservation in sulfate-reducing bacteria. In addition to external H_2 , H_2 originating from the catabolism of organic compounds such as lactate and pyruvate can fuel hydrogenase. The enzymes hydrogenase (H_2ase), cytochrome (cyt) c_3 , and a cytochrome complex (Hmc) are periplasmic proteins. A separate protein shuttles electrons across the cytoplasmic membrane from Hmc to a cytoplasmic iron–sulfur protein (FeS) that supplies electrons to APS reductase (forming SO_3^{2-}) and sulfite reductase (forming H_2S , Figure 14.14b). LDH, lactate dehydrogenase.

(Section 13.19). A few sulfate-reducing bacteria can also grow autotrophically with H_2 . Under these conditions, the organisms use the acetyl-CoA pathway for making acetate as a carbon source. Such species can be cultured in a completely organic-free medium containing only mineral salts, sulfate, CO_2 , and H_2 .

Special Metabolisms of Sulfate-Reducing Bacteria

Certain species of sulfate-reducing bacteria can catalyze unusual reactions not characteristic of all species. These include *disproportionation*, *phosphite oxidation*, and *sulfur reduction*.

Disproportionation is a process in which one molecule of a substance is oxidized while a second molecule is reduced, ultimately forming two different products. For example, *Desulfovibrio sulfodismutans* can disproportionate thiosulfate ($\text{S}-\text{SO}_3^{2-}$) as follows:

Note that in this reaction, the right-hand sulfur atom of $\text{S}-\text{SO}_3^{2-}$ is oxidized (forming SO_4^{2-}), while the left-hand atom is reduced (forming H_2S). The free energy available from the oxidation of thiosulfate by *D. sulfodismutans* is insufficient to couple to substrate-level phosphorylation and so instead is coupled to a proton pump that establishes a proton motive force. Other reduced sulfur compounds such as sulfite (SO_3^{2-}) and sulfur (S^0) can also be disproportionated. These forms of sulfur metabolism allow sulfate-reducing bacteria to recover energy from sulfur intermediates produced from the oxidation of H_2S by sulfur chemolithotrophs that coexist with them in nature and also from

intermediates generated in their own metabolism during SO_4^{2-} reduction (Figure 13.42b).

At least one sulfate-reducing bacterium can couple phosphite (HPO_3^{2-}) oxidation to SO_4^{2-} reduction. This chemolithotrophic reaction yields phosphate and sulfide:

This bacterium, *Desulfotignum phosphitoxidans*, is an autotroph and a strict anaerobe, which by necessity it must be because phosphite spontaneously oxidizes in air. The natural sources of phosphite are likely to be organophosphorous compounds called *phosphonates* that are generated from the anoxic degradation of various organic phosphorous compounds. Along with sulfur disproportionation (also a chemolithotrophic process) and H_2 utilization, phosphite oxidation underscores the diversity of chemolithotrophic reactions carried out by sulfate-reducing bacteria.

Sulfur Reduction

Besides sulfate, most sulfate-reducing bacteria can also conserve energy from the reduction of elemental sulfur to sulfide ($\text{S}^0 + 2 \text{H}^- \rightarrow \text{H}_2\text{S}$). In addition, however, a variety of non-sulfate-reducing *Bacteria* and *Archaea* can also reduce sulfur in anaerobic respiration. These are the *sulfur-reducing* prokaryotes, a large group that typically coexists with sulfate-reducing bacteria in anoxic, sulfur-rich habitats.

The electrons for sulfur reduction come from H_2 or any of a number of organic compounds. For example, *Desulfuromonas acetoxidans* can oxidize acetate or ethanol to CO_2 coupled to the reduction of S^0 to H_2S . Sulfur reducers lack the capacity to activate sulfate to APS (Figure 13.42), and presumably this is what excludes them from using SO_4^{2-} as an electron acceptor. *Desulfuromonas* contains several cytochromes, including an analog of cytochrome c_3 , a key electron carrier in sulfate-reducing bacteria. In culture some sulfur reducers including *Desulfuromonas* can also use Fe^{3+} as an electron acceptor in place of sulfur, but sulfur is probably the major electron acceptor used in nature. It is the reduction of oxidized sulfur compounds and the production of H_2S that connects the sulfur- and sulfate-reducing bacteria in an ecological sense.

MINIQUIZ

- How is SO_4^{2-} converted to SO_3^{2-} during dissimilative sulfate reduction? Physiologically, how does *Desulfuromonas* differ from *Desulfovibrio*?
- Contrast the growth of *Desulfovibrio* on H_2 versus lactate as electron donors.
- Give an example of sulfur disproportionation.

13.19 Acetogenesis

Carbon dioxide (CO_2) is typically abundant in anoxic habitats because it is a major product of the energy metabolisms of anaerobic chemoorganotrophs. Two major groups of strictly anaerobic prokaryotes use CO_2 as an electron acceptor for energy conservation. One of these is the *acetogens*, and we discuss them here. The other group, the *methanogens*, are considered in the

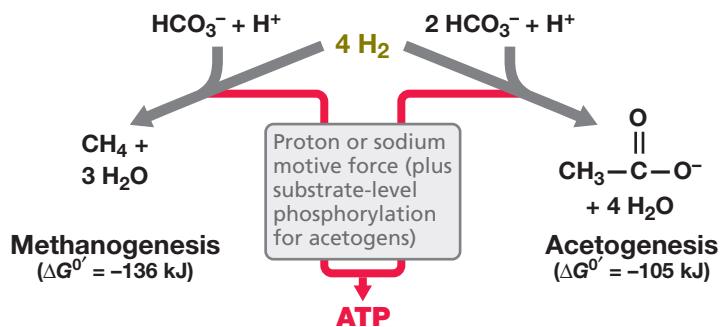

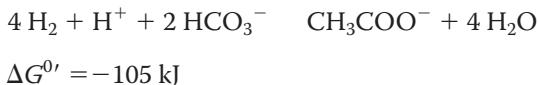

Figure 13.44 The contrasting processes of methanogenesis and acetogenesis. Note the difference in free energy released in the reactions.

next section. Hydrogen (H_2) is a major electron donor for both of these organisms, and an overview of their energy metabolism, **acetogenesis** and **methanogenesis**, is shown in **Figure 13.44**. Both processes are linked to ion pumps, of either protons (H^+) or sodium ions (Na^+), as the mechanism of energy conservation, and these pumps fuel ATPases in the membrane. The pathway of acetogenesis also conserves energy in a substrate-level phosphorylation reaction.

Organisms and Pathway

Acetogens carry out the reaction

In addition to H_2 , electron donors for acetogenesis include various C_1 compounds such as methanol, several methoxylated aromatic compounds, sugars, organic and amino acids, alcohols, and certain nitrogen bases, depending on the organism. Many acetogens can also reduce nitrate (NO_3^-) and thiosulfate ($S_2O_3^{2-}$) in dissimilative metabolisms. However, CO_2 reduction is the major reaction of ecological relevance.

A major unifying thread among acetogens is the pathway of CO_2 reduction. Acetogens reduce CO_2 to acetate by the **acetyl-CoA pathway**, the major pathway in obligate anaerobes for the production or oxidation of acetate (see Figure 13.45). **Table 13.9** lists the groups that produce or oxidize acetate via the acetyl-CoA pathway. Acetogens such as *Acetobacterium woodii* and *Clostridium aceticum* can grow either chemoorganotrophically by fermentation of sugars (reaction 1) or chemolithotrophically and autotrophically through the reduction of CO_2 to acetate with H_2 as electron donor (reaction 2). In either case, the sole product is acetate:

Acetogens catabolize glucose by way of glycolysis, converting glucose into two molecules of pyruvate and two molecules of NADH. From this point, two molecules of acetate are produced:

The third acetate of reaction (1) comes from reaction (2), using the two molecules of CO_2 generated in reaction (3), plus the 2

Most acetogenic bacteria that produce acetate in energy metabolism are gram-positive *Bacteria*, and many are species of the genera *Clostridium* or *Acetobacterium* (Table 13.9). A few other gram-positive and many different gram-negative *Bacteria* and *Archaea* use the acetyl-CoA pathway for autotrophic purposes, reducing CO_2 to acetate as a source of cell carbon. The acetyl-CoA pathway supports autotrophic growth of both autotrophic sulfate-reducing bacteria and methanogens. In addition, some prokaryotes employ the acetyl-CoA pathway not to make acetate for cell carbon purposes but in the reverse direction as a means of oxidizing acetate to CO_2 . These include acetate-utilizing methanogens and sulfate-reducing bacteria.

The Acetyl-CoA Pathway and Energy Conservation in Acetogenesis

Unlike other autotrophic pathways (Section 13.5), the acetyl-CoA pathway of CO_2 fixation is not a cycle. Instead, it catalyzes the reduction of CO_2 along two linear pathways, with one molecule of CO_2 being reduced to the methyl group of acetate and the other to the carbonyl group of acetate. These two C_1 units are then combined to form acetyl-CoA (Figure 13.45).

A key enzyme of the acetyl-CoA pathway is *carbon monoxide (CO) dehydrogenase*. CO dehydrogenase contains Ni, Zn, and Fe as cofactors and catalyzes the reaction

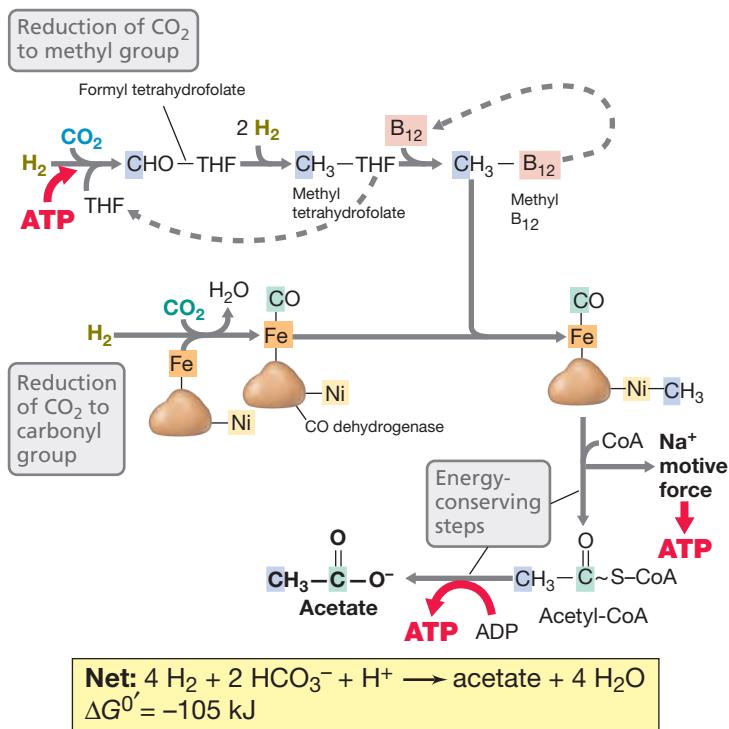

Figure 13.45 Reactions of the acetyl-CoA pathway. Carbon monoxide is bound to Fe and the CH₃ group to nickel in carbon monoxide dehydrogenase. Note that the formation of acetyl-CoA is coupled to the generation of a Na⁺ motive force that drives ATP synthesis, and that ATP is also synthesized in the conversion of acetyl-CoA to acetate. THF, tetrahydrofolate; B₁₂, vitamin B₁₂ in an enzyme-bound intermediate.

The CO produced by CO dehydrogenase ends up as the *carbonyl* carbon of acetate (Figure 13.45). The methyl group of acetate originates from the reduction of CO₂ by a series of reactions in which the coenzyme *tetrahydrofolate* plays a major role (Figure 13.45). The methyl group is then transferred from tetrahydrofolate to an enzyme that contains vitamin B₁₂ as cofactor, and in the final step of the pathway, the methyl group is combined with CO by CO dehydrogenase to form acetyl-CoA. Conversion of acetyl-CoA to acetate plus ATP completes the reaction series (Figure 13.45).

Energy conservation in acetogenesis results from both substrate-level phosphorylation and an ion pump. One ATP is produced during the conversion of each acetyl-CoA to acetate plus ATP (Figure 13.45 and Table 13.3). In addition, however, the synthesis of acetyl-CoA from its component parts, CO and CH₃, releases free energy, some of which is conserved by a Na⁺ pump that couples this to formation of a sodium motive force. This energized state of the membrane drives ATP synthesis from a Na⁺-translocating ATPase. Recall that we saw a similar energetic strategy with the succinate fermenter *Propionigenium*, where succinate decarboxylation was linked to Na⁺ export and a Na⁺-driven ATPase (Section 13.14). Acetogens need the ATP resulting from this reaction to have a net energy gain since the single ATP made by substrate-level phosphorylation is consumed in the first step of the acetyl-CoA pathway (Figure 13.45).

MINIQUIZ

- Draw the structure of acetate and identify the carbonyl group and the methyl group. What key enzyme of the acetyl-CoA pathway produces the carbonyl group of acetate?
- How do acetogens make ATP from the synthesis of acetate?
- If fructose catabolism by glycolysis yields only two acetates, how does *Clostridium aceticum* produce three acetates from fructose?

13.20 Methanogenesis

The biological production of methane—*methanogenesis*—is catalyzed by a group of strictly anaerobic *Archaea* called the **methanogens**. These organisms are present in freshwater sediments (Figure 13.46), sewage sludge digesters (Section 21.6) and other bioreactors, and the intestines of warm-blooded animals, including humans. The reduction of CO₂ by H₂ to form methane (CH₄) is a major pathway of methanogenesis and is a form of anaerobic respiration. We consider the basic properties, phylogeny, and taxonomy of the methanogens in Section 16.2. Here we focus on the bioenergetics and unique biochemistry of methanogenesis.

C₁ Carriers in Methanogenesis

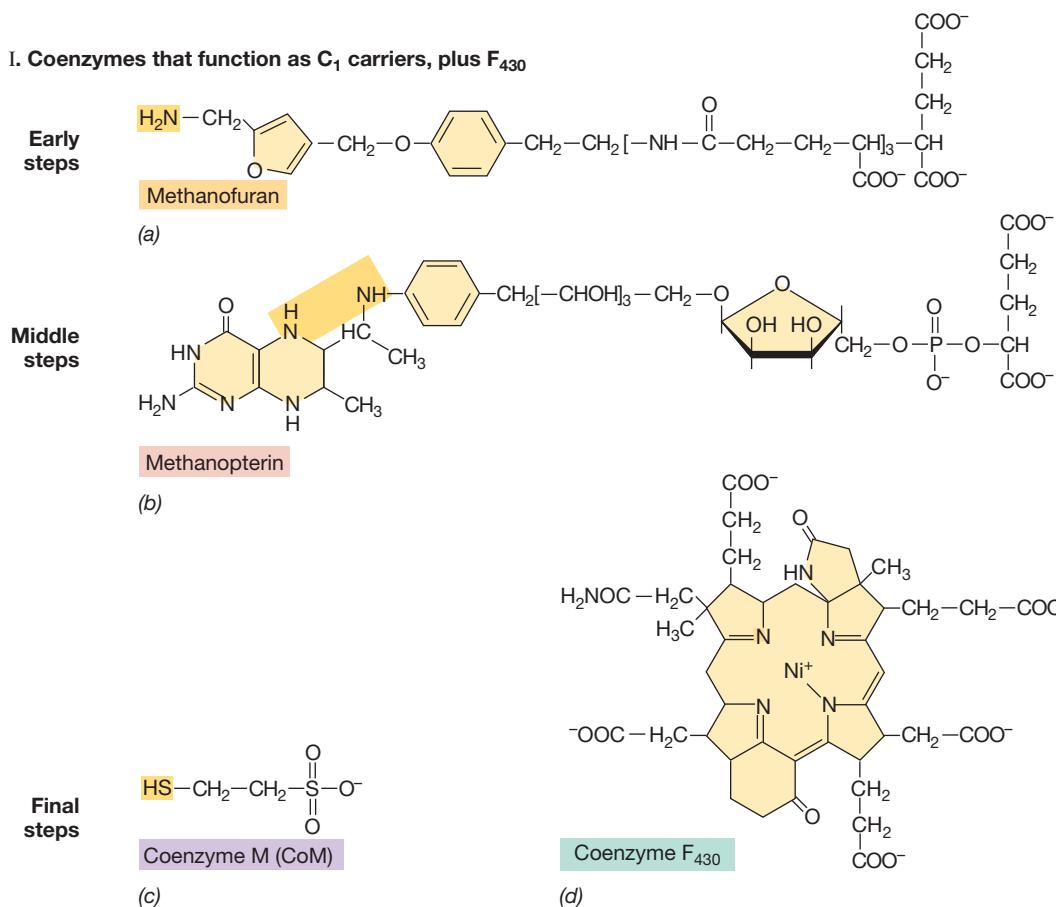

Methanogenesis from CO₂ requires eight electrons, and these electrons are added two at a time. This leads to intermediary oxidation states of the carbon atom from +4 (CO₂) to -4 (CH₄). Several novel coenzymes participate in methanogenesis and can be divided into two classes: (1) those that carry the C₁ unit along its path of enzymatic reduction (*C₁ carriers*) and (2) those that donate electrons (*redox coenzymes*) (Figure 13.47). We consider the C₁ carriers first.

The coenzyme *methanofuran* is required for the first step of methanogenesis. Methanofuran contains the five-membered

John A. Breznak

Figure 13.46 Methanogenesis. Methane is collected in a funnel from swamp sediments where it was produced by methanogens and then ignited in a demonstration experiment.

II. Coenzymes that function as electron donors

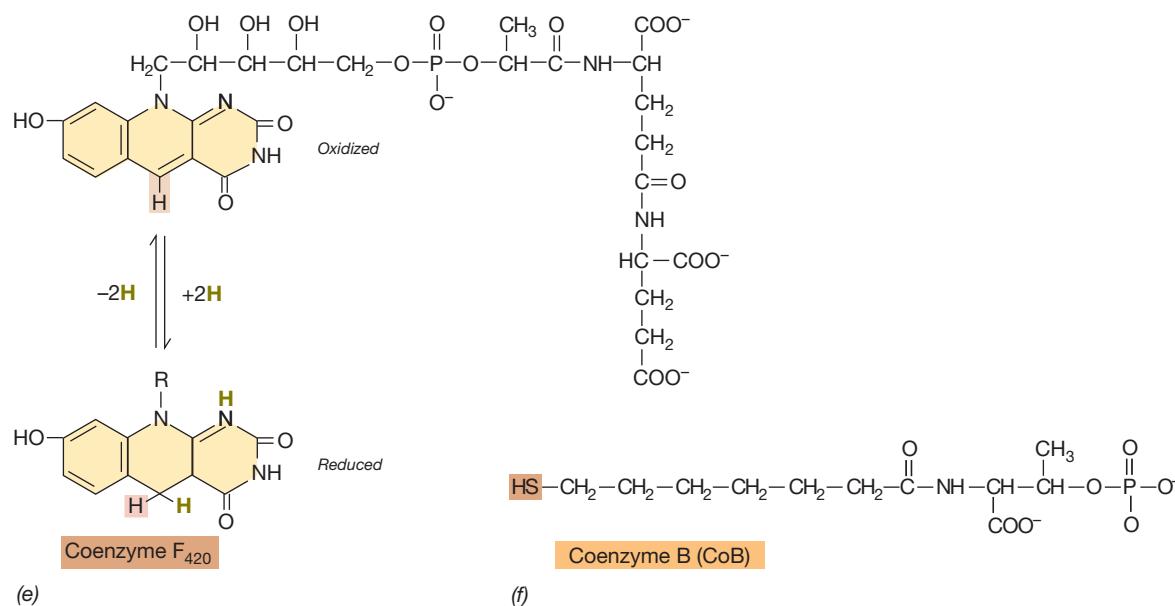

Figure 13.47 Coenzymes of methanogenesis. The atoms shaded in brown or yellow are the sites of oxidation–reduction reactions (brown in F_{420} and CoB) or the position to which the C₁ moiety is attached during the reduction of CO₂ to CH₄ (yellow in methanofuran, methanopterin, and coenzyme M). The colors used to highlight a particular coenzyme (CoB is orange, for example) are also in Figures 13.49 and 13.50 to follow the reactions in each figure. Coenzyme F₄₃₀ participates in the terminal step of methanogenesis catalyzed by the enzyme methyl reductase, with the methyl group binding to Ni⁺ in F₄₃₀ prior to its reduction to CH₄.

furan ring and an amino nitrogen atom that binds CO_2 (Figure 13.47a). *Methanopterin* (Figure 13.47b) is a methanogenic coenzyme that resembles the vitamin folic acid and plays a role analogous to that of tetrahydrofolate (a coenzyme that participates in C_1 transformations; see Figure 13.45) by carrying the C_1 unit in the intermediate steps of CO_2 reduction to CH_4 . *Coenzyme M* (CoM) (Figure 13.47c) is required for the terminal step of methanogenesis, the reduction of the methyl group (CH_3) to CH_4 . Although not a C_1 carrier, the nickel (Ni^{2+})-containing tetrapyrrole *coenzyme F₄₃₀* (Figure 13.47d) also participates in the terminal step of methanogenesis as part of the methyl reductase enzyme complex (discussed later).

Redox Coenzymes

The coenzymes F_{420} and *7-mercaptopantothenoylthreonine phosphate* (also called coenzyme B, CoB) are electron donors in methanogenesis. Coenzyme F_{420} (Figure 13.47e) is a flavin derivative, structurally resembling the flavin coenzyme FMN (Figure 3.16). F_{420} plays a role in methanogenesis as the electron donor in several steps of CO_2 reduction (see Figure 13.49). Coenzyme F_{420} takes its name from the fact that its oxidized form absorbs light at 420 nm and fluoresces blue-green. Such fluorescence is useful for the microscopic identification of a methanogen (Figure 13.48). CoB is required for the terminal step of methanogenesis catalyzed by the *methyl reductase enzyme complex*. As shown in Figure 13.47f, the structure of CoB resembles the vitamin pantothenic acid, which is part of acetyl-CoA (Figure 3.12).

Methanogenesis from $\text{CO}_2 + \text{H}_2$

Electrons for the reduction of CO_2 to CH_4 typically come from H_2 , but a few other substrates can also supply the electrons for CO_2 reduction in some methanogens. Figure 13.49 shows the steps in CO_2 reduction by H_2 :

1. CO_2 is activated by a methanofuran-containing enzyme and reduced to the formyl level. The immediate electron donor is ferredoxin, a strong reductant with a reduction potential (E_0') near -0.4 V .

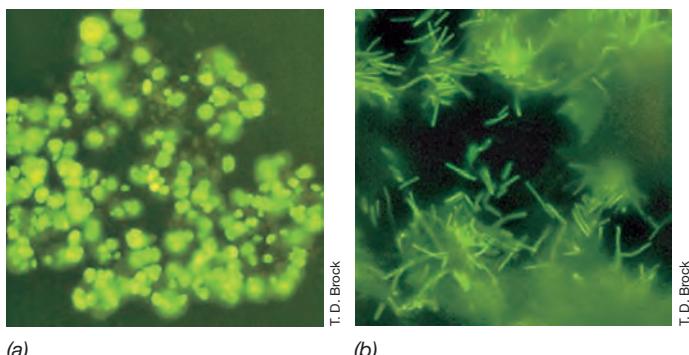

Figure 13.48 Fluorescence due to the methanogenic coenzyme F_{420} .

(a) Autofluorescence in cells of the methanogen *Methanosaerica barkeri* due to the presence of the unique electron carrier F_{420} . A single cell is about $1.7\text{ }\mu\text{m}$ in diameter. The organisms were made visible by excitation with blue light in a fluorescence microscope. (b) F_{420} fluorescence in cells of the methanogen *Methanobacterium formicicum*. A single cell is about $0.6\text{ }\mu\text{m}$ in diameter.

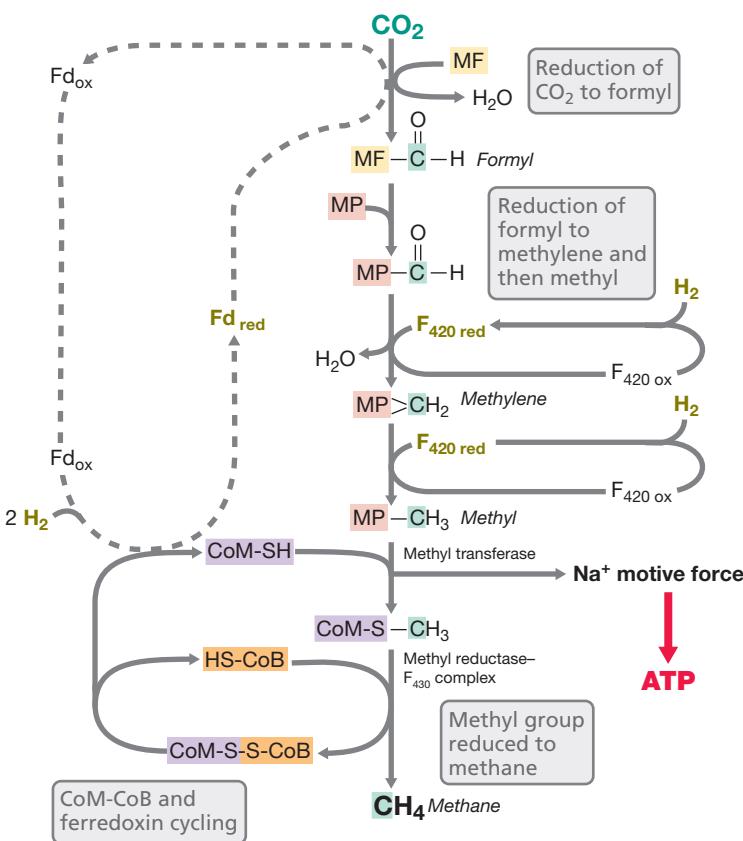

Figure 13.49 Methanogenesis from CO_2 plus H_2 . The carbon atom reduced is highlighted in green, and the source of electrons is highlighted in brown. See Figure 13.47 for the structures of the coenzymes. MF, methanofuran; MP, methanopterin; CoM, coenzyme M; F_{420} red, reduced coenzyme F_{420} ; F_{430} , coenzyme F_{430} ; Fd, ferredoxin; CoB, coenzyme B.

2. The formyl group is transferred from methanofuran to an enzyme containing methanopterin (MP in Figure 13.49). It is subsequently dehydrated and reduced in two separate steps (total of 4 H) to the methylene and methyl levels. The immediate electron donor here is reduced F_{420} .
3. The methyl group is transferred from methanopterin to an enzyme containing CoM by the enzyme methyl transferase. This reaction is highly exergonic and linked to the pumping of Na^+ across the membrane from inside to outside the cell.
4. Methyl-CoM is reduced to methane by methyl reductase. In this reaction, F_{430} and CoB are required. Coenzyme F_{430} removes the CH_3 group from $\text{CH}_3\text{-CoM}$, forming a $\text{Ni}^{2+}\text{-CH}_3$ complex. This complex is reduced by CoB, generating CH_4 and a disulfide complex of CoM and CoB (CoM-S-S-CoB).
5. Free CoM and CoB are regenerated by the reduction of CoM-S-S-CoB with H_2 . Simultaneously, ferredoxin is also reduced by H_2 and is thus ready for the first step of a new round of CO_2 reduction (Figure 13.49).

Methanogenesis from Methyl Compounds and Acetate

We will learn in Section 16.2 that methanogens can form CH_4 from certain methylated compounds such as methanol and acetate, as well as from $\text{H}_2 + \text{CO}_2$. Methanol is catabolized by donating

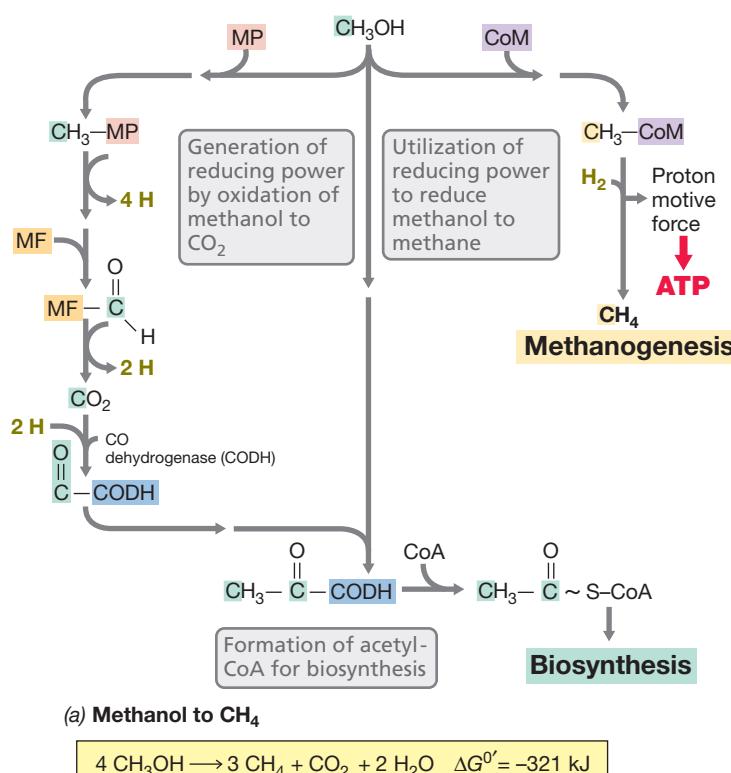

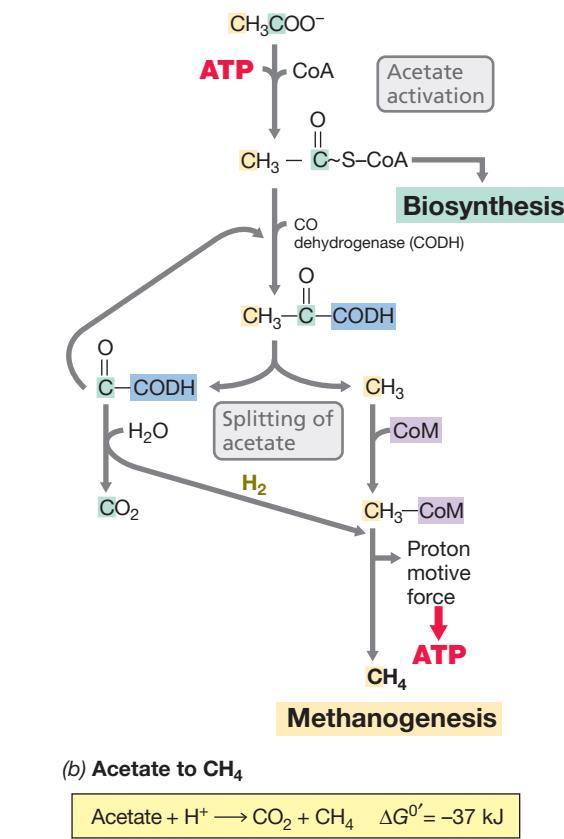

Figure 13.50 **Methanogenesis from methanol and acetate.** Both reaction series contain parts of the acetyl-CoA pathway. (a) For growth on methanol (CH_3OH), most CH_3OH carbon is converted to CH_4 , and a smaller amount is converted to either CO_2 or, via formation of acetyl-CoA, is assimilated into cell material. (b) Acetate is split into CH_4 and CO_2 . Abbreviations and color-coding are as in Figures 13.47 and 13.49; Corr, corrinoid-containing protein; CODH, carbon monoxide dehydrogenase.

methyl groups to an enzyme containing a corrinoid coenzyme to form CH_3 -corrinoid (Figure 13.50a). Corrinoids are the parent structures of compounds such as vitamin B_{12} and contain a porphyrin-like ring with a central cobalt atom. The CH_3 -corrinoid complex then transfers the methyl group to CoM, yielding $\text{CH}_3\text{-CoM}$ from which methane is formed in the same way as in the terminal step of CO_2 reduction. If H_2 is unavailable to drive the terminal step, some of the methanol must be oxidized to CO_2 to yield electrons for this purpose. This occurs by reversal of steps in methanogenesis (Figures 13.49 and 13.50a).

When acetate is the substrate for methanogenesis, it is first activated to acetyl-CoA, which interacts with CO dehydrogenase from the acetyl-CoA pathway (Section 13.19). The methyl group of acetate is then transferred to the corrinoid enzyme to yield CH_3 -corrinoid, and from there it follows the CoM-mediated terminal step of methanogenesis. Simultaneously, the CO group is oxidized to yield CO_2 and electrons (Figure 13.50b).

Autotrophy

Autotrophy in methanogens is supported by the acetyl-CoA pathway (Section 13.19). As we have just seen, parts of this pathway are already integrated into the catabolism of methanol and acetate by methanogens (Figure 13.50). However, methanogens lack the tetrahydrofolate-driven series of reactions of the acetyl-CoA pathway that lead to the production of a methyl

group (Figure 13.45). But this is not a problem because methanogens either derive methyl groups directly from their electron donors (Figure 13.50) or make methyl groups during methanogenesis from $\text{H}_2 + \text{CO}_2$ (Figure 13.49). Thus methanogens have access to abundant methyl groups, and the removal of some for biosynthesis is of little consequence. The carbonyl group of the acetate produced during autotrophic growth of methanogens is derived from the activity of carbon monoxide dehydrogenase, and the terminal step in acetate synthesis is as described for acetogens (Section 13.19 and Figure 13.45).

Energy Conservation in Methanogenesis

Under standard conditions, the free energy of methanogenesis from $\text{H}_2 + \text{CO}_2$ is -131 kJ/mol . Energy conservation in methanogenesis occurs at the expense of a proton or sodium motive force, depending on the substrate used; substrate-level phosphorylation (Section 13.11) does not occur. When methane is formed from $\text{H}_2 + \text{CO}_2$, ATP is produced from the sodium motive force generated during methyl transfer from MP to CoM by the enzyme methyl transferase (Figure 13.49). This energized state of the membrane then drives the synthesis of ATP, probably by way of an H^+ -linked ATPase following conversion of the sodium motive force into a proton motive force by exchange of Na^+ for H^+ across the membrane. The ATP yield per CH_4 produced is about 0.5.

In some methanogens, such as *Methanosarcina*, a nutritionally versatile organism that can make methane from acetate or methanol as well as from $\text{CO}_2 + \text{H}_2$, a different mechanism of energy conservation occurs from acetate or methanol, since the methyl transferase reaction cannot be coupled to the generation of a sodium motive force under these conditions. Instead, in acetate- and methanol-grown cells energy conservation is linked to the terminal step in methanogenesis, the methyl reductase step (Figures 13.49, 13.50, and Figure 13.51). In this reaction, the interaction of CoB with $\text{CH}_3\text{-CoM}$ and methyl reductase forms CH_4 and a heterodisulfide product, CoM-S—S-CoB. The latter is reduced by H_2 to regenerate CoM-SH and CoB-SH (Figure 13.49). This reduction, carried out by the enzyme *heterodisulfide reductase*, is exergonic and is coupled to the pumping of H^+ across the membrane (Figure 13.51). Electrons from H_2 flow to the heterodisulfide reductase through a membrane-associated electron carrier called *methanophenazine*. This compound is reduced by F_{420} and subsequently oxidized by a *b*-type cytochrome; the latter is the electron donor to the heterodisulfide reductase (Figure 13.51). Cytochromes and methanophenazine are absent in methanogens that can use only $\text{H}_2 + \text{CO}_2$ for methanogenesis.

In methanogens we thus see at least two mechanisms for energy conservation: (1) a proton motive force linked to the methylreductase reaction and used to drive ATP synthesis in acetate- or

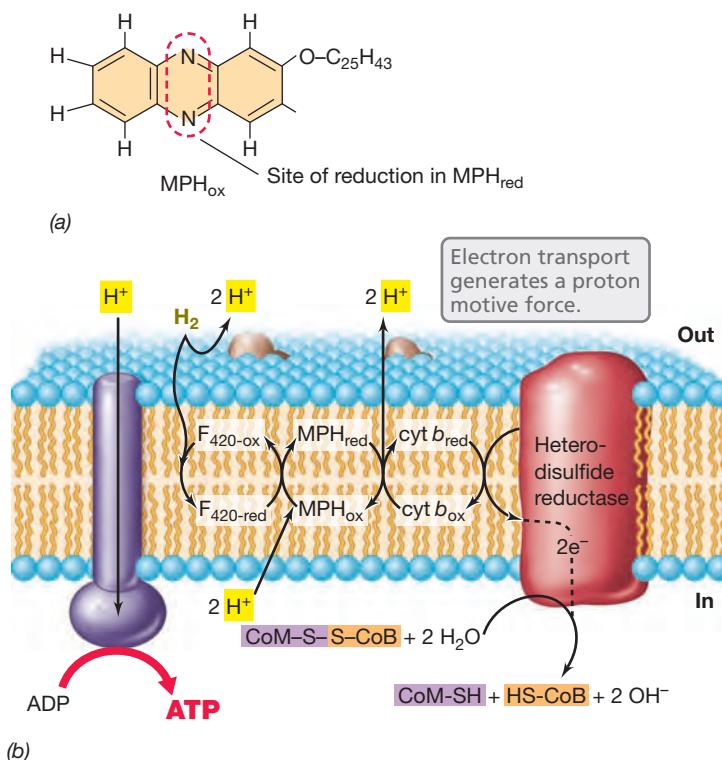

Figure 13.51 Energy conservation in methanogenesis from methanol or acetate. (a) Structure of methanophenazine (MPH in part b), an electron carrier in the electron transport chain leading to ATP synthesis; the central ring of the molecule can be alternately reduced and oxidized. (b) Steps in electron transport. Electrons originating from H_2 reduce F_{420} and then methanophenazine. The latter, through a cytochrome of the *b* type, reduces heterodisulfide reductase with the extrusion of H^+ to the outside of the membrane. In the final step, heterodisulfide reductase reduces CoM-S—S-CoB to HS-CoB and CoB-SH. See Figure 13.47 for the structures of CoM and CoB.

methanol-grown cells, and (2) a sodium motive force (that is likely converted to a proton motive force) during methanogenesis from $\text{H}_2 + \text{CO}_2$.

MINIQUIZ

- Which coenzymes function as C_1 carriers in methanogenesis? As electron donors?
- In methanogens growing on $\text{H}_2 + \text{CO}_2$, how is carbon obtained for cell biosynthesis?
- How is ATP made in methanogenesis when the substrates are $\text{H}_2 + \text{CO}_2$? Acetate?

13.21 Other Electron Acceptors

In addition to the electron acceptors for anaerobic respiration discussed thus far, several metals, metalloids, and halogenated and unhalogenated organic compounds are important electron acceptors for bacteria in nature (Figure 13.52). In addition to these, even protons can be used by a very few strict anaerobes. We consider these forms of anaerobic respiration here.

Metal Reduction

Several metals and metalloids can be reduced in anaerobic respirations. Ferric iron (Fe^{3+}) and manganic ion (Mn^{4+}) are the most important metals reduced. The reduction potential of

Couple	Reaction	E_0'
Fumarate/Succinate	$\text{O}=\text{C}-\text{C}(\text{H})=\text{C}(\text{H})-\text{C}(=\text{O})-\text{O}^- \xrightarrow{2 \text{H}} \text{O}=\text{C}-\text{CH}_2-\text{CH}_2-\text{C}(=\text{O})-\text{O}^-$	+0.03
Trimethylamine-N-oxide (TMAO)/Trimethylamine (TMA)	$\text{H}_3\text{C}-\text{N}(\text{CH}_3)_2 \xrightarrow{2 \text{H}} (\text{CH}_3)_3\text{N} + \text{H}_2\text{O}$	+0.13
Arsenate/Arsenite	$\text{O}=\text{As}(\text{O})_3 \xrightarrow{2 \text{H}} \text{As}(\text{O})_3^- + \text{H}_2\text{O}$	+0.14
Dimethyl sulfoxide (DMSO)/Dimethyl sulfide (DMS)	$\text{H}_3\text{C}-\text{S}-\text{CH}_3 \xrightarrow{2 \text{H}} (\text{CH}_3)_2\text{S} + \text{H}_2\text{O}$	+0.16
Ferric ion/Ferrorous ion	$\text{Fe}^{3+} \xrightarrow{\text{e}^-} \text{Fe}^{2+}$	+0.20
Selenate/Selenite	$\text{O}=\text{Se}(\text{O})_4 \xrightarrow{2 \text{H}} \text{Se}=\text{O} + \text{H}_2\text{O}$	+0.48
Manganic ion/Manganese ion	$\text{Mn}^{4+} \xrightarrow{2 \text{e}^-} \text{Mn}^{2+}$	+0.80
Chlorate/Chloride	$\text{ClO}_3^- \xrightarrow{6 \text{H}} \text{Cl}^- + 3 \text{H}_2\text{O}$	+1.00

Figure 13.52 Some alternative electron acceptors for anaerobic respirations. Note the reaction and E_0' of each redox pair calculated for pH 7.

the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is +0.2 V (at pH 7), and that of the $\text{Mn}^{4+}/\text{Mn}^{2+}$ couple is +0.8 V; thus, several electron donors can couple to Fe^{3+} and Mn^{4+} reduction. In these reactions, electrons typically travel from the donor through an electron transport chain that generates a proton motive force and terminates in a metal reductase system, reducing Fe^{3+} to Fe^{2+} or Mn^{4+} to Mn^{2+} . Much research on the energetics of Fe^{3+} reduction has been done with the gram-negative bacteria *Shewanella* and *Geobacter*; *Shewanella* also reduces Mn^{4+} . Each organism can oxidize several organic electron donors as well as H_2 , and *Geobacter* can also oxidize acetate and the aromatic hydrocarbon toluene linked to Fe^{3+} reduction.

Other inorganic substances can function as electron acceptors for anaerobic respiration, including the metalloids selenium, tellurium, and arsenic, the transition metal vanadium, and various oxidized chlorine compounds (Figure 13.52). Most of the organisms capable of growth with these acceptors are facultative aerobes and can thus grow by aerobic respiration as well. Arsenic, selenium, and tellurium compounds are occasional pollutants in nature and can support anaerobic respirations in various bacteria. The reduction of selenate (SeO_4^{2-}) occurs to selenite (SeO_3^{2-}) and eventually to metallic selenium (Se^0), the reduction of arsenate (AsO_4^{2-}) occurs to the level of arsenite (AsO_3^{2-}), and the reduction of tellurate (TeO_4^{2-}) to tellurite (TeO_3^{2-}). Several chlorate and perchlorate-reducing bacteria have also been isolated and are likely responsible for the removal of these toxic compounds from nature; the typical end product of these reactions is chloride (Cl^-).

The sulfate-reducing bacterium *Desulfotomaculum* can reduce both AsO_4^{3-} to AsO_3^{3-} and sulfate to sulfide, and during this process, the yellow mineral orpiment (As_2S_3) precipitates spontaneously (Figure 13.53). This process is an example of *biomineralization*, the formation of a mineral by bacterial activity. As_2S_3 formation also functions as a means of detoxifying what would otherwise be a toxic compound (arsenic), and thus such microbial activities may have practical applications for the cleanup of arsenic-containing toxic wastes and groundwater.

Dianne K. Newman and Stephen Tay

Right, following growth for two weeks and biomineralization of arsenic trisulfide, As_2S_3 . Center, synthetic sample of As_2S_3 .

Organic Electron Acceptors

Several organic compounds can be electron acceptors in anaerobic respirations. Of those listed in Figure 13.52, the compound that has been most extensively studied is *fumarate*, a citric acid cycle intermediate (➡ Figure 3.22), which is reduced to succinate. The role of fumarate as an electron acceptor for anaerobic respiration derives from the fact that the fumarate–succinate couple has a reduction potential near 0 V, which allows coupling of fumarate reduction to the oxidation of NADH, FADH, or H_2 . Many facultatively aerobic bacteria can grow anaerobically on fumarate as electron acceptor, including *Escherichia coli*.

Trimethylamine oxide (TMAO) and dimethyl sulfoxide (DMSO) (Figure 13.52) are important organic electron acceptors. TMAO is a product of marine fish, and several bacteria can reduce it to trimethylamine (TMA), which has a strong odor and flavor (the odor of spoiled seafood is due primarily to TMA produced by bacterial action). Dimethyl sulfoxide (DMSO), which is reduced to dimethyl sulfide (DMS), is a common natural product and is found in both marine and freshwater environments. The reduction potentials of the TMAO/TMA and DMSO/DMS couples are the same, about +0.15 V, and this means that electron transport chains that terminate with TMAO or DMSO reductases must be rather short. As in fumarate reduction, in the reduction of TMAO and DMSO cytochromes of the *b* type (E_0' near 0 V) function as donors to the reductases.

Several halogenated organic compounds can function as electron acceptors in **reductive dechlorination** (also called *dehalorespiration*). For example, the sulfate-reducing bacterium *Desulfovimonile* grows anaerobically with H_2 or organic electron donors and chlorobenzoate as an electron acceptor that is reduced to benzoate and hydrochloric acid (HCl):

Several other bacteria can reductively dechlorinate, and some of these are restricted to chlorinated compounds as electron acceptors for anaerobic respiration. For example, the bacterium *Dehalococcoides* reduces tri- and tetrachloroethylene to ethene and *Dehalobacterium* converts dichloromethane (CH_2Cl_2) into acetate and formate (Table 13.10). *Dehalococcoides* can also reduce polychlorinated biphenyls (PCBs). PCBs are widespread organic pollutants that contaminate freshwater environments where they accumulate in fish and other aquatic life. However, removal of the chlorine groups from these molecules greatly reduces their toxicity and hence reductive dechlorination is not only a form of energy metabolism but also an environmentally significant process of bioremediation.

Proton Reduction

Perhaps the simplest of all anaerobic respirations is one carried out by the hyperthermophile *Pyrococcus furiosus*. *P. furiosus* is a species of *Archaea* that grows optimally at 100°C (Chapter 16) on sugars and small peptides as electron donors and protons as electron acceptor. This is possible because of a unique biochemical feature of the glycolytic pathway of *P. furiosus*.

During glycolysis, the oxidation of glyceraldehyde 3-phosphate forms 1,3-bisphosphoglyceric acid, an intermediate with

Table 13.10 Characteristics of some major genera of bacteria capable of reductive dechlorination

	Genus				
Property	<i>Dehalobacter</i>	<i>Dehalobacterium</i>	<i>Desulfotobacterium</i>	<i>Desulfomonile</i>	<i>Dehalococcoides</i>

Figure 13.54 Modified glycolysis and proton reduction in anaerobic respiration in the hyperthermophile *Pyrococcus furiosus*. Hydrogen (H₂) production is linked to H⁺ pumping by a hydrogenase that receives electrons from reduced ferredoxin (Fd_{red}). All intermediates from G-3-P downward in the pathway are present in two copies. Compare this figure with classical glycolysis in Figure 3.14. G-3-P, glyceraldehyde 3-phosphate; 3-PGA, 3-phosphoglycerate; PEP, phosphoenolpyruvate.

two energy-rich phosphate bonds; this compound is then converted to 3-phosphoglyceric acid plus ATP (► Figure 3.14). However, in *P. furiosus* this normal glycolytic step is bypassed, and 3-phosphoglyceric acid is formed directly from glyceraldehyde 3-phosphate (Figure 13.54). This prevents *P. furiosus* from making ATP by substrate-level phosphorylation at this step, but this problem is compensated for by the fact that glyceraldehyde 3-phosphate oxidation is coupled to the production of *ferredoxin* rather than NADH; ferredoxin has a more negative E_0' (-0.42 V) than does NAD⁺/NADH (-0.32 V). This highly negative E_0' allows for the coupling of ferredoxin oxidation to the reduction of 2 H⁺ to H₂, and this reaction pumps a proton across the membrane (Figure 13.54). Proton pumping by hydrogenase is analogous to proton pumping by terminal electron carriers in other respirations (► Figure 3.20 and Figure 13.41). Additional ATP is produced by *P. furiosus* by substrate-level phosphorylations in the conversions of phosphoenolpyruvate to pyruvate and acetyl-CoA to acetate (Figure 13.54).

MINIQUIZ

- With H₂ as electron donor, why is reduction of Fe³⁺ a more favorable reaction than reduction of fumarate?
- What is reductive dechlorination and why is it environmentally relevant?
- How does anaerobic glucose catabolism differ in *Lactobacillus* and *Pyrococcus furiosus*?

V • Hydrocarbon Metabolism

Hydrocarbons are widely used by microorganisms as electron donors but must first be oxygenated before they can be catabolized. Here we consider the aerobic catabolism of aliphatic and aromatic hydrocarbons, where oxygenation occurs from O₂. We then proceed to the special case of C₁ hydrocarbon catabolism and finish with a consideration of anoxic hydrocarbon metabolism, a situation where oxygenation of the hydrocarbon is still necessary, but where O₂ obviously plays no role.

13.22 Aerobic Hydrocarbon Metabolism

We previously discussed the role of molecular oxygen (O₂) as an *electron acceptor* in energy-generating reactions. By contrast, O₂ also plays an important role as a *reactant* in the catabolism of hydrocarbons, and oxygenase enzymes are key players in the process.

Oxygenases and Aliphatic Hydrocarbon Oxidation

Oxygenases are enzymes that catalyze the incorporation of O₂ into organic compounds and in some cases, inorganic compounds (Section 13.10). There are two classes of oxygenases: *dioxygenases*, which catalyze the incorporation of *both atoms* of O₂ into the molecule, and *monooxygenases*, which catalyze the incorporation of *only one* of

the two oxygen atoms of O₂ into an organic compound with the second atom of O₂ being reduced to H₂O. For most monooxygenases, the required electron donor is NADH or NADPH.

In the initial oxidation step of a saturated aliphatic hydrocarbon, one of the atoms of the O₂ is incorporated, typically at a terminal carbon atom. This reaction is catalyzed by a monooxygenase, and a typical reaction sequence is shown in Figure 13.55a. The end product of the reaction sequence is a fatty acid of the same length as the original hydrocarbon. The fatty acid is then oxidized by *beta-oxidation*, a series of reactions in which two carbons of the fatty acid are split off at a time (Figure 13.55b). During beta-oxidation, NADH is formed and is oxidized in the electron transport chain for energy conservation purposes. A single round of beta-oxidation releases acetyl-CoA plus a new fatty acid that is two carbon atoms shorter than the original fatty acid. The process of beta-oxidation is then repeated, and another acetyl-CoA molecule is released. The acetyl-CoA formed by beta-oxidation is either oxidized through the citric acid cycle (Figure 3.22) or used to make new cell material. With the exception of how the hydrocarbon is oxygenated, much of the biochemistry of anoxic hydrocarbon catabolism is the same as that shown for aerobic catabolism (Figure 13.55), with beta-oxidation reactions being of prime importance in both cases.

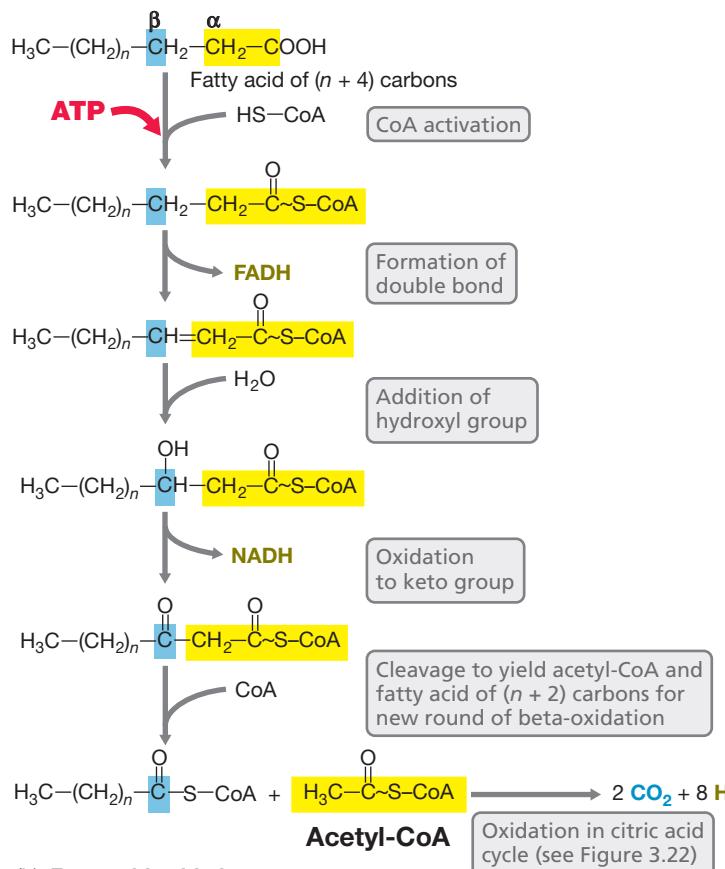

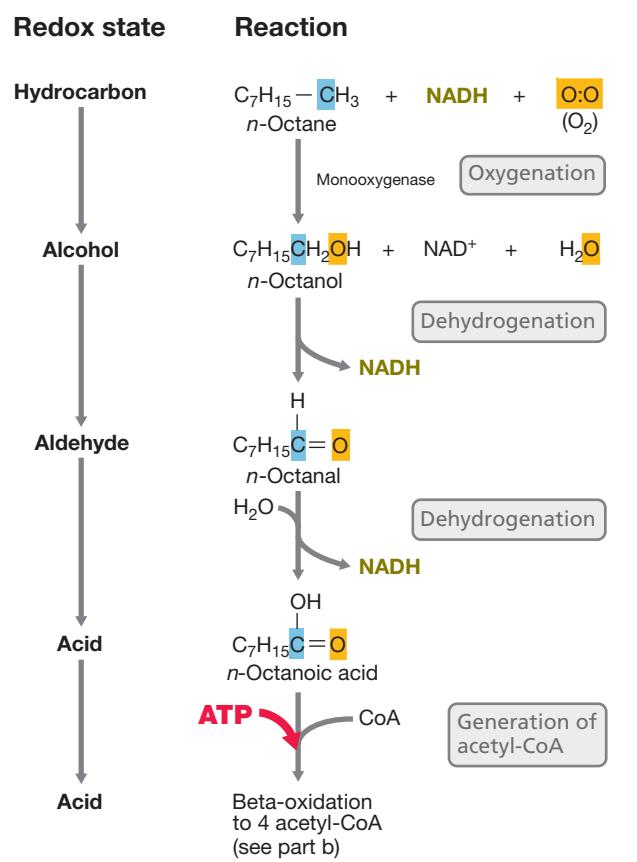

Figure 13.55 Monooxygenase activity and beta oxidation. (a) Steps in the oxidation of an aliphatic hydrocarbon, the first of which is catalyzed by a monooxygenase. (b) Fatty acid oxidation by beta-oxidation leads to the successive formation of acetyl-CoA.

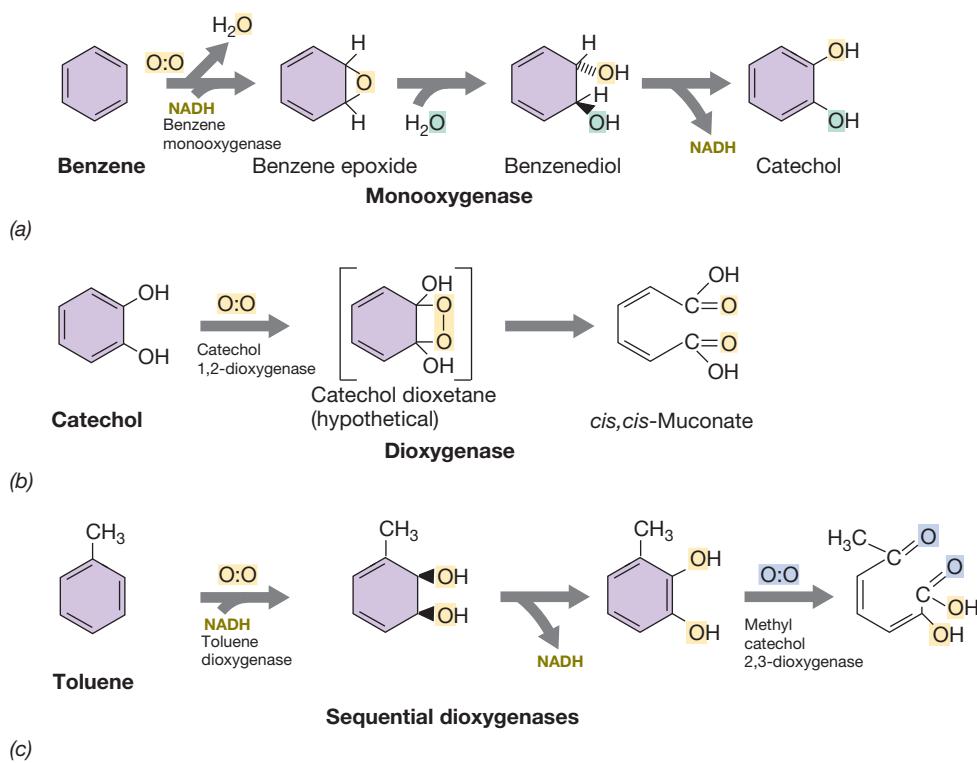

Figure 13.56 Roles of oxygenases in catabolism of aromatic compounds. Monooxygenases introduce one atom of oxygen from O_2 into a substrate, whereas dioxygenases introduce both atoms of oxygen. (a) Hydroxylation of benzene to catechol by a monooxygenase in which NADH is an electron donor. (b) Cleavage of catechol to *cis,cis*-muconate by an intradiol ring-cleavage dioxygenase. (c) The activities of a ring-hydroxylating dioxygenase and an extradiol ring-cleavage dioxygenase in the degradation of toluene. The oxygen atoms that each enzyme introduces are distinguished by different colors. Compare aerobic toluene catabolism to anoxic toluene catabolism shown in Figure 13.59b.

Aromatic Hydrocarbon Oxidation

Many aromatic hydrocarbons can also be used as electron donors aerobically by microorganisms. The metabolism of these compounds, some of which contain multiple rings, such as naphthalene or biphenyls, typically has as its initial stage the formation of catechol or a structurally related compound via catalysis by oxygenase enzymes, as shown in **Figure 13.56**. Once catechol is formed it can be cleaved and further degraded into compounds that can enter the citric acid cycle, such as succinate, acetyl-CoA, and pyruvate.

Several steps in the aerobic catabolism of aromatic hydrocarbons require oxygenases. Figure 13.56a–c shows four different oxygenase-catalyzed reactions, one using a monooxygenase, two using a ring-cleaving dioxygenase, and one using a ring-hydroxylating dioxygenase. As in aerobic aliphatic hydrocarbon catabolism (Figure 13.55), aromatic compounds, whether single or multi-ringed, are typically oxidized completely to CO_2 , with electrons entering an electron transport chain or used to make new cell material.

MINIQUIZ

- How do monooxygenases differ in function from dioxygenases?
- What is the final product of catabolism of a hydrocarbon?
- What is meant by the term “beta-oxidation”?

13.23 Aerobic Methanotrophy

Methane (CH_4) and many other C_1 compounds can be catabolized aerobically by **methylotrophs**. Methylotrophs are organisms that use organic compounds that lack C–C bonds as electron donors and carbon sources. The catabolism of compounds containing only a single carbon atom, such as the hydrocarbon methane (CH_4) and the alcohol methanol (CH_3OH), have been the best studied of these substrates. We focus here on the oxidation of CH_4 as an example of a methylotrophic lifestyle.

Methane Oxidation

The steps in CH_4 oxidation to CO_2 can be summarized as

Not all methylotrophs can use methane. **Methanotrophs** are those methylotrophs that can use CH_4 , and methanotrophy has been especially well studied in the gram-negative bacterium *Methylococcus capsulatus*. Methanotrophs assimilate either all or one-half of their cell carbon (depending on the pathway used) from the C_1 compound formaldehyde (CH_2O).

The initial step in the aerobic oxidation of CH_4 is catalyzed by the enzyme **methane monooxygenase** (MMO). Recall that monooxygenases

incorporate one oxygen atom from O_2 into a carbon compound (Section 13.22 and Figure 13.55a). *M. capsulatus* contains two MMOs, one cytoplasmic and the other membrane-integrated; the latter has been best studied. In the MMO reaction, an atom of oxygen is introduced into CH_4 , forming CH_3OH , and the second atom of O is reduced to form H_2O (Figure 13.57). CH_3OH is oxidized by an alcohol dehydrogenase, yielding formaldehyde (CH_2O) and NADH, and the CH_2O is either oxidized to CO_2 or used to make new cell material.

C_1 Assimilation into Cell Material

At least two distinct pathways exist for the incorporation of C_1 units into cell material in methanotrophs. The **serine pathway** is outlined in **Figure 13.58a**. In this pathway, acetyl-CoA is synthesized from one molecule of CH_2O (produced from the oxidation of CH_3OH , Figure 13.57) and one molecule of CO_2 . The serine pathway requires reducing power and energy in the form of two molecules each of NADH and ATP, respectively, for each acetyl-CoA synthesized. The serine pathway employs a number of enzymes of the citric acid cycle and one enzyme, *serine trans-hydroxymethylase*, unique to the pathway (Figure 13.58a).

An alternative pathway for C_1 incorporation is the **ribulose monophosphate pathway** (Figure 13.58b). This pathway is more energy efficient than the serine pathway because *all* of the carbon for cell material is derived from CH_2O . Because CH_2O is at the same oxidation level as cell material, no reducing power is needed

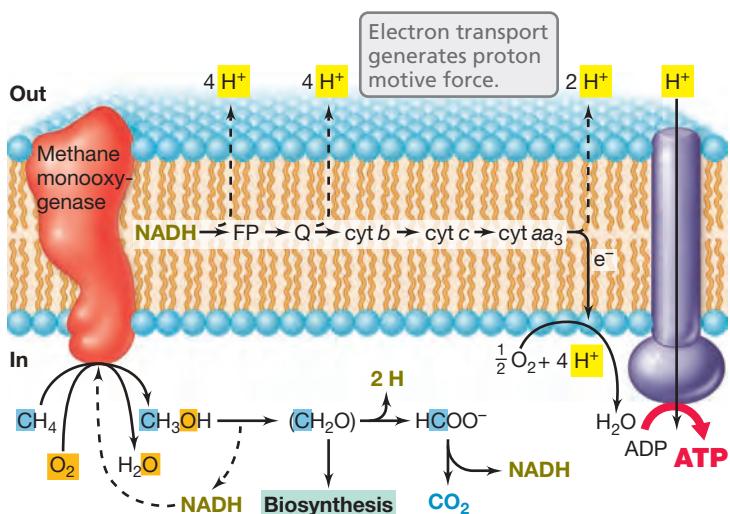

Figure 13.57 Oxidation of methane by methanotrophic bacteria. CH_4 is oxidized to CH_3OH by the membrane-integrated enzyme methane monooxygenase (MMO). A proton motive force is established from electron flow in the membrane, and this fuels ATPase. Note how carbon for biosynthesis comes from CH_2O . FP, flavoprotein; cyt, cytochrome; Q, quinone.

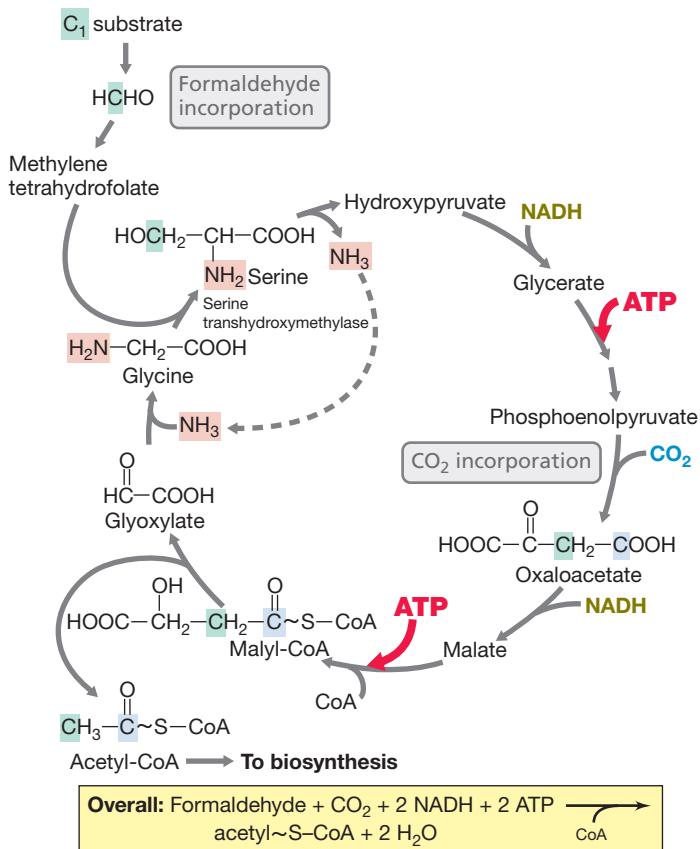

for its incorporation. Hence, all of the NADH from the oxidation of methane can be oxidized in the electron transport chain.

The ribulose monophosphate pathway consumes one molecule of ATP for each molecule of glyceraldehyde 3-phosphate (G-3-P) synthesized (Figure 13.58b); two G-3-Ps can then be converted into glucose by reversal of the glycolytic pathway (► Figure 3.14). The enzymes *hexulosephosphate synthase*, which condenses one molecule of formaldehyde with one molecule of ribulose 5-phosphate, and *hexulose 6-P isomerase* (Figure 13.58b) are unique to the ribulose monophosphate pathway. The remaining enzymes of this pathway are enzymes of intermediary metabolism widely distributed in bacteria.

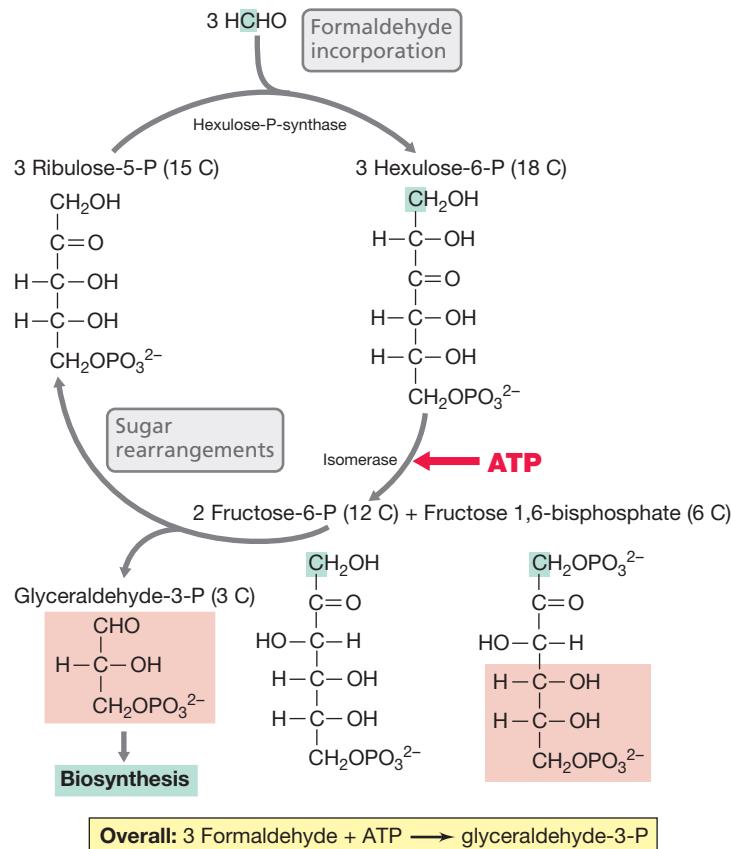

We thus see that aerobic methanotrophs share with other aerobic hydrocarbon degraders the need for oxygenase enzymes. However, since their biosyntheses start from C_1 compounds, methanotrophs differ from other hydrocarbon degraders in their need for special pathways for incorporating C_1 units into cell material.

MINIQUIZ

- When using CH_4 as electron donor, why is *Methylococcus capsulatus* an obligate aerobe?
- Why does the oxidation of CH_4 to CH_3OH require reducing power?
- In which two ways does the ribulose monophosphate pathway save energy over reactions of the serine pathway?

(a) The serine pathway

(b) The ribulose monophosphate pathway

Figure 13.58 The serine and ribulose monophosphate pathways for the assimilation of C_1 units into cell material by methylotrophic bacteria. (a) Serine pathway. The product, acetyl-CoA, is used as the starting point for making new cell material. The key enzyme of the pathway is serine transhydroxymethylase. (b) Ribulose monophosphate pathway. Three molecules of CH_2O are required, with the product being glyceraldehyde 3-phosphate. The key enzyme of this pathway is hexulosephosphate synthase. The sugar rearrangements require enzymes of the pentose phosphate pathway (► Figure 3.26).

13.24 Anoxic Hydrocarbon Metabolism

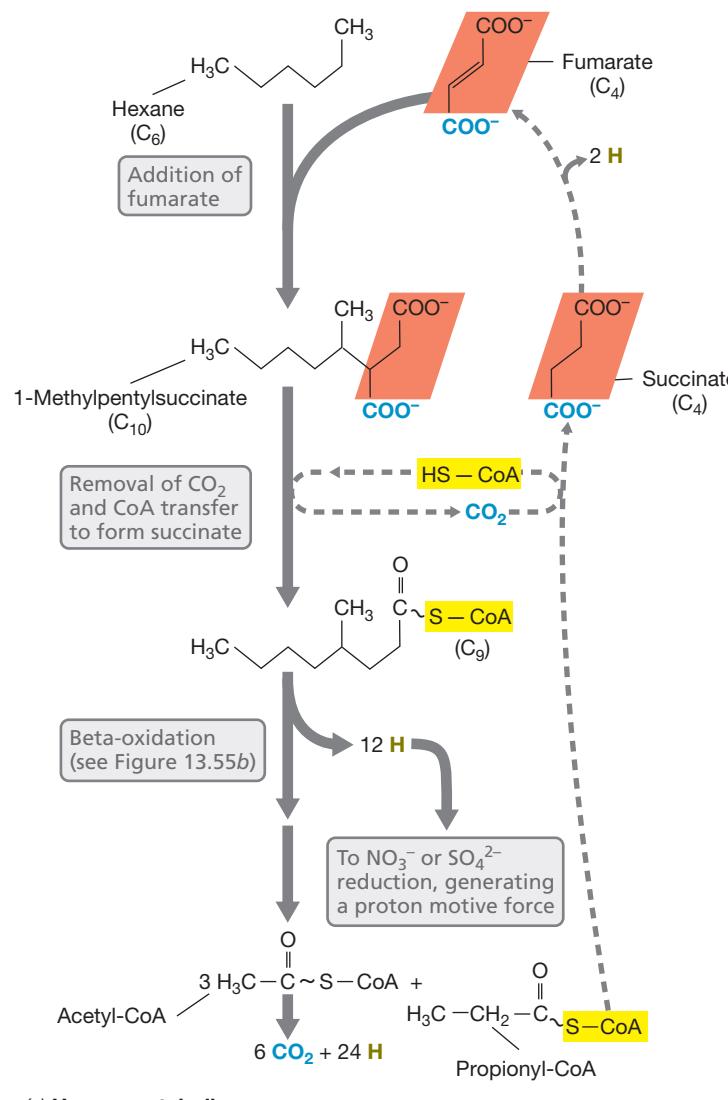

We saw how hydrocarbons can be catabolized *aerobically* in the preceding two sections. Now we consider their *anoxic* catabolism. Anoxic hydrocarbon oxidation can be linked to the reduction of nitrate, sulfate, or ferric iron in anaerobic respirations.

Aliphatic Hydrocarbons

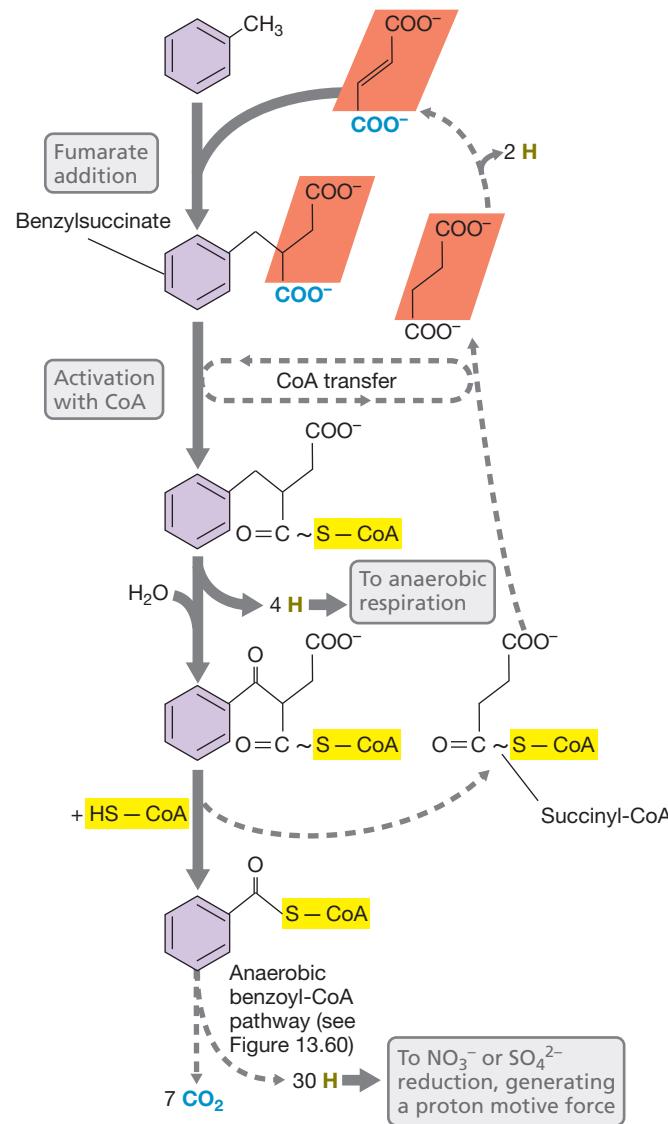

Aliphatic hydrocarbons are straight-chain saturated or unsaturated organic compounds, and many are substrates for denitrifying and sulfate-reducing bacteria. Saturated aliphatic hydrocarbons as long as C₂₀ support growth, although shorter-chain hydrocarbons are more soluble and readily catabolized. The mechanism of anoxic hydrocarbon degradation has been well studied for hexane (C₆H₁₄) metabolism in denitrifying bacteria (NO₃⁻ as electron acceptor). However,

the mechanism appears to be the same for the anoxic catabolism of longer-chain hydrocarbons and for anoxic hydrocarbon oxidation linked to other electron acceptors, and so we focus on the hexane/nitrate system here.

In anoxic hexane metabolism, hexane is modified on carbon atom 2 by attachment of a molecule of *fumarate*, a C₄ intermediate of the citric acid cycle (Figure 3.22), forming the compound *1-methylpentylsuccinate* (Figure 13.59a). The enzymatic addition of fumarate to hexane effectively oxygenates the hexane and allows the molecule to be further catabolized anaerobically. Following the addition of coenzyme A, a series of reactions occurs that includes beta-oxidation (Figure 13.55b) and regeneration of fumarate. The electrons generated during beta-oxidation generate a proton motive force and are then consumed in nitrate or sulfate reduction.

(a) Hexane catabolism

(b) Toluene catabolism

Figure 13.59 Anoxic catabolism of two hydrocarbons. (a) In anoxic catabolism of the aliphatic hydrocarbon hexane, the addition of fumarate provides the oxygen atoms necessary to form a fatty acid derivative that can be catabolized by beta-oxidation (see Figure 13.55) to yield acetyl-CoA. Electrons (H) generated from hexane catabolism are used to reduce sulfate or nitrate in anaerobic respirations. (b) Fumarate addition during the anoxic catabolism of the aromatic hydrocarbon toluene forms benzylsuccinate.

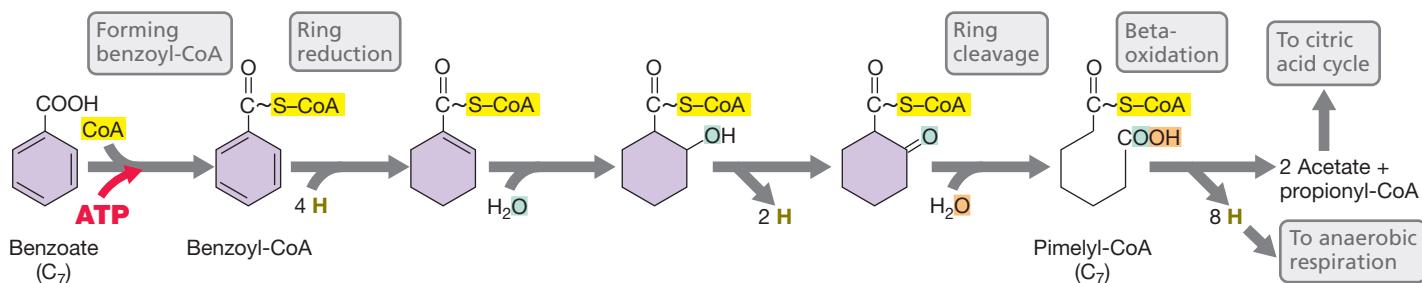

Figure 13.60 Anoxic degradation of benzoate by the benzoyl-CoA pathway. This pathway operates in the purple phototrophic bacterium *Rhodopseudomonas palustris* and many other facultative bacteria, both phototrophic and chemotrophic. Note that all intermediates of the pathway are bound to coenzyme A. The acetate produced is further catabolized in the citric acid cycle.

Aromatic Hydrocarbons

Aromatic hydrocarbons can be degraded anaerobically by some nitrate, ferric iron, and sulfate-reducing bacteria. For anoxic catabolism of the aromatic hydrocarbon toluene, oxygen needs to be added to the compound to begin catabolism, and this occurs by the addition of fumarate, as in aliphatic hydrocarbon catabolism (Figure 13.59a). The reaction series eventually yields benzoyl-CoA, which is further degraded by ring reduction (Figure 13.59b). Benzene (C_6H_6) can also be catabolized anaerobically, likely by a similar mechanism. Multi-ringed aromatic hydrocarbons such as naphthalene ($C_{10}H_8$) can be degraded by certain sulfate-reducing and denitrifying bacteria. In contrast to other hydrocarbons, the oxygenation of multi-ringed hydrocarbons occurs by the addition of CO_2 to the ring to form a carboxylic acid derivative rather than by fumarate addition. But this carboxylation reaction serves the same purpose as oxygenase reactions (Figures 13.55a and 13.56) or the addition of fumarate (Figure 13.59); an O atom becomes part of the hydrocarbon and facilitates its catabolism.

Many bacteria can catabolize certain aromatic hydrocarbons anaerobically, including even fermentative and phototrophic bacteria. However, except for toluene, only aromatic compounds that already contain an O atom are degraded, typically by a common mechanism. In contrast to aerobic catabolism that occurs by way

of ring oxidation (Figure 13.56), anaerobic catabolism proceeds by ring reduction. Benzoate catabolism by the “benzoyl-CoA pathway” is a common theme of this biochemistry (Figure 13.60). Benzoate catabolism in this pathway begins by forming the coenzyme A derivative followed by ring cleavage to yield fatty or dicarboxylic acids that can be further catabolized to intermediates of the citric acid cycle (Figure 13.60).

Anoxic Methane Oxidation

Methane (CH_4) can be degraded under anoxic conditions by a consortium of two organisms, a sulfate-reducing bacterium plus a species of *Archaea* phylogenetically related to methanogens (Figure 13.61). The archaeal component, called ANME (anoxic methanotroph), of which there are several types, oxidizes CH_4 as an electron donor. Electrons from methane oxidation are then transferred to the sulfate reducer, which uses them to reduce SO_4^{2-} to H_2S (Figure 13.61b).

The mechanism of anoxic methane oxidation (AMO) remains unclear, but it is thought that the methanotroph oxidizes CH_4 to CO_2 by reversing the steps of methanogenesis and electrons are transferred to the sulfate reducer in some organic molecule (Figure 13.61b). Regardless of the mechanism, the coupled reaction yields only a small amount of free energy (-18 kJ), and how

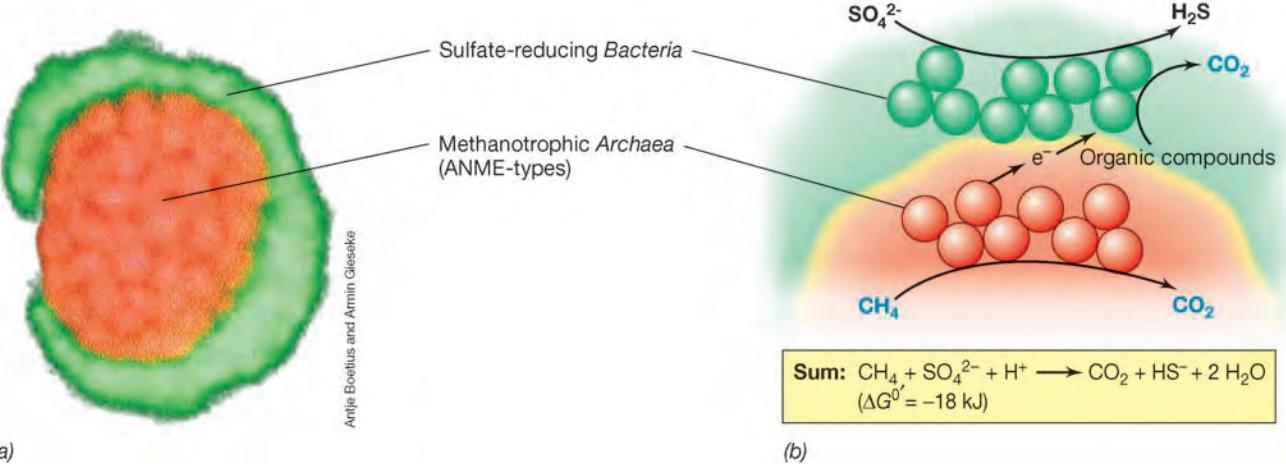

Figure 13.61 Anoxic methane oxidation. (a) Methane-oxidizing cell aggregates from marine sediments. The aggregates contain methanotrophic *Archaea* (red) surrounded by sulfate-reducing bacteria (green). Each cell type has been stained by a different FISH probe (☞ Section 18.4). The aggregate is about $30\text{ }\mu\text{m}$ in diameter. (b) Mechanism for the cooperative degradation of CH_4 . An organic compound or some other carrier of reducing power transfers electrons from methanotroph to sulfate reducer.

this energy is converted into ATP and split between the methanotroph and the sulfate reducer remains a major unanswered question. One possibility could be an ion pump. As we have seen in Sections 13.14 and 13.15, ion pumps can operate at very low energy yields, and thus an ion pump might play a role in the energetics of AMO as well.

AMO is not limited to sulfate-reducing bacteria consortia. Methane-oxidizing denitrifying consortia are active in anoxic environments where CH_4 and NO_3^- coexist in significant amounts, such as certain freshwater sediments. In laboratory enrichments of these consortia, some contain ANME-type methanotrophs while others are totally free of *Archaea*. AMO linked to ferric iron (Fe^{3+}) and manganic ion (Mn^{4+}) reduction are also known.

One denitrifying bacterium employs a remarkable mechanism for AMO and does not require a second organism to carry out the process. *Methylophilus oxyfera* oxidizes CH_4 with NO_3^- as an electron acceptor, and during CH_4 oxidation, electrons reduce NO_3^- employing most of the steps we have seen previously in denitrifying bacteria such as *Pseudomonas* (Section 13.17). These include the reduction of NO_3^- to NO_2^- , and further reduction to N_2 (Figure 13.41c). But unlike *Pseudomonas*,

in *M. oxyfera* NO_2^- is reduced to N_2 by way of nitric oxide (NO) without first producing nitrous oxide (N_2O) as an intermediate (Figure 13.41c). Instead, *M. oxyfera* splits NO into N_2 and O_2 ($2 \text{NO} \rightarrow \text{N}_2 + \text{O}_2$) and then uses the O_2 produced as the electron acceptor for CH_4 oxidation. In other words, the organism *produces its own O₂* as an oxidant for electrons generated during the oxidation of CH_4 to CO_2 (see more on page 433).

Several metabolic strategies have evolved to catabolize methane, probably the most abundant hydrocarbon on Earth. These along with the myriad of other energy-conserving mechanisms we have seen in this chapter demonstrate the impressive breadth of microbial metabolic diversity. We now take this background and put it into the context of the organisms themselves in the next four chapters.

MINIQUIZ

- Why is toluene a hydrocarbon whereas benzoate is not?
- How is hexane oxygenated during anoxic catabolism?
- What is AMO and which organisms participate in the process?

BIG IDEAS

13.1 • In photosynthesis, ATP is generated from light and then consumed in the reduction of CO_2 . Two forms of photosynthesis are known: oxygenic, where O_2 is produced (for example, cyanobacteria), and anoxygenic, where it is not (for example, purple and green bacteria). Chlorophylls and bacteriochlorophylls reside in membranes where the light reactions of photosynthesis are carried out. Antenna chlorophylls harvest light energy and transfer it to a reaction center.

13.2 • Accessory pigments including carotenoids and phycobilins absorb light and transfer the energy to reaction center chlorophyll, thus broadening the wavelengths of light usable in photosynthesis. Carotenoids also play an important photoprotective role in preventing photooxidative damage to cells.

13.3 • Electron transport reactions occur in the photosynthetic reaction center of anoxygenic phototrophs, forming a proton motive force and ATP. Reducing power for CO_2 fixation comes from substances such as H_2S , and NADH production in purple bacteria requires reverse electron transport.

13.4 • In oxygenic photosynthesis, H_2O donates electrons to drive CO_2 fixation, and O_2 is a by-product. There are two separate but interconnected photosystems in oxygenic phototrophs, PSI and PSII, whereas anoxygenic phototrophs contain a single photosystem.

13.5 • Autotrophy is supported in most phototrophic and chemolithotrophic bacteria by the Calvin cycle, in which the enzyme RubisCO plays a key role. Carboxysomes contain crystalline RubisCO and function to concentrate CO_2 , the key substrate for this enzyme. The reverse citric acid and hydroxypropionate cycles are autotrophic pathways in green sulfur and green nonsulfur bacteria, respectively.

13.6 • Chemolithotrophs oxidize inorganic electron donors to conserve energy and obtain reducing power. Energy conservation occurs from respiratory processes that generate a proton motive force. Most chemolithotrophs can grow autotrophically.

13.7 • The chemolithotrophic hydrogen bacteria use H_2 as an electron donor, reducing O_2 to H_2O . The enzyme hydrogenase is required to oxidize H_2 , and H_2 also supplies reducing power for the fixation of CO_2 in these autotrophs.

13.8 • Reduced sulfur compounds such as H_2S , $\text{S}_2\text{O}_3^{2-}$, and S^0 are electron donors for energy conservation in sulfur chemolithotrophs. Electrons from these substances enter electron transport chains, yielding a proton motive force. Sulfur chemolithotrophs are also autotrophs and fix CO_2 by the Calvin cycle.

13.9 • Chemolithotrophic iron bacteria oxidize Fe^{2+} as an electron donor. Most iron bacteria grow at acidic pH and are often associated with acidic pollution from mineral and coal

mining. A few chemolithotrophic and phototrophic bacteria can oxidize Fe^{2+} to Fe^{3+} anaerobically.

13.10 • The ammonia-oxidizing *Bacteria* and *Archaea* produce nitrite from ammonia, which is then oxidized by nitrite-oxidizing *Bacteria* to nitrate. Anoxic ammonia oxidation (anammox) consumes both ammonia and nitrite, forming N_2 . The anammox reaction occurs within a membrane-enclosed compartment called the anammoxosome.

13.11 • In the absence of external electron acceptors, organic compounds can be catabolized anaerobically only by fermentation. Most fermentations require that an energy-rich organic compound be formed that can yield ATP by substrate-level phosphorylation. Redox balance is achieved by the production of fermentation products.

13.12 • The lactic acid fermentation is carried out by homofermentative species, where lactate is the sole product, and heterofermentative species, where lactate, ethanol, and CO_2 are produced. The mixed-acid fermentation typical of enteric bacteria yields various acids plus neutral products (ethanol, butanediol), depending on the organism.

13.13 • Clostridia ferment sugars, amino acids, and other organic compounds, with butyric acid being a major product. Butyrate production allows for an additional ATP to be produced. *Propionibacterium* produces propionate, acetate, and CO_2 in a secondary fermentation of lactate where energy conservation by both substrate-level phosphorylation and anaerobic respiration occurs.

13.14 • Energy conservation in *Propionigenium*, *Oxalobacter*, and *Malonomonas* is linked to decarboxylation reactions that pump Na^+ or H^+ across the membrane; ATPases use the energy in the ion gradient to form ATP. The reactions catalyzed by these organisms yield insufficient free energy to make ATP by substrate-level phosphorylation.

13.15 • In syntrophy two organisms cooperate to degrade a compound that neither can degrade alone. In this process H_2 produced by one organism is consumed by the partner. H_2 consumption affects the energetics of the reaction carried out by the H_2 producer, allowing it to make ATP where it otherwise could not.

13.16 • Although O_2 is the most widely used electron acceptor in energy-yielding metabolism, certain other inorganic and organic compounds can be used as electron acceptors. Anaerobic respiration yields less energy than aerobic respiration but can proceed in environments where O_2 is absent.

13.17 • Nitrate is a common electron acceptor in anaerobic respiration. Nitrate reduction is catalyzed by the enzyme nitrate reductase, reducing NO_3^- to NO_2^- . Many bacteria that use NO_3^- in anaerobic respiration produce gaseous nitrogen compounds (NO , N_2O , or N_2) as final end products of reduction (denitrification).

13.18 • Sulfate-reducing bacteria are obligately anaerobic bacteria that reduce SO_4^{2-} to H_2S in a process in which SO_4^{2-} must first be activated to adenosine phosphosulfate (APS). Disproportionation is an additional energy-yielding strategy for certain species. Some organisms, such as *Desulfuromonas*, cannot reduce SO_4^{2-} but can reduce S^0 to H_2S .

13.19 • Acetogens are strict anaerobes that reduce CO_2 to acetate, usually with H_2 as electron donor. The mechanism of acetate formation is the acetyl-CoA pathway, a pathway widely distributed in obligate anaerobes for either autotrophic purposes or acetate oxidation.

13.20 • Methanogenesis is the production of CH_4 from $\text{CO}_2 + \text{H}_2$ or from acetate or methanol by strictly anaerobic methanogenic *Archaea*. Several unique coenzymes are required for methanogenesis, and energy conservation is linked to either a proton motive or sodium motive force.

13.21 • Besides inorganic nitrogen and sulfur compounds and CO_2 , several other substances can function as electron acceptors for anaerobic respiration. These include Fe^{3+} , Mn^{4+} , fumarate, certain organic and chlorinated organic compounds, and even protons.

13.22 • In addition to its role as a terminal electron acceptor, O_2 can also be a substrate. In aerobic metabolism, oxygenases introduce atoms of oxygen from O_2 into hydrocarbons. Once oxygenated, aliphatic hydrocarbons can be further degraded by beta-oxidation and aromatic hydrocarbons by ring splitting and oxidation.

13.23 • Methanotrophy is the use of CH_4 as both carbon source and electron donor, and the enzyme methane monooxygenase is a key enzyme in the aerobic catabolism of methane. In methanotrophs, C_1 units are assimilated into cell material as formaldehyde or formaldehyde plus CO_2 by the ribulose monophosphate or serine pathways, respectively.

13.24 • Hydrocarbons can be oxidized under anoxic conditions following addition of the dicarboxylic acid fumarate. Aromatic compounds are catabolized anaerobically by ring reduction and cleavage to form intermediates that can be catabolized in the citric acid cycle. Methane can be oxidized under anoxic conditions by consortia containing sulfate-reducing or denitrifying *Bacteria* and methanotrophic *Archaea*.

REVIEW OF KEY TERMS

Acetogenesis energy metabolism in which acetate is produced from either H₂ plus CO₂ or from organic compounds

Acetyl-CoA pathway a pathway of autotrophic CO₂ fixation and acetate oxidation widespread in obligate anaerobes including methanogens, acetogens, and sulfate-reducing bacteria

Anaerobic respiration use of an electron acceptor other than O₂ in an electron transport-based oxidation leading to a proton motive force

Anammox anoxic ammonia oxidation

Anoxygenic photosynthesis photosynthesis in which O₂ is not produced

Antenna pigments light-harvesting chlorophylls or bacteriochlorophylls in photocomplexes that funnel energy to the reaction center

Autotroph an organism that uses CO₂ as its sole carbon source

Bacteriochlorophyll the chlorophyll pigment of anoxygenic phototrophs

Calvin cycle the biochemical pathway for CO₂ fixation in many autotrophic organisms

Carboxysomes crystalline inclusions of RubisCO

Carotenoid a hydrophobic accessory pigment present along with chlorophyll in photosynthetic membranes

Chemolithotroph a microorganism that oxidizes inorganic compounds as electron donors in energy metabolism

Chlorophyll a light-sensitive, Mg-containing porphyrin of phototrophic organisms that initiates the process of photophosphorylation

Chlorosome a cigar-shaped structure present in the periphery of cells of green sulfur and green nonsulfur bacteria and containing the antenna bacteriochlorophylls (*c*, *d*, or *e*)

Denitrification anaerobic respiration in which NO₃⁻ or NO₂⁻ is reduced to nitrogen gases, primarily N₂

Fermentation anaerobic catabolism of an organic compound in which the compound serves as both an electron donor and an electron acceptor and in which ATP is usually produced by substrate-level phosphorylation

Heterofermentative producing a mixture of products, typically lactate, ethanol, and CO₂, from the fermentation of glucose

Homofermentative producing only lactic acid from the fermentation of glucose

Hydrogenase an enzyme, widely distributed in anaerobic microorganisms, capable of oxidizing or evolving H₂

Hydroxypyruvate pathway an autotrophic pathway found in *Chloroflexus* and a few *Archaea*

Methanogen a methane-producing member of the *Archaea*

Methanogenesis the biological production of CH₄

Methanotroph an organism that oxidizes CH₄

Methylotroph an organism capable of growth on compounds containing no C—C bonds; some methylotrophs are methanotrophic

Mixotroph an organism in which an inorganic compound serves as the electron donor in energy metabolism and organic compounds serve as the carbon source

Nitrification the microbial oxidation of ammonia to nitrate

Oxygenase an enzyme that catalyzes the incorporation of oxygen from O₂ into organic or inorganic compounds

Oxygenic photosynthesis photosynthesis carried out by cyanobacteria and green plants in which O₂ is evolved

Photophosphorylation the production of ATP in photosynthesis

Photosynthesis the series of reactions in which ATP is synthesized by light-driven reactions and CO₂ is fixed into cell material

Phototroph an organism that uses light as an energy source

Phycobiliprotein the antenna pigment complex in cyanobacteria that contains phycocyanin and allophycocyanin or phycoerythrin coupled to proteins

Phycobilisome an aggregate of phycobiliproteins

Reaction center a photosynthetic complex containing chlorophyll or bacteriochlorophyll and several other components, within which occur the initial electron transfer reactions of photosynthetic electron flow

Reductive dechlorination an anaerobic respiration in which a chlorinated organic compound is used as an electron acceptor, usually with the release of Cl⁻

Reverse citric acid cycle a mechanism for autotrophy in green sulfur bacteria and a few other autotrophic *Bacteria*, and also in some *Archaea*

Reverse electron transport the energy-dependent movement of electrons against the thermodynamic gradient to form a strong reductant from a weaker electron donor

Ribulose monophosphate pathway a reaction series in certain methylotrophs in which formaldehyde is assimilated into cell material using ribulose monophosphate as the C₁ acceptor molecule

RubisCO the acronym for ribulose bisphosphate carboxylase, a key enzyme of the Calvin cycle

Secondary fermentation a fermentation in which the substrates are the fermentation products of other organisms

Serine pathway a reaction series in certain methylotrophs in which CH₂O plus CO₂ are assimilated into cell material by way of the amino acid serine

Stickland reaction the fermentation of an amino acid pair

Syntrophy a process whereby two or more microorganisms cooperate to degrade a substance neither can degrade alone

Thylakoids membrane stacks in cyanobacteria or in the chloroplast of eukaryotic phototrophs

REVIEW QUESTIONS

- What are the major differences between oxygenic and anoxygenic phototrophs? (Section 13.1)
- What are the functions of light-harvesting and reaction center chlorophylls? Why would a mutant incapable of making light-harvesting chlorophylls (such mutants can be readily isolated in the laboratory) probably not be a successful competitor in nature? (Section 13.1)
- What accessory pigments are present in phototrophs, and what are their functions? (Section 13.2)
- How does light result in ATP production in an anoxygenic phototroph? In what ways are photosynthetic and respiratory electron flow similar? In what ways do they differ? (Section 13.3)
- How is reducing power for autotrophic growth obtained in a purple bacterium? In a cyanobacterium? (Sections 13.3 and 13.4)
- How does the reduction potential (E_0') of chlorophyll a in PSI and PSII differ? Why must the reduction potential of PSII chlorophyll a be so highly electropositive? (Section 13.4)
- What two enzymes are unique to the Calvin cycle? What reactions do these enzymes carry out? What would be the consequences if a mutant arose that lacked either of these enzymes? (Section 13.5)
- Which organisms employ the hydroxypropionate or reverse citric acid cycles as autotrophic pathways? (Section 13.5)
- Compare and contrast the utilization of H_2S by a purple phototrophic bacterium and by a colorless sulfur bacterium such as *Beggiatoa*. What role does H_2S play in the metabolism of each organism? (Sections 13.3, 13.6, and 13.8)
- Which inorganic electron donors are used by the organisms *Ralstonia*, *Thiobacillus*, and *Acidithiobacillus*? (Sections 13.7–13.9)
- Contrast classical nitrification with anammox in terms of oxygen requirements, organisms involved, and the need for monooxygenases. (Section 13.10)
- Define the term substrate-level phosphorylation. How does it differ from oxidative phosphorylation? What compound(s) do fermentative bacteria need to synthesize in order to make ATP by substrate-level phosphorylation? (Section 13.11)
- What are the major fermentation products of the following bacteria: *Lactobacillus*, *Clostridium*, *Propionibacterium*, *Escherichia*? (Sections 13.12 and 13.13)
- Give an example of a fermentation that does not employ substrate-level phosphorylation. How is energy conserved in this fermentation? (Section 13.14)
- Why is syntrophy also called “interspecies H_2 transfer”? (Section 13.15)
- Why is NO_3^- a better electron acceptor for anaerobic respiration than is SO_4^{2-} ? (Section 13.16)
- What is the difference in nitrate respiration by *Escherichia coli* and *Pseudomonas*? (Section 13.17)
- Why is the enzyme hydrogenase useful to *Desulfovibrio* even when it is not grown on H_2 as electron donor? (Section 13.18)
- Compare and contrast acetogens with methanogens in terms of (1) substrates and products of their energy metabolism, (2) ability to use organic compounds as electron donors in energy metabolism, and (3) phylogeny. (Sections 13.19 and 13.20)
- Compare and contrast ferric iron reduction with reductive dechlorination in terms of (1) product of the reduction and (2) environmental significance. (Section 13.21)
- How do monooxygenases differ from dioxygenases in terms of the reactions they catalyze? Why are oxygenases necessary for the aerobic catabolism of hydrocarbons? (Section 13.22)
- How does a methanotroph differ from a methanogen? Which pathway for C_1 assimilation found in methanotrophs is most energetically efficient and why? (Section 13.23)
- How do denitrifying and sulfate-reducing bacteria degrade hydrocarbons anaerobically and without oxygenases? (Section 13.24)

APPLICATION QUESTIONS

- Where are the photosynthetic pigments located in a phototrophic purple bacterium? A cyanobacterium? A green alga? Considering the function of chlorophyll pigments, why are they not located elsewhere in the cell, for example, in the cytoplasm or in the cell wall? (Section 13.1)
- The growth rate of the phototrophic purple bacterium *Rhodobacter* is about twice as fast when the organism is grown *phototrophically* in a medium containing malate as the carbon source as when it is grown with CO_2 as the carbon source (with H_2 as the electron donor). Discuss the reasons why this is true, and list the nutritional class in which we would place *Rhodobacter* when growing under each of the two different conditions.
- Although physiologically distinct, chemolithotrophs and chemoorganotrophs share a number of features with respect to

the production of ATP. Discuss these common features along with reasons why the growth yield (grams of cells per mole of substrate consumed) of a chemoorganotroph respiring glucose is so much higher than for a chemolithotroph respiring sulfur.

- A fatty acid such as butyrate cannot be fermented in pure culture, although its anaerobic catabolism under other conditions occurs readily. How do these conditions differ, and why does the latter allow for butyrate catabolism? How then can butyrate be fermented in mixed culture?
- When methane is made from CO_2 (plus H_2) or from methanol (in the absence of H_2), various steps in the metabolic pathways are shared in common. Compare and contrast methanogenesis from these two substrates, highlighting the similarities and differences in the processes.

14 • Functional Diversity of *Bacteria*

microbiologynow

One Culture Away

Microbiologists continue to discover novel microbial processes that impact the biosphere, and the newly discovered bacterium *Methylomirabilis oxyfera* is one such example. Biological methane (CH_4) oxidation was once thought to require oxygen (O_2). Recently, however, methane oxidation has been observed in a variety of anoxic environments. Methane is a powerful greenhouse gas, and microbial consumption of methane has a major role in balancing the global methane cycle. The model for anaerobic methane oxidation was previously based on a known metabolic partnership between sulfate-reducing bacteria and methanogens able to reverse the pathway of methane production. The discovery of *M. oxyfera*, however, proves the adage that where there is energy, microorganisms will find a way to use it.

M. oxyfera emerged from an anaerobic enrichment culture begun with anoxic sediment from a canal in the Netherlands (photo). The canal received runoff from agricultural fields and contained both nitrate and methane. The enrichment culture coupled the oxidation of methane to denitrification, a process that had never before been seen. Surprisingly, however, *M. oxyfera*, though growing anaerobically, was using the standard aerobic pathway of methane oxidation! How is this possible?

M. oxyfera was found to use a novel pathway of denitrification in which two molecules of nitric oxide (NO) are used to make N_2 and O_2 ; the O_2 is then used immediately as the electron acceptor for the oxidation of methane.¹ Thus, O_2 production is central to the methane metabolism of *M. oxyfera* even though the bacterium inhabits anoxic environments. *M. oxyfera* also has a unique polyhedral morphology (photo inset) and belongs to a novel phylum of *Bacteria*, NC-10, from which no previous species had been isolated. The discovery of *M. oxyfera* shows that major discoveries in microbiology are often just “one culture away.”

The microbial world is one of immense diversity, in both form and function. Microorganisms have been evolving for more than 3.8 billion years and have diversified to fill every available habitat on Earth. In Chapter 12 we considered the evolution of microbial life and the phylogenetic tools that have revealed it. In Chapter 13 we examined the enormous metabolic diversity of microorganisms.

In this and the next three chapters we focus on microbial diversity itself, including that of *Bacteria*, *Archaea*, and *Eukarya*.

In the present chapter we consider the *functional diversity* of particular groups of *Bacteria*. In particular we focus on organisms that share distinct physiological or ecological characteristics that do not necessarily affiliate with a single coherent phylogenetic group.

I • Functional Diversity as a Concept

Microbial diversity can be understood in terms of both phylogenetic diversity and functional diversity. In Section 14.1 we define and contrast the concepts of phylogenetic diversity and functional diversity.

14.1 Making Sense of Microbial Diversity

Phylogenetic diversity is the component of microbial diversity that deals with evolutionary relationships between microorganisms. Most fundamentally, phylogenetic diversity deals with the diversity of evolutionary lineages such as phyla, genera, and species. At

its broadest, phylogenetic diversity encompasses the genetic and genomic diversity of evolutionary lineages and so can be defined on the basis of either genes or organisms (☞ Section 12.5). Most commonly, though, phylogenetic diversity is defined on the basis of ribosomal RNA gene phylogeny, which is thought to reflect the phylogenetic history of the entire organism (☞ Section 12.4). Phylogenetic diversity is the overarching theme of our coverage of microbial diversity in Chapters 15–17.

Functional diversity is the component of microbial diversity that deals with diversity in form and function as it relates to microbial physiology and ecology. It is useful to consider

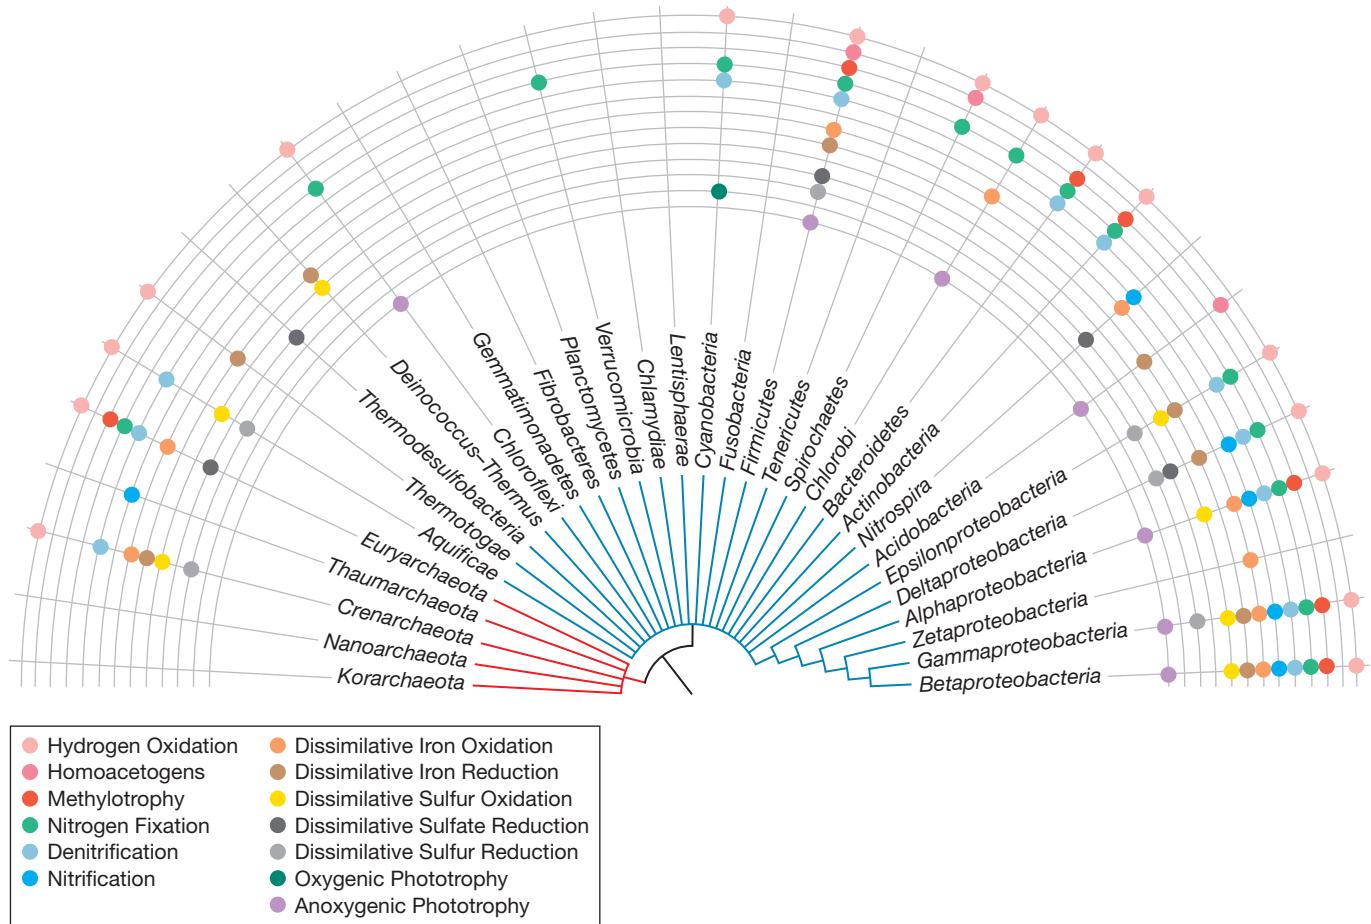

Figure 14.1 Major functional traits mapped across major phyla of *Bacteria* and *Archaea*. The dendrogram shows relationships between microbial phyla as inferred by analysis of 16S ribosomal RNA gene sequences. Blue branches are used to denote phyla of *Bacteria* and red branches phyla of *Archaea*. Colored circles indicate phyla that contain at least one species with a functional trait indicated in the color key.

microbial diversity in terms of functional groupings because organisms with common traits and common genes often share physiological characteristics and have similar ecological roles. In many cases, functional traits align with phylogenetic groups (for example, in Sections 14.3, 14.4, 14.6, 14.7, 14.20). Microbial functional diversity, however, often does not correspond with phylogenetic diversity as defined by the 16S ribosomal RNA gene. We will see many examples in this chapter where functional traits are widely distributed among the *Bacteria* and *Archaea* (Figure 14.1).

At least three reasons can be offered for why a functional trait is shared between divergent organisms with dissimilar 16S ribosomal RNA gene sequences. The first is **gene loss**, a situation where a trait present in the common ancestor of several lineages is subsequently lost in some lineages but retained in others which over evolutionary time became quite divergent. The second is **convergent evolution**, in which a trait has evolved independently in two or more lineages and is not encoded by homologous genes shared by these lineages. The third is **horizontal gene transfer** (Sections 6.12 and 12.5), a situation where genes that confer a particular trait are homologous and have been exchanged between distantly related lineages.

Functional diversity can be further defined in terms of physiological diversity, ecological diversity, and morphological diversity. *Physiological diversity* relates to the functions and activities

of microorganisms. Physiological diversity is most commonly described in terms of microbial metabolism and cellular biochemistry (Chapter 13). *Ecological diversity* relates to relationships between organisms and their environments. Organisms with similar physiological characteristics can have different ecological strategies (Section 14.11). Causes and consequences of ecological diversity will also be considered when we consider the science of microbial ecology in Chapter 19. *Morphological diversity* relates to the outward appearance of an organism (Sections 14.20–14.24). In some cases, the morphology of a group is so distinctive that the group is essentially defined by this property, for example, with the spirochetes (Section 14.22).

The concepts of physiological, ecological, and morphological diversity are often intertwined. The examples provided in this chapter are meant to be illustrative and not exhaustive, and we will consider other organisms with important ecological functions in Chapters 15–17 and 19–22.

MINIQUIZ

- Why is it necessary to consider microbial diversity in terms of phylogenetic diversity and functional diversity?
- What are three reasons that functional traits might not correspond with distinct phylogenetic groups as defined by 16S ribosomal RNA gene sequences?

II • Diversity of Phototrophic Bacteria

In this section we consider the diversity of phototrophic microorganisms, those microorganisms that conserve energy from light. We will see that phototrophy is widespread within the domain *Bacteria* and that several distinct types of phototrophs can be defined on the basis of their physiological traits.

14.2 Overview of Phototrophic Bacteria

The ability to conserve energy from light evolved early in the history of life, when the Earth was anoxic (Section 12.2). Photosynthesis originated within the *Bacteria*, and the first phototrophic organisms were *anoxygenic phototrophs*, organisms that do not generate O₂ as a product of photosynthesis (Section 13.3). Instead of H₂O, these early phototrophs likely used H₂, ferrous iron, or H₂S as the electron donor for photosynthesis. Anoxygenic photosynthesis is present in five bacterial phyla: the *Proteobacteria*, *Chlorobi*, *Chloroflexi*, *Firmicutes*, and *Acidobacteria*. Oxygenic photosynthesis is known only within the *Cyanobacteria* (Figure 14.1). There is extensive metabolic diversity among the anoxygenic phototrophs, which are found in a wide range of habitats. It is clear that horizontal gene exchange has had a major impact on the evolution of photosynthesis and on the distribution of photosynthetic genes across the phylogenetic tree of *Bacteria*.

Phototrophic bacteria have several common features. All phototrophic bacteria use chlorophyll-like pigments and various accessory pigments to harvest energy from light and transfer this energy to a membrane-bound reaction center where it is used

to drive electron transfer reactions that ultimately result in the production of ATP (Sections 13.1–13.4). Anoxygenic phototrophic bacteria have either a type I or type II photosystem. The terms “type I” and “type II” refer to the structure of the photosynthetic reaction center. Type I photosystems are most similar to photosystem I of oxygenic phototrophs while type II photosystems are most similar to photosystem II of oxygenic phototrophs. Both types of photosystems are present in cyanobacteria (Section 13.4), whereas only one type or the other is present in anoxygenic phototrophs. In some cases photosynthetic pigments are found in the cytoplasmic membrane, but often they are present in intracellular photosynthetic membrane systems that originate from invaginations of the cytoplasmic membrane. These internal membranes allow phototrophic bacteria to increase the amount of pigment they contain for better use of light of low intensities.

Many phototrophic bacteria couple light energy to carbon fixation through a variety of different mechanisms (Section 13.5), but not all phototrophs fix CO₂; some instead either prefer or require organic sources of carbon to support growth. We will see that many of the characteristics of phototrophic bacteria, including their membrane systems and photosynthetic pigments, have evolved as a result of niche adaptation for the light environment.

MINIQUIZ

- What form of photosynthesis was most likely the first to appear on Earth?

14.3 Cyanobacteria

Key Genera: *Prochlorococcus*, *Crocospaera*, *Synechococcus*, *Trichodesmium*, *Oscillatoria*, *Anabaena*

Cyanobacteria comprise a large, morphologically and ecologically heterogeneous group of oxygenic, phototrophic *Bacteria*. As we saw in Section 12.2, these organisms were the first oxygen-evolving phototrophic organisms on Earth, and over billions of years converted the once anoxic atmosphere of Earth to the oxygenated atmosphere we see today.

Phylogeny and Classification of Cyanobacteria

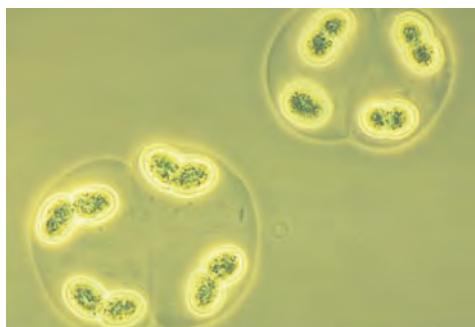

The morphological diversity of the *Cyanobacteria* is impressive (Figure 14.2). Both unicellular and filamentous forms are known, and there is considerable variation within these morphological types. Cyanobacterial cells range in size from 0.5 µm in diameter to cells as large as 100 µm in diameter. *Cyanobacteria* can be divided into five morphological groups: (1) *Chroococcales* are unicellular, dividing by binary fission (Figure 14.2a); (2) *Pleurocapsales* are unicellular, dividing by multiple fission (colonial) (Figure 14.2b); (3) *Oscillatoriales* are filamentous nonheterocystous forms (Figure 14.2c); (4) *Nostocales* are filamentous, divide along a single axis, and are capable of cellular differentiation (Figure 14.2d); and (5) *Stigonematales* are morphologically similar to *Nostocales* except that cells divide in multiple planes forming branching filaments (Figure 14.2e). Finally, the **prochlorophytes** are a lineage of unique unicellular *Cyanobacteria* once thought to be distinct but now classified within the *Chroococcales*. Table 14.1 lists some major genera currently recognized in each group.

Some of the major morphological classifications of *Cyanobacteria* correspond to coherent phylogenetic groups, but others do

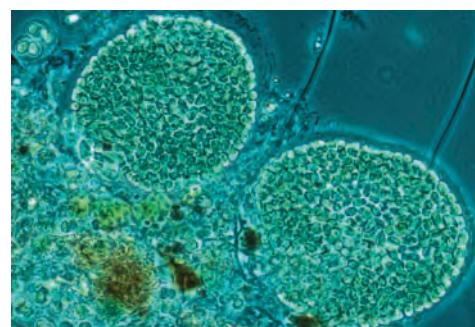

Table 14.1 Genera and grouping of cyanobacteria

Group	Genera
Group I, Chroococcales. Unicellular or cell aggregates	<i>Gloeothece</i> (Figure 14.2a), <i>Gloeobacter</i> , <i>Synechococcus</i> , <i>Cyanothece</i> , <i>Gloeocapsa</i> , <i>Synechocystis</i> , <i>Chamaesiphon</i> , <i>Merismopedia</i> , <i>Crocospaera</i> (Figure 14.7a), <i>Prochlorococcus</i> , <i>Prochloron</i>
Group II, Pleurocapsales. Reproduce by formation of small spherical cells called baecocytes produced through multiple fission	<i>Pleurocapsa</i> (Figure 14.2b), <i>Dermocarpa</i> , <i>Xenococcus</i> , <i>Dermocarpella</i> , <i>Myxosarcina</i> , <i>Chroococcidiopsis</i>
Group III, Oscillatoriales. Undifferentiated filamentous cells that divide by binary fission in a single plane	<i>Lyngbya</i> (Figure 14.2c), <i>Spirulina</i> (Figure 14.5), <i>Arthrosira</i> , <i>Oscillatoria</i> (Figure 14.6a–b), <i>Microcoleus</i> , <i>Pseudanabaena</i> , <i>Trichodesmium</i> (Figure 14.7b)
Group IV, Nostocales. Filamentous cells that produce heterocysts	<i>Nodularia</i> (Figures 14.2d), <i>Nostoc</i> , <i>Calothrix</i> (Figure 14.8a–b), <i>Anabaena</i> (Figure 14.6c), <i>Cylindrospermum</i> , <i>Scytonema</i> , <i>Richelia</i> (Figure 14.7c)

(a) Unicellular, *Gloeothece*; a single cell measures 5–6 µm in diameter; (b) colonial, *Pleurocapsa*; these structures contain hundreds of cells and are > 50 µm in diameter; (c) filamentous, *Lyngbya*; a single cell measures about 10 µm wide; (d) filamentous heterocystous, *Nodularia*; a single cell measures about 10 µm wide; (e) filamentous branching, *Fischerella*; a cell is about 10 µm wide. See how morphological diversity relates to phylogenetic diversity in Figure 14.3.

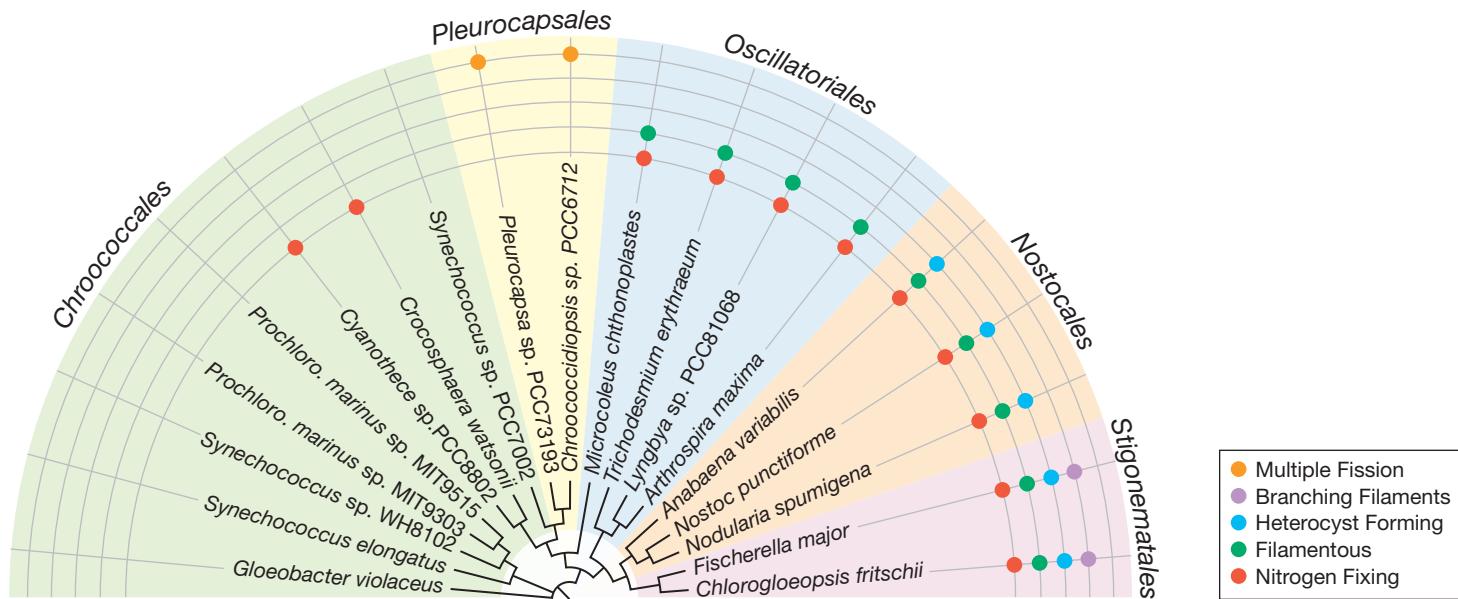

Figure 14.3 Taxonomically informative traits mapped onto the phylogeny of *Cyanobacteria*. The dendrogram depicts phylogenetic relationships inferred from analysis of conserved protein families in cyanobacterial genomes. Colored circles are used to indicate species traits as indicated by the key. Color shading is used to indicate taxonomic groupings. “Prochloro.” is used to indicate *Prochlorococcus*, which is a distinct group within the *Chroococcales*. Note that the *Chroococcales* and *Oscillatoriales* are not monophyletic in origin, meaning that these traits have arisen independently on multiple occasions in the phylogeny.

Stigonematales share a common ancestor and form a coherent phylogenetic group indicating a single origin of cellular differentiation within the *Cyanobacteria* (Figure 14.3). All *Stigonematales* share a single ancestor within the clade composed of *Nostocales* and *Stigonematales*, indicating that the capacity to form branching filaments arose only once within the lineage of *Cyanobacteria* capable of cellular differentiation (Figure 14.3). In contrast, unicellular and simple filamentous *Cyanobacteria* (*Chroococcales* and *Oscillatoriales*, respectively) are dispersed in the cyanobacterial phylogeny, and these morphological groups do not represent coherent evolutionary lineages (Figure 14.3).

Physiology and Photosynthetic Membranes

Cyanobacteria are oxygenic phototrophs and therefore have both type I and type II photosystems. All species are able to fix CO₂ by the Calvin cycle, many can fix N₂, and most can synthesize their own vitamins. Cells harvest energy from light and fix CO₂ during the day. During the night, cells generate energy by fermentation or aerobic respiration of carbon storage products such as glycogen. While CO₂ is the predominant source of carbon for most species, some cyanobacteria can assimilate simple organic compounds such as glucose and acetate if light is present, a process called *photoheterotrophy*. A few cyanobacteria, mainly filamentous species, can also grow in the dark on glucose or sucrose, using the sugar as both carbon and energy source. Finally, when sulfide concentrations are high, some cyanobacteria are able to switch from oxygenic photosynthesis to anoxygenic photosynthesis using hydrogen sulfide rather than water as electron donor for photosynthesis (Figure 13.15).

Cyanobacteria have specialized membrane systems called *thylakoids* that increase the ability of cells to harvest light energy

(Figure 13.10). The cell wall of cyanobacteria contains peptidoglycan and is structurally similar to that of gram-negative bacteria. Photosynthesis takes place in the thylakoid membrane, a complex and multilayered photosynthetic membrane system containing photopigments and proteins that mediate photosynthesis (Sections 13.1 and 13.2). In most unicellular cyanobacteria, the thylakoid membranes are arranged in regular concentric circles around the periphery of the cytoplasm (Figure 14.4). Cyanobacteria produce chlorophyll *a*, and most also have characteristic pigments called **phycobilins** (Figure 13.10), which function as accessory pigments in photosynthesis. One class of phycobilins, *phycocyanins*, are blue and, together with the green chlorophyll *a*, are responsible for the blue-green color of most cyanobacteria. Some cyanobacteria produce *phycoerythrin*, a red phycobilin, and species producing phycoerythrin are red or brown. Photopigments are fluorescent and emit light when visualized using a

M. R. Edwards

fluorescence microscope (Figure 14.5). Prochlorophytes, such as *Prochlorococcus* and *Prochloron*, are unique among *Cyanobacteria* in that all members of this group contain chlorophyll *a* and *b* but do not contain phycobilins.

Motility and Cellular Structures

Cyanobacteria possess several mechanisms for motility. Many cyanobacteria exhibit gliding motility (Section 2.18). Gliding occurs only when a cell or filament is in contact with a solid surface or with another cell or filament. In some cyanobacteria, gliding is not a simple translational movement but is accompanied by rotations, reversals, and flexing of filaments. Most gliding species exhibit directional movement toward light (phototaxis), and chemotaxis (Section 2.19) may occur as well. *Synechococcus* exhibits an unusual form of swimming motility that does not require flagella or any other extracellular organelle. The cell surface of *Synechococcus* has specialized proteins that provide direct thrust through a mechanism that has yet to be resolved. Gas vesicles (Section 2.15) are also found in a variety of aquatic cyanobacteria and are important in positioning cells in the water column. The function of gas vesicles is to regulate cell buoyancy such that cells can remain in a position in the water column where light intensity is optimal for photosynthesis.

Cyanobacteria are able to form a variety of structures associated with energy storage, reproduction, and survival. Many cyanobacteria produce extensive mucilaginous envelopes, or sheaths, that bind groups of cells or filaments together (Figure 14.2a). Some filamentous cyanobacteria can form *hormogonia* (Figure 14.6), short, motile filaments that break off from longer filaments to facilitate dispersal in times of stress. Some species also form resting structures called *akinetes* (Figure 14.6c), which protect the organism during periods of darkness, desiccation, or cold. Akinetes are cells with thickened outer walls. When conditions improve, akinetes germinate by breaking down their outer wall and initiating growth of a new vegetative filament. Many cyanobacteria also

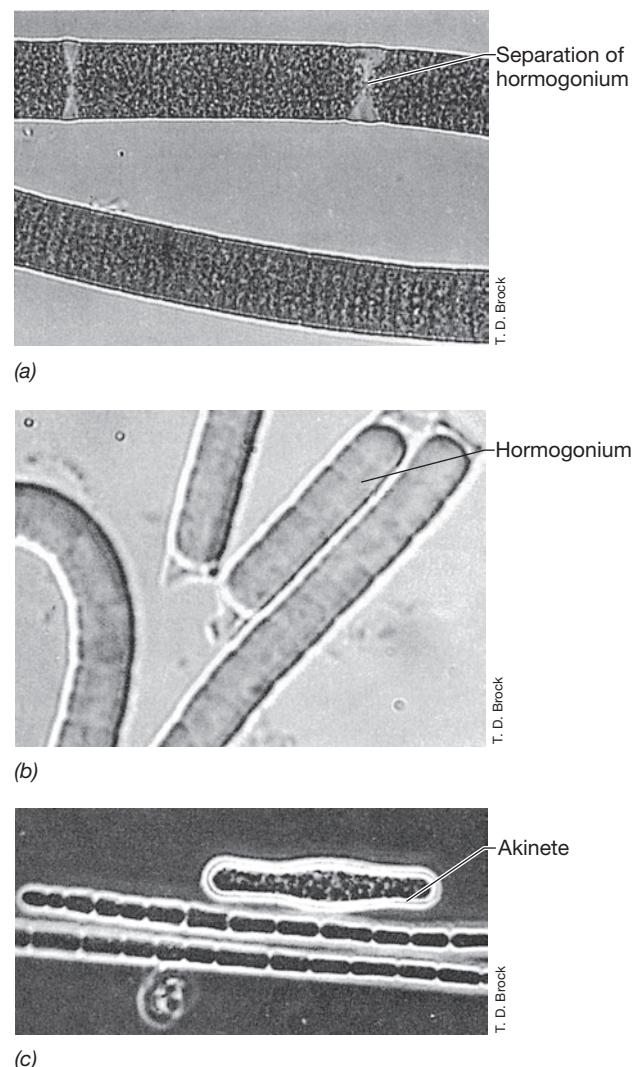

Figure 14.6 Structural differentiation in filamentous cyanobacteria. (a) Initial stage of hormogonium formation in *Oscillatoria*. Notice the empty spaces where the hormogonium is separating from the filament. (b) Hormogonium of a smaller *Oscillatoria* species. Notice that the cells at both ends are rounded. Cells are about 10 μm wide. Differential interference contrast microscopy. (c) Akinete (resting spore) of *Anabaena* in a phase-contrast micrograph, cells about 5 μm wide.

form a structure called *cyanophycin*. This structure is a copolymer of aspartic acid and arginine and is a nitrogen storage product; when nitrogen in the environment becomes deficient, cyanophycin is broken down and used as a cellular nitrogen source. Many species of the *Nostocales* and *Stigonematales* are also able to form heterocysts, as discussed next.

Heterocysts and Nitrogen Fixation

Many cyanobacteria are capable of nitrogen fixation (Figure 14.3). The nitrogenase enzyme, however, is inhibited by oxygen and thus nitrogen fixation cannot occur along with oxygenic photosynthesis (Section 3.17). Cyanobacteria have evolved several regulatory mechanisms for separating nitrogenase activity from photosynthesis (Section 7.13). For example, many unicellular cyanobacteria, such as *Cyanothece* and *Crocospheara* (Figure 14.7a), fix nitrogen only at night when photosynthesis does

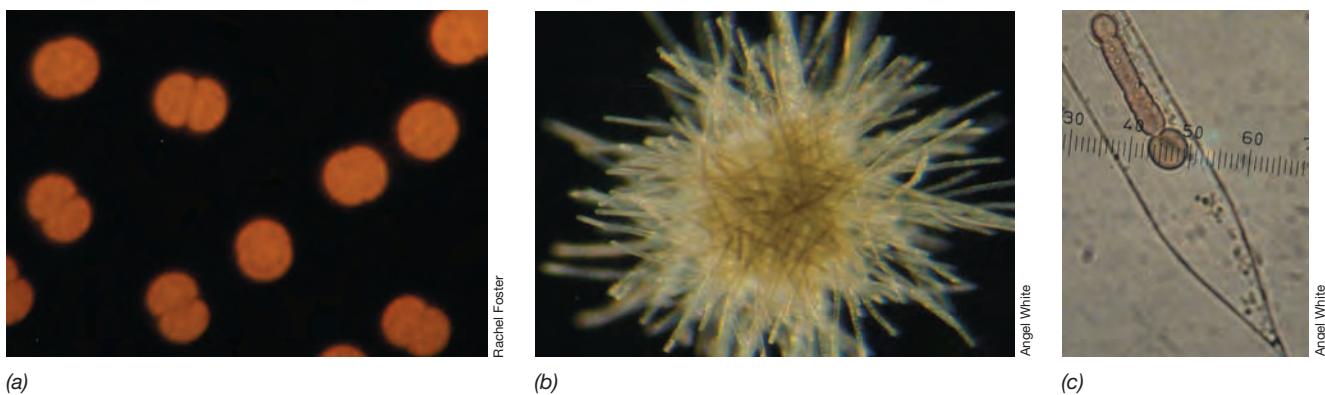

Figure 14.7 Marine cyanobacteria that fix N_2 . (a) Unicellular *Crocosphaera*-like cells in the process of dividing; cells are approximately 5 μm diameter. (b) Colonial “tuft” of *Trichodesmium*. The tuft is composed of many attached undifferentiated unbranching filaments and has a diameter of approximately 100 μm . (c) A diatom containing the cyanobacterial symbiont *Richelia* (scale in micrometers). The *Richelia* symbiont is an unbranching filament with a terminal heterocyst; cells are about 5 μm wide.

not occur. In contrast, the filamentous cyanobacteria *Trichodesmium* (Figure 14.7b) fixes nitrogen only during the day through a mechanism that remains somewhat unclear, but appears to require transient suppression of photosynthetic activity within filaments. Finally, many filamentous cyanobacteria of the *Nostocales* and *Stigonematales* facilitate nitrogen fixation by forming specialized cells called *heterocysts*, either on the ends of filaments (Figure 14.8a, b) or along the filament (Figure 14.8c, d).

Heterocysts arise from differentiation of vegetative cells and are the sites of nitrogen fixation in heterocystous cyanobacteria. Heterocysts are surrounded by a thickened cell wall that slows the diffusion of O_2 into the cell and permits nitrogenase activity to

occur in an anoxic environment. Heterocysts lack photosystem II (Figure 14.8), the oxygen-evolving photosystem that generates reducing power from H_2O (Section 13.4). Without photosystem II, heterocysts are unable to fix CO_2 and thus lack the necessary electron donor (pyruvate) for nitrogen fixation. However, heterocysts have intercellular connections with adjacent vegetative cells that allow for mutual exchange of materials between these cells. Fixed carbon is imported by the heterocyst from adjacent vegetative cells, and this is oxidized to yield electrons for nitrogen fixation. The products of photosynthesis move from vegetative cells to heterocysts, and fixed nitrogen moves from heterocysts to vegetative cells (Section 7.13 and Figure 7.28).

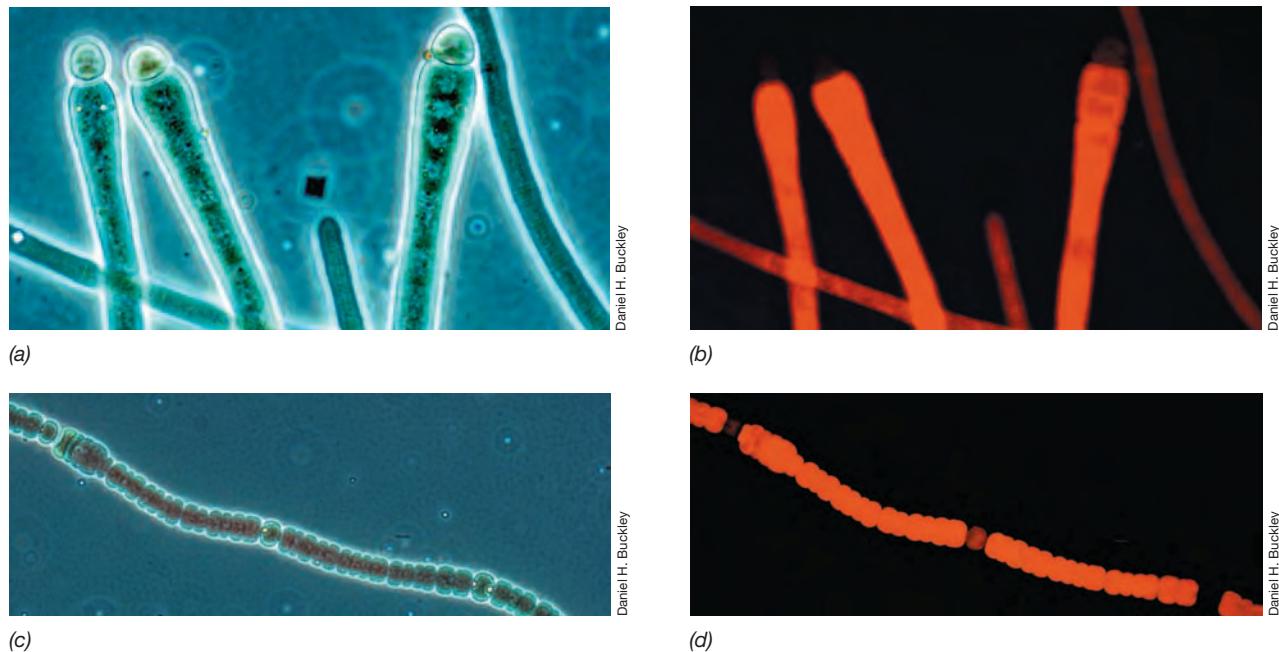

Figure 14.8 Heterocysts. Differentiation of heterocysts causes the loss of photopigments and inability to carry out photosynthesis. (c) Phase-contrast micrograph of *Fischerella*. (d) Fluorescence micrograph of the same *Fischerella* filaments; cells are about 10 μm wide. See how heterocyst formation is regulated at the genetic level in the well-studied cyanobacterium, *Anabaena* in Figure 7.28.

Ecology of Cyanobacteria

Cyanobacteria are of central importance to the productivity of the oceans. Small unicellular cyanobacteria, such as *Synechococcus* and *Prochlorococcus* (Section 19.10), are the most abundant phototrophs in the oceans. Together these organisms contribute 80% of marine photosynthesis and 35% of all photosynthetic activity on Earth.

Cyanobacterial nitrogen fixation represents the dominant input of new nitrogen into vast segments of Earth's oceans, particularly in oligotrophic tropical and subtropical waters. Marine nitrogen fixation is dominated by two groups of cyanobacteria, the unicellular species and the filamentous *Trichodesmium*. *Crocospaera* (Figure 14.7a) and relatives dominate nitrogen fixation in most of the Pacific Ocean and are widespread in tropical and subtropical habitats. *Trichodesmium* is the dominant nitrogen-fixing bacterium in the North Atlantic Ocean and parts of the Pacific where dissolved iron concentrations are elevated. *Trichodesmium* forms macroscopically visible tufts of filaments (Figure 14.7b) and relies on gas vesicles to remain suspended in the photic zone where it is often observed in dense masses of cells called *blooms*. In addition, other marine nitrogen-fixers including species of *Calothrix* and *Richelia* form symbiotic associations with diatoms (Figure 14.7c); these symbiotic associations are often observed in tropical and subtropical oceans. Finally, heterocystous cyanobacteria such as *Nodularia* (Figure 14.2d) and *Anabaena* can sometimes dominate nitrogen fixation in cold waters of the Northern Hemisphere and are often observed in the Baltic Sea.

Cyanobacteria are also widely found in terrestrial and freshwater environments. In general, they are more tolerant of environmental extremes, particularly extremes of desiccation, than are algae (eukaryotes). Cyanobacteria are often the dominant or sole oxygenic phototrophic organisms in hot springs, saline lakes, desert soils, and other extreme environments. In some of these environments, cyanobacterial mats of variable thickness may form (Figure 19.9). Freshwater lakes, especially those rich in inorganic nutrients, often develop blooms of cyanobacteria, especially

in late summer when temperatures are warmest (Figures 19.1 and 19.17). A few cyanobacteria are symbionts of liverworts, ferns, and cycads, and a number are phototrophic components of lichens, a symbiosis between a phototroph and a fungus (Section 22.1).

Several metabolic products of cyanobacteria are of considerable practical importance. Some cyanobacteria produce potent neurotoxins, and toxic blooms may form when massive accumulations of cyanobacteria develop. Animals ingesting water containing these toxic products may be killed. Many cyanobacteria are also responsible for the production of earthy odors and flavors in some freshwater, and if such waters are used as drinking water sources, aesthetic problems may arise. The major compound produced is geosmin, a substance also produced by many actinomycetes (Section 15.12).

MINIQUIZ

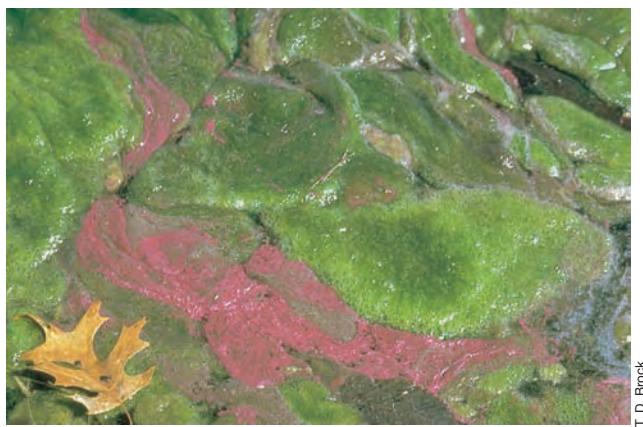

- What are the differentiating properties of the five major morphological groups of *Cyanobacteria*?
- What is a heterocyst and what is its function?

14.4 Purple Sulfur Bacteria

Key Genera: *Chromatium*, *Ectothiorhodospira*

Purple sulfur bacteria are anoxygenic phototrophs that use hydrogen sulfide (H_2S) as an electron donor for photosynthesis. Purple sulfur bacteria are a phylogenetically coherent group found within the order *Chromatiales* in the *Gammaproteobacteria*.

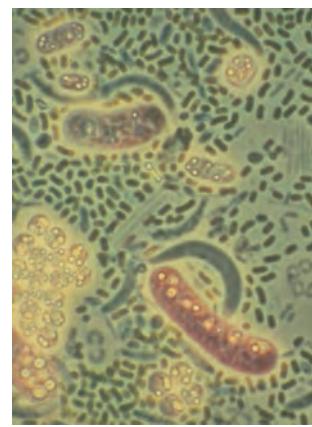

Purple sulfur bacteria are generally found in illuminated anoxic zones where H_2S is present. Such habitats occur commonly in lakes, marine sediments, and “sulfur springs,” where H_2S produced geochemically or biologically can support the growth of purple sulfur bacteria (Figure 14.9). Purple sulfur bacteria are also commonly found in microbial mats (Section 19.5) and in salt

(b) *Thiospirillum jenense*, a very large, polarly flagellated spiral; cells are about 30 μm long. Note the sulfur globules. (c) *Thiopedia rosea*; cells are about 1.5 μm wide. (d) Phase-contrast micrograph of cells of *Ectothiorhodospira mobilis*; cells are about 0.8 μm wide. Note external sulfur globules (arrow).

marsh sediments. The characteristic color of purple sulfur bacteria comes from their carotenoids, accessory pigments involved in light harvesting (Section 13.2). These bacteria use a type II photosystem (Figure 13.3), contain either bacteriochlorophyll *a* or *b*, and carry out CO₂ fixation by the Calvin cycle (Section 13.5).

During autotrophic growth of purple sulfur bacteria, H₂S is oxidized to elemental sulfur (S⁰), which is deposited as sulfur granules (Figure 14.10). When sulfide is limiting, the sulfur is used as an electron donor for photosynthesis, resulting in the oxidation of S⁰ to sulfate (SO₄²⁻). Many purple sulfur bacteria can also use other reduced sulfur compounds as photosynthetic electron donors; for example, thiosulfate (S₂O₃²⁻) is commonly used to grow laboratory cultures.

The purple sulfur bacteria form two families: the *Chromatiaceae* and the *Ectothiorhodospiraceae*. Species of the two families are readily distinguished by the location of sulfur granules and by their photosynthetic membranes. *Chromatiaceae*, including the genera *Chromatium* and *Thiocapsa*, store S⁰ granules *inside* their cells (in the periplasmic space) and have vesicular intracellular photosynthetic membrane systems (Figure 14.11). These

Figure 14.11 Membrane systems of phototrophic purple bacteria as revealed by transmission electron microscopy. (a) *Ectothiorhodospira mobilis*, showing the photosynthetic membranes in flat sheets (lamellae). (b) *Allochromatium vinosum*, showing the membranes as individual, spherical vesicles.

organisms are common in stratified lakes containing sulfide and in the anoxic sediments of salt marshes. *Ectothiorhodospiraceae*, including the two main genera *Ectothiorhodospira* and *Halorhodospira*, oxidize H₂S to S⁰ that is deposited *outside* the cell (Figure 14.10d) and have lamellar intracellular photosynthetic membrane systems (Figure 14.11). These genera are also interesting because many species are extremely halophilic (salt-loving) or alkaliphilic (alkalinity-loving) and are among the most extreme in these characteristics of all known *Bacteria*. These organisms are typically found in saline lakes, soda lakes, and salterns, where abundant levels of SO₄²⁻ support sulfate-reducing bacteria (Section 20.4 and Section 14.9), the organisms that produce H₂S.

Purple sulfur bacteria are often observed in high density in meromictic (permanently stratified) lakes. Meromictic lakes form layers because they have denser (usually saline) water on the bottom and less dense (usually freshwater) water nearer the surface. If sufficient sulfate is present to support sulfate reduction, sulfide is produced in the sediments and diffuses upward into the anoxic bottom waters. The presence of sulfide and light in the anoxic layers of the lake allow purple sulfur bacteria to form dense cell masses, usually in association with green phototrophic bacteria (Figure 14.9b).

MINIQUIZ

- What is the source of the purple color from which the purple sulfur bacteria get their name?
- Where would you expect to find purple sulfur bacteria?

14.5 Purple Nonsulfur Bacteria and Aerobic Anoxygenic Phototrophs

Purple Nonsulfur Bacteria

Key Genera: *Rhodospirillum*, *Rhodoferax*, *Rhodobacter*

The **purple nonsulfur bacteria** are the most metabolically versatile of all microorganisms. Despite their name, they are not always purple; these organisms synthesize an array of carotenoids (➡ Section 13.2) that can lend them a variety of spectacular colors (Figure 14.12). Together, these pigments give purple bacteria their colors, usually purple, red, or orange. Purple nonsulfur bacteria are typically photoheterotrophs (a condition where light is the energy source and an organic compound is the carbon source), and species are able to use a wide range of carbon sources and electron donors for photosynthesis, including organic acids, amino acids, alcohols, sugars, and even aromatic compounds like benzoate or toluene. Like purple sulfur bacteria, purple nonsulfur bacteria use a type II photosystem, and contain either bacteriochlorophyll *a* or *b*. The purple nonsulfur bacteria are morphologically and phylogenetically diverse (Figure 14.13) and reside within the *Alphaproteobacteria* (e.g., *Rhodospirillum*, *Rhodobacter*, *Rhodopseudomonas*) or *Betaproteobacteria* (e.g., *Rubrivivax*, *Rhodoferax*).

Purple nonsulfur bacteria are able to conserve energy through a variety of metabolic processes. For example, some species can grow photoautotrophically using H₂, low levels of H₂S, or even ferrous iron (Fe²⁺) as the electron donor for photosynthesis with CO₂ fixation carried out by the Calvin cycle. Most species are also able to grow in darkness by using aerobic respiration of organic or even some inorganic compounds; synthesis of the photosynthetic machinery is typically repressed by O₂. Finally, some species can

Figure 14.12 Photograph of liquid cultures of phototrophic purple bacteria showing the color of species with various carotenoid pigments. The blue culture is a carotenoidless mutant strain of *Rhodospirillum rubrum* showing that bacteriochlorophyll *a* is actually blue. The bottle on the far right (*Rhodobacter sphaeroides* strain G) lacks one of the carotenoids of the wild type and thus is greener.

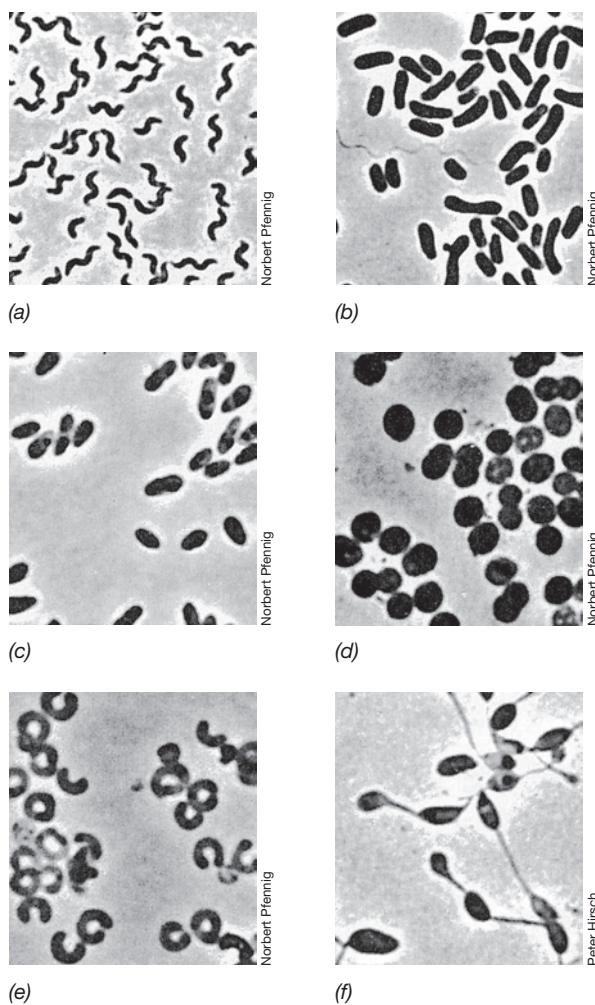

Figure 14.13 Representatives of several genera of purple nonsulfur bacteria. (a) *Phaeospirillum fulvum*; cells are about 3 µm long. (b) *Rhodoblastus acidophilus*; cells are about 4 µm long. (c) *Rhodobacter sphaeroides*; cells are about 1.5 µm wide. (d) *Rhodopila globiformis*; cells are about 1.6 µm wide. (e) *Rhodocyclus purpureus*; cells are about 0.7 µm in diameter. (f) *Rhodomicrobium vannielii*; cells are about 1.2 µm wide.

also grow by fermentation or anaerobic respiration using a variety of electron donors and acceptors.

Enrichment and isolation of purple nonsulfur bacteria is easy using a mineral salts medium supplemented with an organic acid as carbon source. Such media, inoculated with a mud, lake water, or sewage sample and incubated anaerobically in the light, invariably select for purple nonsulfur bacteria. Enrichment cultures can be made even more selective by omitting fixed nitrogen sources (for example, ammonia) or organic nitrogen sources (for example, yeast extract or peptone) from the medium and supplying a gaseous headspace of N₂. Virtually all purple nonsulfur bacteria can fix N₂ and will thrive under such conditions, rapidly outcompeting other bacteria.

Aerobic Anoxygenic Phototrophs

Key Genera: *Roseobacter*, *Erythrobacter*

The **aerobic anoxygenic phototrophs** are obligate aerobic heterotrophs that use light as a supplemental source of energy to support growth. Like purple nonsulfur bacteria, aerobic anoxygenic

phototrophs are phylogenetically diverse and are *Alphaproteobacteria* or *Betaproteobacteria*. The primary physiological difference with the purple nonsulfur bacteria is that aerobic anoxygenic phototrophs are strict heterotrophs and employ anoxygenic photosynthesis only under oxic conditions as a supplemental source of energy. Aerobic anoxygenic phototrophs contain bacteriochlorophyll *a* and a type II photosystem, but are unable to fix CO₂ and must rely on organic carbon for growth. Carotenoids of various types lend colors of yellow, orange, or pink to cultures.

Aerobic anoxygenic phototrophs are only able to photosynthesize when grown on a day/night cycle. Under these conditions, bacteriochlorophyll *a* is made only in the dark and then used to conserve energy by photophosphorylation when the light returns. Aerobic anoxygenic phototrophs can account for as much as a quarter of the microbial community inhabiting coastal marine waters and 5% of gross photosynthesis in such systems (☞ Section 19.10). Common genera found in coastal marine habitats include *Roseobacter* and *Erythrobacter*.

MINIQUIZ

- What are some similarities between purple nonsulfur bacteria and aerobic anoxygenic phototrophs? What are the differences between these two groups?
- Where would you expect to find aerobic anoxygenic phototrophs?

14.6 Green Sulfur Bacteria

Key Genera: *Chlorobium*, *Chlorobaculum*, “*Chlorochromatium*”

Green sulfur bacteria are a phylogenetically coherent group of anoxygenic phototrophs that forms the phylum *Chlorobi*. Green sulfur bacteria have little metabolic versatility and they are typically nonmotile and strictly anaerobic anoxygenic phototrophic bacteria. The group is also morphologically restricted and includes primarily short to long rods (Figure 14.14).

Like purple sulfur bacteria, green sulfur bacteria oxidize hydrogen sulfide (H₂S) as an electron donor for autotrophic growth, oxidizing it first to sulfur (S⁰) and then to sulfate (SO₄²⁻). But

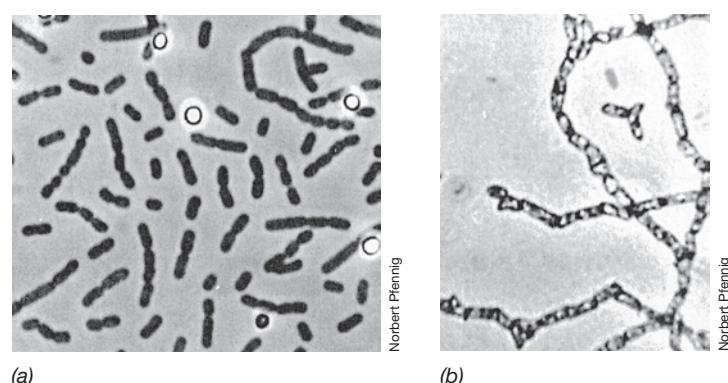

Figure 14.14 Phototrophic green sulfur bacteria. (a) *Chlorobium limicola*; cells are about 0.8 µm wide. Note the spherical sulfur granules deposited extracellularly. (b) *Chlorobium clathratiforme*, a bacterium forming a three-dimensional network; cells are about 0.8 µm wide.

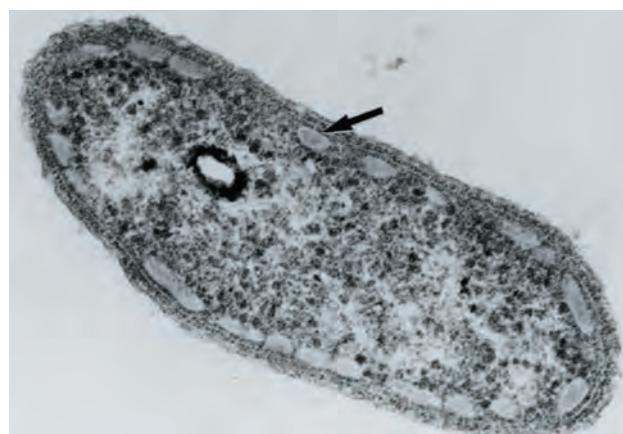

Figure 14.15 The thermophilic green sulfur bacterium *Chlorobaculum tepidum*. Transmission electron micrograph. Note chlorosomes (arrow) in the cell periphery. A cell is about 0.7 µm wide.

unlike most purple sulfur bacteria, the S⁰ produced by green sulfur bacteria is deposited only outside the cell (Figure 14.14a). Autotrophy is supported not by the reactions of the Calvin cycle, as in purple bacteria, but instead by a reversal of steps in the citric acid cycle (☞ Section 13.5 and Figure 13.19a), a unique means of autotrophy in phototrophic bacteria.

Pigments and Ecology

Green sulfur bacteria contain bacteriochlorophyll *c*, *d*, or *e* and house these pigments in unique structures called **chlorosomes** (Figure 14.15). A small amount of bacteriochlorophyll *a* is present in the reaction center and FMO protein, which connects the chlorosome to the cytoplasmic membrane (☞ Figure 13.7b). Chlorosomes are oblong bacteriochlorophyll-rich bodies bounded by a thin, nonunit membrane and attached to the cytoplasmic membrane in the periphery of the cell (Figure 14.15 and ☞ Figure 13.7). Chlorosomes function to funnel energy into the photosystem, and this eventually leads to ATP synthesis. Unlike purple anoxygenic phototrophs, green sulfur bacteria use a type I photosystem. Both green- and brown-colored species of green sulfur bacteria are known, the brown-colored species containing bacteriochlorophyll *e* and carotenoids that turn dense cell suspensions brown (Figure 14.16).

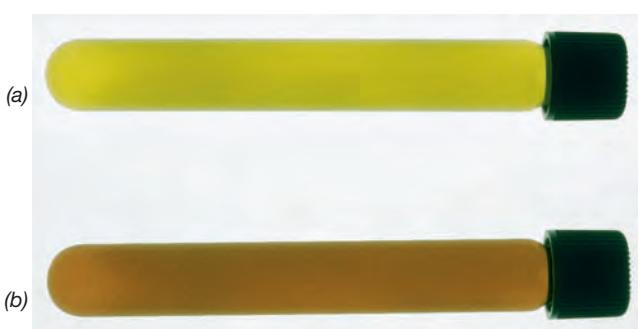

Figure 14.16 Green and brown chlorobia. Tube cultures of (a) *Chlorobaculum tepidum* and (b) *Chlorobaculum phaeobacteroides*. Cells of *C. tepidum* contain bacteriochlorophyll *c* and green carotenoids, and cells of *C. phaeobacteroides* contain bacteriochlorophyll *e* and isorenieratene, a brown carotenoid.

Like purple sulfur bacteria (Section 14.4), green sulfur bacteria live in anoxic, sulfidic aquatic environments. However, the chlorosome is a very efficient light-harvesting structure, which allows green sulfur bacteria to grow at light intensities much lower than those required by other phototrophs. Green sulfur bacteria also tend to have a greater tolerance of H₂S than do other anoxygenic phototrophs. As a result, green sulfur bacteria are typically found at the greatest depths of all phototrophic microorganisms in lakes or microbial mats, where light intensities are low and H₂S levels are the highest. As an example, a species of green sulfur bacteria isolated from a deep-sea hydrothermal vent (➡ Section 19.13) was found to be growing phototrophically on the weak glow of infrared radiation emitted from the geothermally heated rock. One species, *Chlorobaculum tepidum* (Figure 14.15), is thermophilic and forms dense microbial mats in high-sulfide hot springs. *C. tepidum* also grows rapidly and is amenable to genetic manipulation by both conjugation and transformation. Because of these features, *C. tepidum* has become the model organism for studying the molecular biology of green sulfur bacteria.

Green Sulfur Bacteria Consortia

Certain species of green sulfur bacteria form an intimate two-membered association, called a **consortium**, with a chemo-organotrophic bacterium. In the consortium, each organism benefits, and thus a variety of such consortia containing different phototrophic and chemotrophic components probably exist in nature. The phototrophic component, called the *epibiont*, is physically attached to the nonphototrophic central cell (Figure 14.17) and communicates with it in various ways (➡ Section 22.2).

The name “*Chlorochromatium aggregatum*” (not a formal name because this is a mixed culture) has been used to describe a commonly observed green-colored consortium that is green because the epibionts are green sulfur bacteria that contain green-colored carotenoids (Figure 14.17b). Evidence that the epibionts are indeed green sulfur bacteria comes from pigment analyses, the presence of chlorosomes (Figure 14.17d), and phylogenetic staining (Figure 14.17c). A structurally similar consortium called “*Pelochromatium roseum*” is brown because its epibionts produce brown-colored carotenoids (➡ Figures 22.3 and 22.4). We examine the symbiotic nature of the *Chlorochromatium* consortium in more detail in Section 22.2.

MINIQUIZ

- Which pigments are present in the chlorosome?
- What evidence exists that the epibionts of green bacterial consortia are truly green sulfur bacteria?

14.7 Green Nonsulfur Bacteria

Key Genera: *Chloroflexus*, *Heliothrix*, *Roseiflexus*

Green nonsulfur bacteria are anoxygenic phototrophs of the phylum *Chloroflexi*. The latter contains several distinct lineages, one of which, the class *Chloroflexi*, contains green nonsulfur

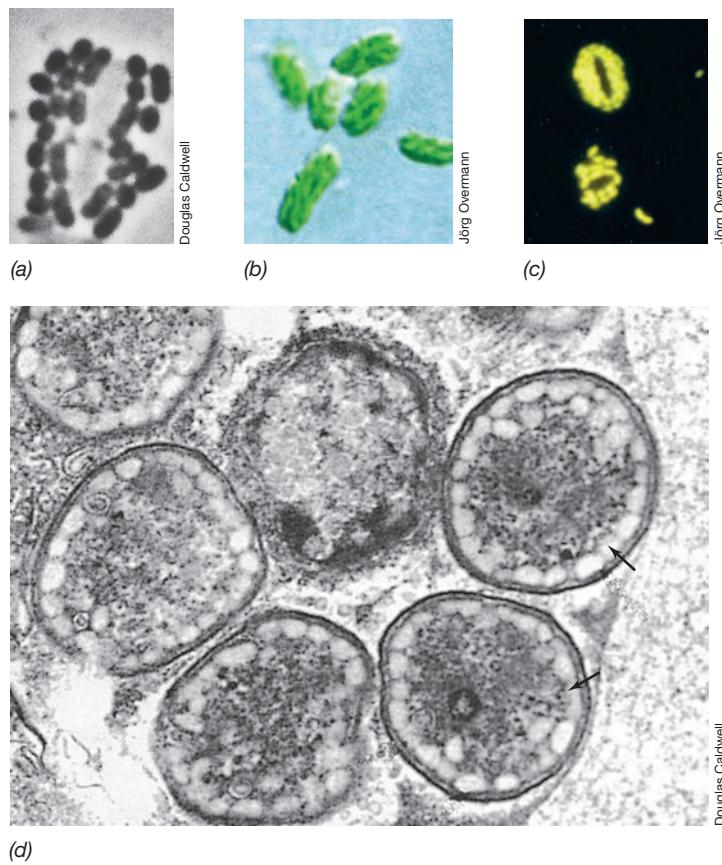

Figure 14.17 “*Chlorochromatium aggregatum*.” Consortia of green sulfur bacteria and a chemoorganotroph. (a) In a phase-contrast micrograph, the nonphototrophic central organism is lighter in color than the pigmented phototrophic bacteria. (b) Green carotenoids lend their color to the phototrophs in a differential interference contrast micrograph. (c) A fluorescence micrograph shows the cells stained with a phylogenetic FISH probe specific for green sulfur bacteria. (d) Transmission electron micrograph of a cross section through a single consortium; note the chlorosomes (arrows) in the epibionts. The entire consortium is about 3 µm in diameter.

bacteria. The remainder of the phylum contains metabolically diverse organisms including both aerobic and anaerobic chemo-organotrophs as well as the *Dehalococcoidetes*, a group of dehalogenating bacteria that use halogenated organic compounds as electron acceptors in anaerobic respiration (➡ Section 13.21). Analyses of 16S ribosomal RNA sequences from environmental samples (➡ Section 18.5) indicate that species of the phylum *Chloroflexi* are widespread and that most species in the phylum have yet to be cultivated in isolation; thus the metabolic diversity of this phylum remains poorly characterized.

All cultured representatives of the green nonsulfur bacteria are filamentous bacteria that are capable of gliding motility. *Chloroflexus*, one of the most studied of the green nonsulfur bacteria, forms thick microbial mats in neutral to alkaline hot springs along with thermophilic cyanobacteria (Figure 14.18; ➡ Figure 19.9b). Green nonsulfur bacteria grow best as photoheterotrophs using simple carbon sources as electron donors for photosynthesis. However, growth also occurs photoautotrophically using H₂ or

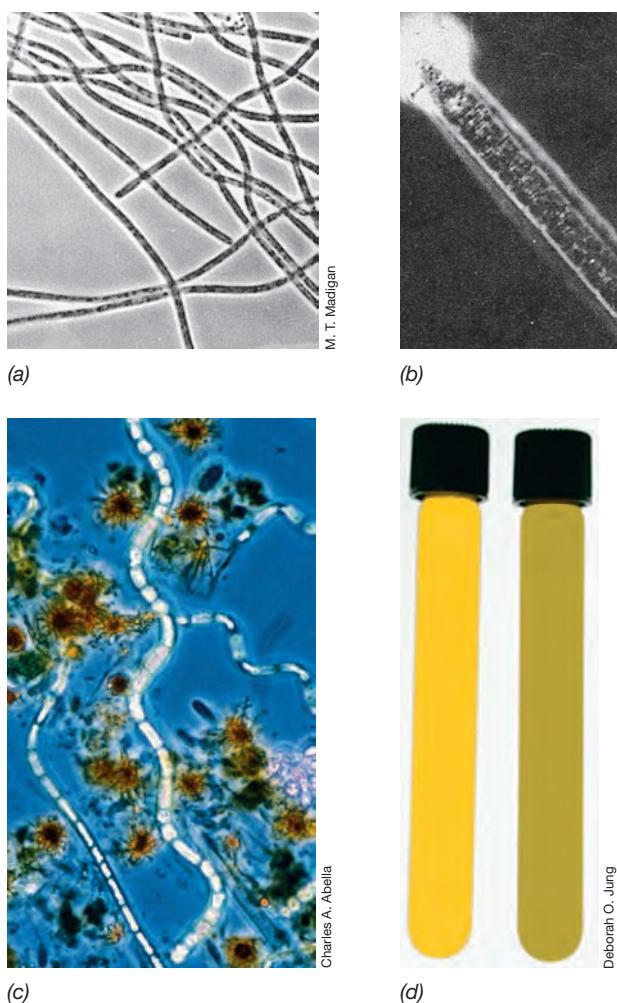

Figure 14.18 Green nonsulfur bacteria. (a) Phase-contrast micrograph of the anoxygenic phototroph *Chloroflexus aurantiacus*; cells are about 1 μm in diameter. (b) Phase-contrast micrograph of the large phototroph *Oscillochloris*; cells are about 5 μm wide. The brightly contrasting material on the top is a holdfast, used for attachment. (c) Phase-contrast micrograph of filaments of a *Chloronema* species; the cells are wavy filaments and about 2.5 μm in diameter. (d) Tube cultures of *C. aurantiacus* (right) and *Roseiflexus* (left). *Roseiflexus* is yellow because it lacks bacteriochlorophyll *c* and chlorosomes.

H_2S as electron donors for photosynthesis. The hydroxypropionate cycle, a pathway of CO_2 incorporation unique to only a few *Bacteria* and *Archaea*, supports autotrophic growth (Section 13.5). Most green nonsulfur bacteria also grow well in the dark by aerobic respiration of a wide variety of carbon sources. The photosynthetic features of the green nonsulfur bacteria are a “hybrid” between those of both green sulfur bacteria (Section 14.6) and purple phototrophic bacteria (Sections 14.4–14.5). Green nonsulfur bacteria have reaction centers that contain bacteriochlorophyll *a* and chlorosomes that contain bacteriochlorophyll *c* (Figure 14.15) and in this way are similar to green sulfur bacteria. However, in contrast to green sulfur bacteria, green nonsulfur bacteria use a type II photosystem and in this way resemble purple sulfur bacteria.

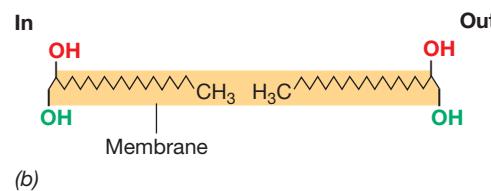

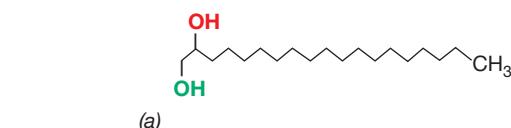

Figure 14.19 The unusual lipids of *Thermomicrombium*. (a) Membrane lipids from *Thermomicrombium roseum* contain long-chain diols like the one shown here (13-methyl-1,2-nonadecanediol). Note that unlike the lipids of other *Bacteria* or of *Archaea*, neither ester- nor ether-linked side chains are present. (b) To form a bilayer membrane, dialcohol molecules oppose each other at the methyl groups, and the —OH groups are the inner and outer hydrophilic surfaces. Small amounts of the diols have fatty acids esterified to the secondary —OH group (shown in red), whereas the primary —OH group (shown in green) can bond a hydrophilic molecule like phosphate.

Other *Chloroflexi*

In addition to *Chloroflexus*, other phototrophic green nonsulfur bacteria include the thermophile *Heliothrix* and the large-celled mesophiles *Oscillochloris* (Figure 14.18b) and *Chloronema* (Figure 14.18c). *Oscillochloris* and *Chloronema* form rather large cells, 2–5 μm wide and up to several hundred micrometers long (Figure 14.18c). Species of both genera inhabit freshwater lakes containing H_2S . *Roseiflexus* and *Heliothrix* are similar to *Chloroflexus* in their filamentous morphology and thermophilic lifestyle, but differ in a major photosynthetic property. *Roseiflexus* and *Heliothrix* lack bacteriochlorophyll *c* and chlorosomes and thus more closely resemble purple phototrophic bacteria (Sections 14.4, 14.5) than *Chloroflexus*. This can be seen in cultures of *Roseiflexus* that are yellow-orange instead of green from their extensive carotenoid pigments and lack of bacteriochlorophyll *c* (Figure 14.18d).

Thermomicrombium is a chemotrophic genus of *Chloroflexi* and a strictly aerobic, gram-negative rod, growing optimally in complex media at 75°C. Besides its phylogenetic properties, *Thermomicrombium* is also of interest because of its membrane lipids (Figure 14.19). Recall that the lipids of *Bacteria* and *Eukarya* contain fatty acids esterified to glycerol (Section 2.7). By contrast, the lipids of *Thermomicrombium* are formed on 1,2-dialcohols instead of glycerol, and have neither ester nor ether linkages (Figure 14.19). In addition, cells of *Thermomicrombium* contain only small amounts of peptidoglycan, and the cell wall is composed primarily of protein.

MINIQUIZ

- In what ways do *Chloroflexus* and *Roseiflexus* resemble *Chlorobium*? *Rhodobacter*?
- What is unique about *Thermomicrombium*?

(b) *Heliophilum fasciatum* cell bundles as observed by electron microscopy. (c) Phase-contrast micrograph of endospores from *Heliobacterium gestii*. Most heliobacteria cells are about 1–2 μm in diameter.

14.8 Other Phototrophic Bacteria

Key Genera: *Heliobacterium*, *Chloracidobacterium*

Heliobacteria

Heliobacteria are a phylogenetically coherent group of phototrophic gram-positive *Bacteria* found within the phylum *Firmicutes*. The heliobacteria are anoxygenic phototrophs and produce a unique pigment, bacteriochlorophyll *g* (➡ Figure 13.3) and use a type I photosystem. Heliobacteria grow photoheterotrophically using a narrow range of organic compounds including pyruvate, lactate, acetate, or butyrate, and the group contains five genera: *Heliobacterium*, *Heliophilum*, *Heliorestis*, *Heliomonas*, and *Heliobacillus*. All known heliobacteria form rod-shaped or filamentous cells (Figure 14.20), although *Heliophilum* is unusual because its cells form into bundles (Figure 14.20b) that are motile as a unit.

Heliobacteria are strict anaerobes, but in addition to phototrophic growth, they can grow chemotrophically in darkness by pyruvate fermentation (as can many clostridia, close relatives of the heliobacteria). Heliobacteria produce endospores, the highly resistant structures produced by certain gram-positive bacteria (➡ Section 2.16). Like the endospores of *Bacillus* or *Clostridium* species, the endospores of heliobacteria (Figure 14.20c) contain elevated calcium (Ca^{2+}) levels and the signature molecule of the endospore, *dipicolinic acid*. Heliobacteria reside in soil, especially paddy (rice) field soils, where their nitrogen fixation activities may benefit rice productivity. A large diversity of heliobacteria have also been found in highly alkaline environments, such as soda lakes and surrounding alkaline soils.

Phototrophic Acidobacteria

A novel group of anoxygenic phototrophs has been discovered growing in photosynthetic microbial mats of a thermal spring in Yellowstone National Park. *Chloracidobacterium thermophilum* is a thermophilic oxygen-tolerant anoxygenic phototroph of the phylum *Acidobacteria* (➡ Section 15.21). Similar to green sulfur bacteria, *C. thermophilum* produces bacteriochlorophyll *a* and *c*, the latter in chlorosomes (Figure 14.21), and uses

a type I photosystem. However, unlike green sulfur bacteria, *C. thermophilum* can also grow aerobically, as is true for the aerobic anoxygenic phototrophs (Section 14.5). In terms of its carbon metabolism, *C. thermophilum* is a photoheterotroph that uses short-chain fatty acids as electron donors for photosynthesis, but unlike green sulfur or green nonsulfur bacteria, it is incapable of autotrophy.

MINIQUIZ

- What types of anoxygenic phototrophs use chlorosomes?
- What kind of phototrophic bacteria make spores?

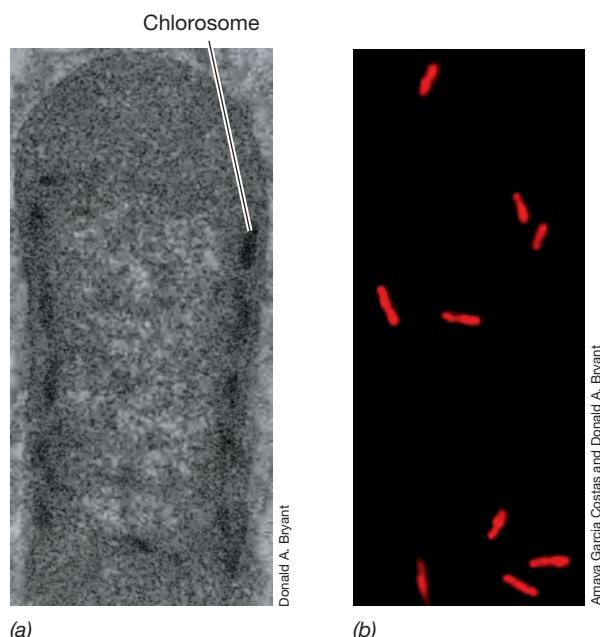

Figure 14.21 Chlorosomes in *Chloracidobacterium thermophilum*, a phototrophic member of the phylum *Acidobacteria*. (a) Electron micrograph of *C. thermophilum* showing chlorosomes. (b) Fluorescence photomicrograph of *C. thermophilum*. The red color is the fluorescence of bacteriochlorophyll *c* present in chlorosomes. A cell of *C. thermophilum* is about 0.8 μm wide.

III • Bacterial Diversity in the Sulfur Cycle

Sulfur metabolism may have fueled the earliest forms of life on our planet (☞ Section 12.1), and the sulfur cycle (☞ Section 20.4) continues to support an enormous diversity of micro-organisms. In this section we consider the diversity of organisms capable of *dissimilative sulfur metabolism*; that is, organisms that conserve energy through the oxidation or reduction of sulfur compounds (☞ Sections 13.8 and 13.18).

The remarkable diversity of prokaryotes capable of dissimilative sulfur metabolism is in part a function of the chemical diversity in which sulfur occurs in the biosphere. Sulfur has eight oxidation states that range from its most oxidized form, sulfate (SO_4^{2-} , oxidation state of +6), to thiosulfate ($\text{S}_2\text{O}_3^{2-}$, oxidation state of +2), to elemental sulfur (S^0 , oxidation state of 0), and finally to hydrogen sulfide (H_2S , oxidation state of -2), its most reduced form. In addition, sulfur compounds can take on diverse chemical forms including inorganic sulfur compounds, organosulfur compounds, and metal sulfides.

In this section we will focus on the diversity of **dissimilative sulfate-reducers**, **dissimilative sulfur-reducers**, and **dissimilative sulfur-oxidizers**. Anoxygenic phototrophs, such as the purple and green sulfur bacteria discussed in Sections 14.4–14.6, are also important links in the sulfur cycle. However, here we restrict our focus to chemotrophic dissimilative metabolisms.

14.9 Dissimilative Sulfate-Reducing Bacteria

Key Genera: *Desulfovibrio*, *Desulfobacter*

Sulfate-reducing bacteria gain energy by coupling the oxidation of H₂ or organic compounds to the reduction of SO₄²⁻ (anaerobic respiration). There are more than 30 known genera of sulfate reducers found across five phyla of *Bacteria* and *Archaea* (Figure 14.22). Most sulfate reducers reside in the *Delta proteobacteria*, though sulfate reducers are also found in the *Firmicutes* (e.g., *Desulfovibrion* and *Desulfovibrio*), *Thermodesulfobacteria* (e.g.,

Thermodesulfobacterium), and *Nitrospira* (e.g., *Thermodesulfovibrio*). Sulfate reduction also occurs in *Archaeoglobus*, a genus of the archaeal phylum *Euryarchaeota*.

Physiology of Sulfate-Reducing Bacteria

Sulfate-reducing bacteria are morphologically and biochemically diverse. The biochemistry of sulfate reduction was discussed in Section 13.18, so here we consider some of the more general physiological properties of this group. Sulfate reducers are generally obligate anaerobes, and strict anoxic techniques must be used in their cultivation (**Figure 14.23g**).

Sulfate reducers use H₂ or organic compounds as electron donors for growth, and the range of organics used is fairly broad. Lactate and pyruvate are almost universally used, and many species also oxidize short-chain alcohols (ethanol, propanol, and butanol) as electron donors. Some species, such as *Desulfosarcina* and *Desulfonema*, grow chemolithotrophically and autotrophically with H₂ as an electron donor, SO₄²⁻ as an electron acceptor, and CO₂ as the sole carbon source. A few sulfate reducers can oxidize hydrocarbons as electron donors (see Section 13.24).

There are two physiological types of dissimilative sulfate-reducers, the *complete oxidizer*, which can oxidize acetate and other fatty acids completely to CO₂, and the *incomplete oxidizers*, which are unable to oxidize acetate to CO₂. The latter group includes the best studied of the sulfate-reducing bacteria, *Desulfovibrio* (Figure 14.23a), along with *Desulfomonas*, *Desulfotomaculum*, and *Desulfobulbus* (Figure 14.23c). The acetate oxidizers include *Desulfobacter* (Figure 14.23d), *Desulfococcus*, *Desulfovarcina* (Figure 14.23e), and *Desulfonema* (Figure 14.23b), among many others. These bacteria specialize in the complete oxidation of fatty acids, in particular acetate, reducing SO₄²⁻ to H₂S. These two physiological groups are not phylogenetically coherent but instead are distributed widely across the phylogeny of sulfate-reducing bacteria (Figure 14.22).

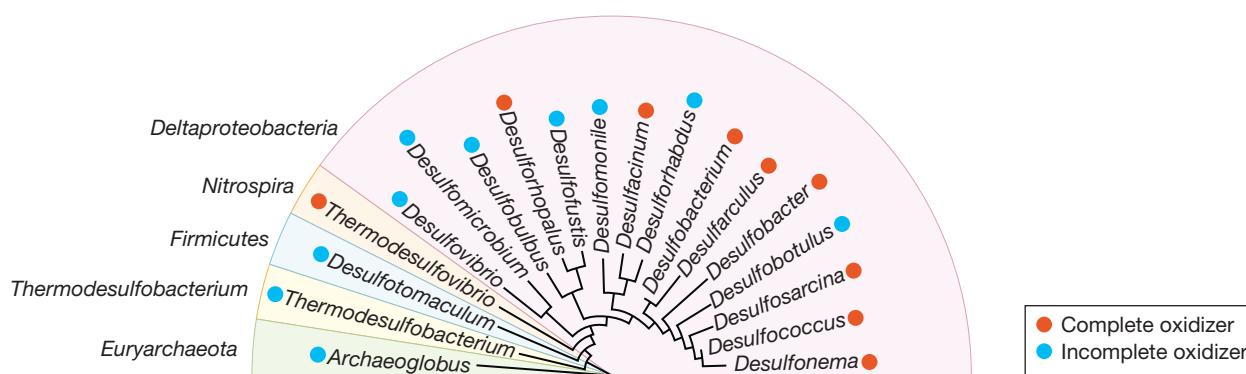

Figure 14.22 Dissimilative sulfate-reducers. The dendrogram depicts phylogenetic relationships among some genera of sulfate reducers as inferred by analysis of their 16S ribosomal RNA gene sequences. Color shading is used to differentiate the five main phyla that contain genera of sulfate reducers. Colored circles indicate whether species are complete oxidizers, which are able to oxidize acetate to CO_2 , or incomplete oxidizers, which cannot oxidize acetate. The physiology of sulfate-reducing bacteria is covered in Section 13.18, and their role in the sulfur cycle in Section 20.4.

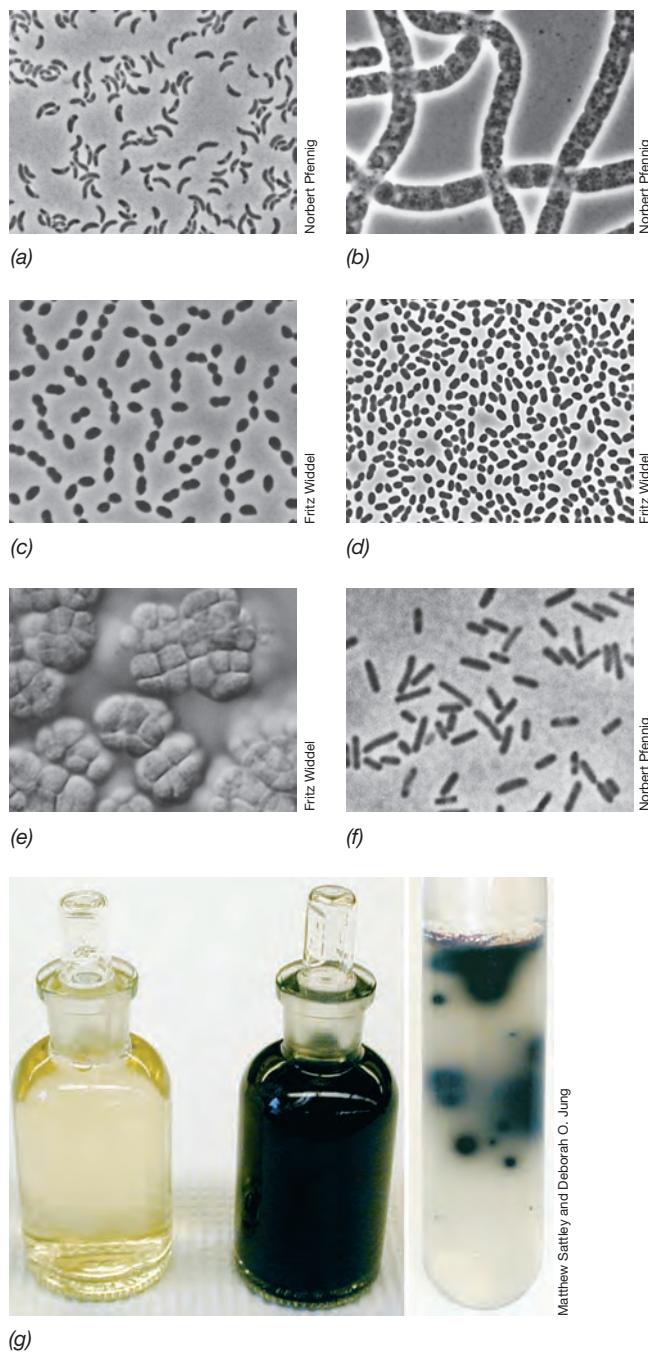

Figure 14.23 Representative sulfate-reducing and sulfur-reducing bacteria. (a) *Desulfovibrio desulfuricans*; cell diameter about 0.7 μm . (b) *Desulfonema limicola*; cell diameter 3 μm . (c) *Desulfovibulus propionicus*; cell diameter about 1.2 μm . (d) *Desulfovibacter postgatei*; cell diameter about 1.5 μm . (e) *Desulfosarcina variabilis*; cell diameter about 1.25 μm . (f) *Desulfuromonas acetoxidans*; cell diameter about 0.6 μm . (g) Enrichment culture of sulfate-reducing bacteria. Left, sterile medium; center, a positive enrichment showing black FeS; right, colonies of sulfate-reducing bacteria in a dilution tube. Photos a-d and f are phase-contrast photomicrographs; part e is an interference contrast micrograph.

Some sulfate-reducing bacteria can exploit alternative metabolic pathways. In addition to SO_4^{2-} or S^0 , some sulfate reducers can also reduce nitrate and sulfonates (such as isethionate, $\text{HO}-\text{CH}_2-\text{CH}_2-\text{SO}_3^-$). Certain organic compounds can also be fermented by sulfate-reducing bacteria. The most common of these

is pyruvate, which is fermented by way of the phosphoroclastic reaction to acetate, CO_2 , and H_2 (☞ Figure 13.30). Moreover, although generally obligate anaerobes, a few sulfate-reducing bacteria are quite O_2 -tolerant (primarily strains that coexist with O_2 -producing cyanobacteria in microbial mats). At least one species, *Desulfovibrio oxydclineae*, can actually grow with O_2 as the electron acceptor under microaerophilic conditions.

Ecology of Sulfate-Reducing Bacteria

Sulfate reducers are widespread in aquatic and terrestrial environments that contain SO_4^{2-} and become anoxic as a result of microbial decomposition. Sulfate reducers are abundant in marine sediments, and the H_2S they generate is responsible for the pungent smell (like that of rotten eggs) often encountered near coastal ecosystems. *Desulfotomaculum*, phylogenetically a species of *Firmicutes* (gram-positive *Bacteria*), consists of endospore-forming rods found primarily in soil. Growth and reduction of SO_4^{2-} by *Desulfotomaculum* in certain canned foods leads to a type of spoilage called *sulfide stinker*. Species of *Thermodesulfobacterium*, *Thermodesulfovibrio*, and *Archaeoglobus* (an archaeon) are all thermophilic and found in geothermally heated environments such as hot springs, hydrothermal vents, and oil reserves. The remaining genera of sulfate reducers are indigenous to anoxic marine and freshwater environments and can occasionally be isolated from the mammalian gut.

The enrichment of *Desulfovibrio* species is straightforward in an anoxic lactate–sulfate medium containing ferrous iron (Fe^{2+}). A reducing agent, such as thioglycolate or ascorbate, is required to achieve a low reduction potential (E_0') in the medium. When sulfate-reducing bacteria grow, the H_2S formed from SO_4^{2-} reduction combines with the ferrous iron to form black, insoluble ferrous sulfide (Figure 14.23g). Purification can be accomplished by diluting the culture in molten agar tubes (☞ Section 18.2 and Figure 18.3). Upon solidification, individual cells of sulfate-reducing bacteria become distributed throughout the agar and grow to form black colonies (Figure 14.23g) that can be removed aseptically to yield pure cultures.

MINIQUIZ

- What are the typical electron donors used by dissimilative sulfate-reducers?
- What bacterial phyla are known to contain dissimilative sulfate-reducers?

14.10 Dissimilative Sulfur-Reducing Bacteria

Key Genera: *Desulfuromonas*, *Wolinella*, *Sulfobolbus*

Here we consider the dissimilative sulfur-reducers, microorganisms that are able to use respiratory sulfur reduction to conserve energy. Dissimilative sulfur-reducing bacteria can reduce S^0 and other oxidized forms of sulfur to H_2S but are unable to reduce SO_4^{2-} . There are more than 25 genera of dissimilative sulfur-reducers spread across five bacterial and archaeal phyla (Figure 14.1).

Most sulfur-reducing bacteria are *Proteobacteria*, primarily *Deltaproteobacteria* (e.g., *Desulfuromonas*, *Pelobacter*, *Desulfurella*, *Geobacter*), with some genera residing in the *Epsilon*- (e.g., *Wolinella* and *Sulfurospirillum*) and *Gammaproteobacteria* (e.g., *Shewanella* and *Pseudomonas mendocina*). Other sulfur-reducing bacteria are species of *Firmicutes* (e.g., *Desulfitobacterium* and *Ammonifex*), *Aquificae* (e.g., *Desulfurobacterium* and *Aquifex*), *Synergistetes* (e.g., *Dethiosulfovibrio*), or *Deferribacteres* (e.g., *Geovibrio*). The sulfur-reducing *Archaea*—of which there are many—are all genera of *Crenarchaeota* (e.g., *Acidianus*, *Sulfolobus*, *Pyrodictium*, and *Thermodiscus*).

Physiology and Ecology of Sulfur-Reducing Bacteria

The physiology of sulfur reducers is more diverse than that of sulfate reducers. Most sulfur reducers are obligate anaerobes, but facultatively aerobic species are common. Sulfur reducers are often able to reduce electron acceptors such as nitrate, ferrous iron, or thiosulfate as alternatives to S^0 . Like sulfate reducers (Section 14.9), the physiology of sulfur reducers is characterized by whether they completely oxidize acetate and other fatty acids to CO_2 . Species of *Desulfuromonas* (Figure 14.23f) are complete oxidizers that grow anaerobically by coupling the oxidation of acetate, succinate, ethanol, or propanol to the reduction of S^0 . In contrast, *Sulfospirillum* and *Wolinella* are incomplete oxidizers and cannot use acetate as an electron donor. *Sulfospirillum* can reduce S^0 using either H_2 or formate as electron donor.

Dissimilative sulfur-reducing bacteria reside in many of the same habitats as dissimilative sulfate-reducing bacteria and often form associations with bacteria that oxidize H_2S to S^0 , such as green sulfur bacteria (Section 14.6). The S^0 produced from H_2S oxidation is then reduced back to H_2S during metabolism of the sulfur reducer, completing an anoxic sulfur cycle (☞ Section 20.4).

MINIQUIZ

- What are the typical electron donors used by dissimilative sulfur-reducers?
- What bacterial phyla contain dissimilative sulfur-reducers?

14.11 Dissimilative Sulfur-Oxidizing Bacteria

Key Genera: *Thiobacillus*, *Achromatium*, *Beggiatoa*

Dissimilative sulfur-oxidizers are **chemolithotrophs** that oxidize reduced sulfur compounds such as H_2S , S^0 , thiosulfate, or thiocyanate (SCN^-) as electron donors in energy conservation. These organisms are common in environments such as marine sediments, sulfur springs, and hydrothermal systems where H_2S produced by sulfate- or sulfur-reducing bacteria (Sections 14.9–14.10), or abiotically by geothermal reactions, is released into oxygenated waters (Figure 14.24). The sulfur oxidizers are found in three phyla of *Bacteria* (*Proteobacteria*, *Aquificae*, *Deinococcus–Thermus*) and one of *Archaea* (*Crenarchaeota*) (Figure 14.1). Most sulfur-oxidizing bacteria are *Beta-* (*Thiobacillus*), *Gamma-* (*Achromatium*, *Beggiatoa*) and *Epsilonproteobacteria* (*Thiovulum*, *Thiomicrospira*).

Figure 14.24 Habitats of sulfur oxidizers. (a) A sulfide-containing artesian spring in Florida (USA). The outside of the spring is coated with a mat of *Thiothrix* (see Figure 14.26b). The mat is about 1.5 m in diameter. (b) Hydrothermal chimneys at Cathedral Hill in the Guaymas Basin, 2000 m depth. Sulfide-rich waters vent from the chimneys, which are covered by mats composed of orange, white, and yellow cells of *Beggiatoa*.

Physiological Diversity of Sulfur-Oxidizing Bacteria

The morphological and physiological diversity of sulfur oxidizers is significant. Cells can be less than 1 micrometer in diameter (e.g., *Thiomicrospira denitrificans*) or as large as 750 micrometers in diameter (e.g., *Thiomargarita namibiensis*). Most sulfur oxidizers are obligate aerobes; however, species of *Thiomargarita* and *Thiomicrospira* can also reduce NO_3^- in denitrification (☞ Section 13.17 and Section 14.13). Many species oxidize H_2S to elemental sulfur (S^0), which they deposit as either intracellular or extracellular granules for later use as an electron donor if H_2S becomes limiting.

Some sulfur chemolithotrophs are *obligate chemolithotrophs*, locked into a lifestyle of using inorganic instead of organic compounds as electron donors. When growing in this fashion, they are also autotrophs, converting CO_2 into cell material by reactions of the Calvin cycle. **Carboxysomes** are often present in cells of obligate chemolithotrophs (Figure 14.25a). These structures contain high levels of Calvin cycle enzymes and probably increase the rate at which these organisms fix CO_2 (☞ Section 13.5).

Other sulfur chemolithotrophs are *facultative chemolithotrophs*, facultative in the sense that they can grow either chemolithotrophically (and thus, also as autotrophs) or chemoorganotrophically. Most species of *Beggiatoa* can obtain energy from the oxidation

(a)

(b)

Figure 14.25 Nonfilamentous sulfur chemolithotrophs. (a) Transmission electron micrograph of cells of the chemolithotrophic sulfur-oxidizer *Halothiobacillus neapolitanus*. A single cell is about 0.5 μm in diameter. Note the polyhedral bodies (carboxysomes) distributed throughout the cell (arrows) (☞ Figure 13.18). (b) *Achromatium*. Cells photographed by differential interference contrast microscopy. The small globular structures near the periphery of the cells (arrow) are elemental sulfur, and the large granules are calcium carbonate. A single *Achromatium* cell is about 25 μm in diameter.

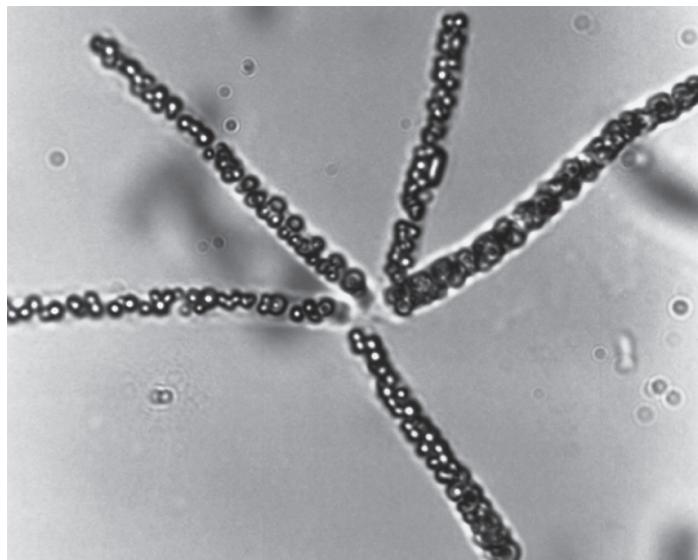

of inorganic sulfur compounds but lack enzymes of the Calvin cycle. They thus require organic compounds as carbon sources. Organisms with such a nutritional lifestyle are called **mixotrophs**.

Thiobacillus* and *Achromatium

The genus *Thiobacillus* and related genera contain several gram-negative, rod-shaped *Betaproteobacteria*, indistinguishable morphologically from most other gram-negative rods (Figure 14.25a); they are the best studied of the sulfur chemolithotrophs. The oxidation of H_2S , S^0 , or thiosulfate by *Thiobacillus* generates sulfuric acid (H_2SO_4), and thus thiobacilli are often acidophilic. One highly acidophilic species, *Acidithiobacillus ferrooxidans*, can also grow chemolithotrophically by the oxidation of Fe^{2+} and is a major biological agent for the oxidation of this metal. Iron pyrite (FeS_2) is a major natural source of ferrous iron as well as of sulfide. The oxidation of FeS_2 , especially in mining operations, can be both beneficial (because leaching of the ore releases the iron from the sulfide mineral) and ecologically disastrous (the environment can become acidic and contaminated with toxic metals such as aluminum, cadmium, and lead) (☞ Section 21.2).

(a)

(b)

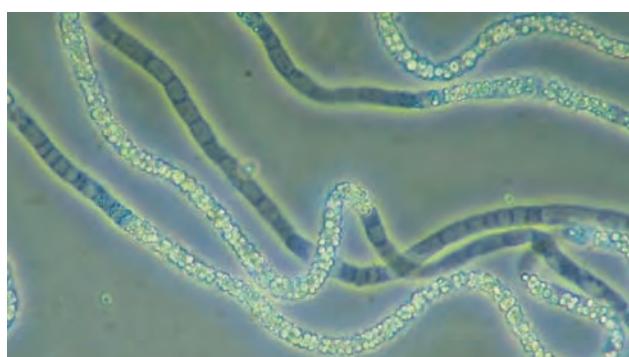

Figure 14.26 *Thiothrix*. (a) Filaments of *Thiothrix* attached to plant material found in the outwash stream of a sulfidic cave in Frasassi, Italy. From the plant branch point, the longest branch is about 4 mm long. (b) Phase-contrast photomicrograph of a rosette of cells of *Thiothrix* isolated from the sulfide-containing artesian spring shown in Figure 14.24a. Note the internal sulfur globules produced from the oxidation of sulfide. Each filament is about 4 μm in diameter.

Achromatium is a spherical sulfur-oxidizing chemolithotroph that is common in freshwater sediments of neutral pH containing H_2S . Cells of *Achromatium* are large cocci that can have diameters of 10–100 μm (Figure 14.25b). *Achromatium* is a species of *Gammaproteobacteria* and is specifically related to purple sulfur bacteria, such as its phototrophic counterpart *Chromatium* (Section 14.4 and Figure 14.10a). Like *Chromatium*, cells of *Achromatium* store S^0 internally (Figure 14.25b); the granules later disappear as S^0 is oxidized to SO_4^{2-} . Cells of *Achromatium* also store large granules of calcite (CaCO_3) (Figure 14.25b), possibly as a carbon source (in the form of CO_2) for autotrophic growth. The physiology of chemolithotrophic sulfur oxidizers is discussed in Section 13.8.

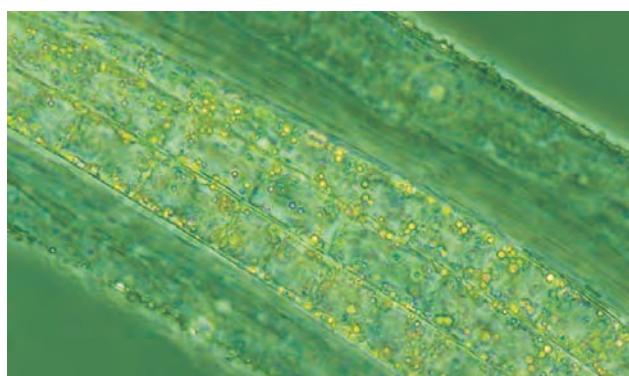

Ecological Diversity and Strategies of Sulfide-Oxidizing Bacteria

Aerobic sulfide-oxidizers provide a case study that demonstrates the degree of ecological diversification that can occur among microorganisms that share the same basic metabolic features. The chemical oxidation of H_2S to H_2SO_4 is spontaneous and rapid in the presence of O_2 . Hence, aerobic H_2S -oxidizers have evolved diverse ecological strategies that allow them to metabolize two molecules that otherwise react with each other spontaneously. We consider here six different strategies used by aerobic sulfide-oxidizers to cope with the chemical instability of H_2S in the presence of O_2 .

1. *Thiothrix* is a filamentous sulfur chemolithotroph of the *Gamma-proteobacteria* (Figure 14.26). *Thiothrix* forms filaments that group together at their ends by way of a holdfast to form cell arrangements called *rosettes* (Figure 14.26b). The ecological strategy of *Thiothrix* is to use its holdfast to position itself in high-flow environments downstream from a source of H_2S . Such environments are common near sulfur springs and in creeks draining sulfidic salt marshes where abundant H_2S is produced and carried away in waters rich with O_2 (Figure 14.26a). Physiologically, *Thiothrix* is an obligately aerobic mixotroph, and in this and most other respects it resembles *Beggiatoa*.
2. *Beggiatoa* are filamentous, gliding, sulfur-oxidizing *Gamma-proteobacteria* that are usually large in both diameter and length, consisting of many short cells attached end to end (Figure 14.27a). Filaments can flex and twist so that many filaments become intertwined to form a complex tuft. *Beggiatoa* is found primarily in microbial mats, sediments, sulfur springs, and hot springs. The ecological strategy of *Beggiatoa* is to use gliding motility to position itself at the point where H_2S and O_2 co-occur in an environment. For example, *Beggiatoa* in microbial mats can move vertically by as much as several centimeters per day in response to cyanobacterial O_2 production, moving up to obtain O_2 when photosynthesis ceases at night and down

during the day when photosynthetic O_2 production at the mat surface causes H_2S to be found deeper in the mat.

3. The genus *Thiomargarita* contains some of the largest bacteria ever observed, with diameters that can be 0.75 mm (Figure 14.28).

(a)

Figure 14.28 The giant sulfide-oxidizing bacterium, *Thiomargarita*. (a) *Thiomargarita namibiensis* recovered from the Namibian upwelling (off the Namibian coast, southwest Africa). Cells are about 100 μm in diameter. (b) Dividing cells of vacuole-containing sulfide-oxidizers recovered from the same location. Fluorescence micrograph showing ribosomes of *Thiomargarita* stained with a fluorescent nucleic acid probe. Ribosomes are found in the cytoplasm, which is present as a thin layer along the outer edge of the cells. The cytoplasm is squeezed between the cell wall and the large central vacuole, which appears dark in the image. Cells are about 50 μm wide.

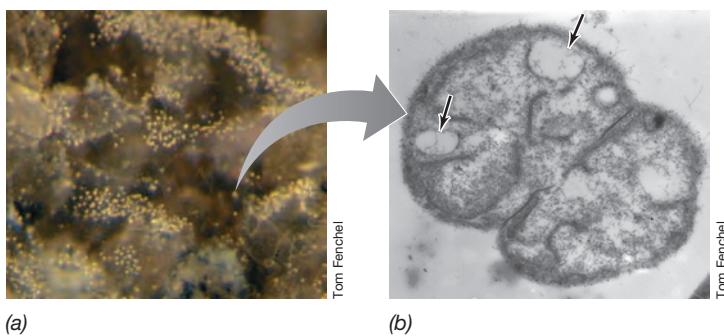

Figure 14.29 The sulfur-oxidizing *Thiovulum*. (a) Macrograph of cells of *Thiovulum* (yellow dots) that formed a thin veil in marine sand containing H₂S (large, irregular structures are sand grains). (b) Transmission electron micrograph of a dividing cell of *Thiovulum*. Sulfur (S⁰) globules are shown with arrows. Single cells of *Thiovulum* are typically 10–20 µm in diameter.

Thiomargarita is nonmotile, and its ecological strategy is to separate in time the oxidation of H₂S from the reduction of O₂. To accomplish this, *Thiomargarita* contains a giant vacuole (Figure 14.28b) that it fills with high concentrations of nitrate (NO₃⁻). This vacuole can fill almost the entire volume of the cell. Cells live in sulfide-rich marine sediments that are mixed occasionally with O₂-rich waters, such as that in salt marshes and in ocean upwelling zones. When buried in sediment, cells oxidize H₂S to S⁰ anaerobically by reducing NO₃⁻ stored in the vacuole to ammonium (NH₄⁺). They then store the S⁰ as intracellular granules (Figure 14.28a). When turbulent waters mix the cells into the water column where H₂S is lacking, they switch to the aerobic oxidation of stored S⁰. The energy they gain from S⁰ oxidation is used to refill their vacuole with NO₃⁻ from the water column so they will be able to survive the next period of anoxia.

4. *Thioploca* are large filamentous bacteria that use a strategy similar to that of *Thiomargarita*. *Thioploca* also have intracellular S⁰ granules and large vacuoles filled with NO₃⁻ (Figure 14.27b). However, filaments of *Thioploca* are motile by gliding and they occur in large sheaths that can be filled with many parallel filaments (Figure 14.27b). Sheaths are arranged vertically in the sediments and filaments glide up and down in the sheaths, going down to anaerobically respire H₂S using stored NO₃⁻ as electron acceptor and going up to aerobically respire S⁰ and to refill their vacuoles with NO₃⁻ (Figure 19.10).
5. *Thiovulum* are found in freshwater and marine habitats in which sulfide-rich muds interface with oxic zones (Figure 14.29). *Thiovulum* cells are fairly large (10–20 µm), and when motile,

they swim at exceptionally high speed, perhaps the fastest of all known bacteria (~0.6 mm/sec). The ecological strategy of *Thiovulum* is to actually control the flow of nutrients to cells. *Thiovulum* cells secrete a slime that links cells together in a veil-like structure that can be centimeters in diameter (Figure 14.29a). The veils, composed of many *Thiovulum* cells, are formed over a source of H₂S. Cells have long flagella that attach to the veil and to solid surfaces. Since the terminal end of the flagellum is attached and immobile, flagellar rotation causes cells to rotate along their flagellar axis. The simultaneous unidirectional rotation of all of the *Thiovulum* cells in the veil creates a flow of water through the veil, allowing the cells to generate and regulate the gradients of H₂S and O₂ they require to generate energy.

6. The final ecological strategy of sulfur chemolithotrophs is for the sulfur bacterium to form a symbiotic association with a eukaryote. There are diverse symbiotic associations in which the host provides a mechanism for regulating H₂S and O₂ levels and the sulfide-oxidizing symbiont fixes CO₂ and provides a source of carbon and energy to the host. The best example is the tubeworm *Riftia*, which contains sulfide-oxidizing endosymbionts and lives at deep-sea hydrothermal vents (Section 22.12). A variety of other such symbiotic associations are present at hydrothermal vent ecosystems, including symbionts living in the gill tissue of the giant clam *Calyptogena magnifica* and on the surface of the yeti crab, which farms sulfide-oxidizing bacteria by waving its claws over sulfide-rich vent fluid. Symbioses involving invertebrates are also common in the sulfide-rich marine sediments of shallow coastal systems. For example, bivalves in the family *Solemyidae* burrow into sulfide-rich sediments and pump sulfide- and oxygen-rich water over gills that contain sulfide-oxidizing bacteria.

From these examples it should be clear how ecological diversity drives bacteria that carry out the same energy metabolism—in this case sulfide oxidation—to best exploit the different environments they inhabit. In each case, the goal of the organism is the same, to obtain the electron donor and acceptor it needs. But also in each case, the strategy to accomplish this is unique and the best fit to both the properties of the organism and the habitat it exploits.

MINIQUIZ

- Describe the energy and carbon metabolism of *Thiobacillus* in terms of how ATP and new cell material are made.
- What are some ecological strategies that sulfur oxidizers use to compete with chemical oxidation of H₂S?

IV • Bacterial Diversity in the Nitrogen Cycle

All forms of life must assimilate nitrogen for growth and thus all organisms must catalyze certain nitrogen transformations. The *Bacteria* and *Archaea*, however, are the only domains in which representatives exist that can conserve energy from the transformation of inorganic nitrogen species. In this section we will consider the

diversity of three physiological groups of bacteria that participate in the nitrogen cycle: *diazotrophs*, *nitrifiers*, and *denitrifiers*. The physiology of these groups was considered in Sections 3.17, 13.10, and 13.17. We start our tour of microbial diversity in the nitrogen cycle by considering those bacteria that fix atmospheric nitrogen.

14.12 Diversity of Nitrogen-Fixing Bacteria

Key Genera: *Mesorhizobium*, *Desulfovibrio*, *Azotobacter*

Diazotrophs are microorganisms that fix dinitrogen gas (N_2) into NH_3 that can be assimilated as a source of nitrogen for cells. Nitrogen fixation is an assimilative process and requires ATP and the enzyme nitrogenase (➡ Section 3.17). Diazotrophs typically fix N_2 only when other forms of N are absent, and nitrogenase expression is inhibited when NH_3 is available to cells (➡ Section 3.17). Nitrogenase is irreversibly inhibited by O_2 and this is one cause of ecological diversification among diazotrophs; we will see that different organisms have evolved different solutions to protecting nitrogenase from O_2 .

Nitrogen fixation is widespread among microorganisms, and it is thought that the last universal common ancestor possessed the enzyme nitrogenase. The *nifH* gene encodes the dinitrogenase reductase component of nitrogenase and is used as a measure of diazotroph diversity (➡ Section 18.5). More than 30,000 unique *nifH* gene sequences have been described spanning nine bacterial phyla and one archaeal phylum (Figure 14.1). The phylogenetic distribution of nitrogenase in the tree of life has been influenced strongly by horizontal gene exchange. As a result, the phylogeny of *nifH* is largely inconsistent with the 16S ribosomal RNA gene phylogeny (Figure 14.30). We consider here the diversity of both symbiotic and free-living diazotrophs.

Symbiotic Diazotrophs

Diazotrophs form several symbiotic relationships with plants, animals, and fungi. These relationships are generally defined by the host providing a hospitable environment, including a source of carbon and energy and a system for regulating oxygen concentrations, and the microbial symbiont providing in return a supply of fixed nitrogen to the host.

The symbiosis between rhizobia and leguminous plants is one of the best-characterized nitrogen-fixing symbiotic associations (➡ Section 22.3). Root-nodule-forming bacteria are *Alphaproteobacteria* (e.g., *Mesorhizobium*, *Bradyrhizobium*, *Sinorhizobium*), *Betaproteobacteria* (e.g., *Burkholderia*), or *Actinobacteria* (e.g., *Frankia*). Other genera of symbiotic diazotrophs are found in association with shipworms (*Teredinibacter*), termite guts (*Treponema*) (➡ Section 22.10), endomycorrhizal fungi (*Glomeribacter*) (➡ Section 17.12), and several fungi, algae, and plants (*Cyanobacteria*) (➡ Sections 22.1 and 22.5). These different symbioses have evolved independently multiple times as a result of convergent evolution (Figure 14.30).

Free-Living Diazotrophs

Free-living diazotrophs need a mechanism for protecting nitrogenase from oxygen (➡ Sections 3.17 and 7.13). The simplest solution to this problem is to grow only in anoxic environments. The origin of nitrogen fixation predates the origin of oxygenic photosynthesis and thus the first nitrogen-fixing organisms were free-living anaerobes. Obligately anaerobic free-living diazotrophs are common in anoxic environments including marine and freshwater sediments and microbial mats. Obligately anaerobic free-living diazotrophs are found in the bacterial phyla *Firmicutes* (e.g., *Clostridium*), *Chloroflexi* (e.g., *Oscillochloris*), *Chlorobi* (e.g.,

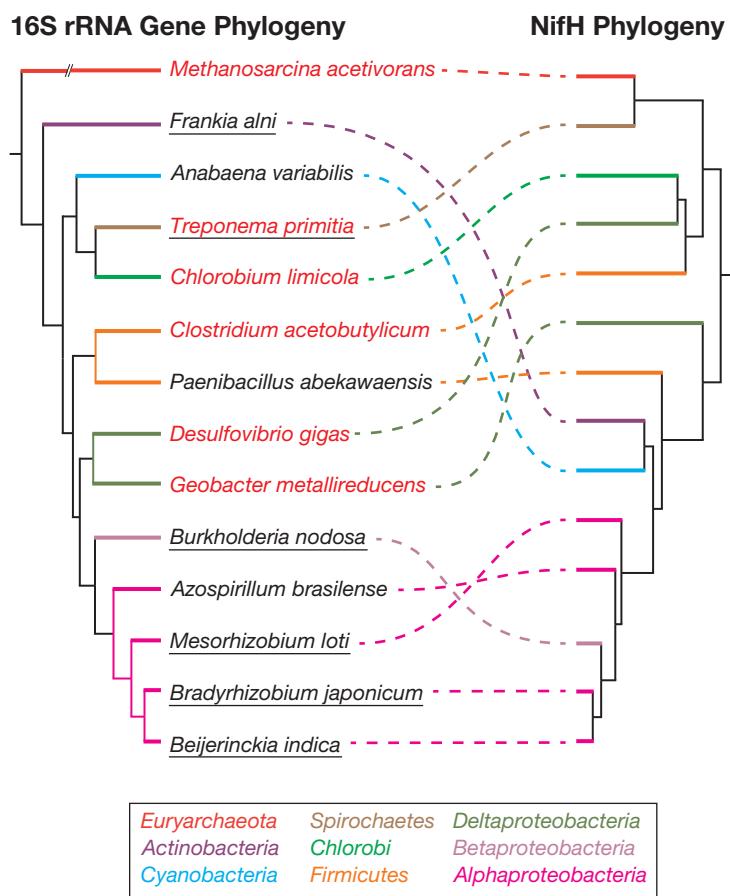

Figure 14.30 Relationships among diazotrophic (nitrogen-fixing) bacteria as inferred from 16S ribosomal RNA gene sequences and NifH amino acid sequences. Branches in each tree are colored to indicate phyla. The dashed lines indicate branches shared between the two trees. The incongruence between the two trees has resulted from multiple horizontal transfer events of the *nifH* gene. Red text denotes obligate anaerobes and underlined text indicates species that form symbioses with Eukarya.

Chlorobium), *Spirochaetes* (e.g., *Spirochaeta*), and *Proteobacteria* (e.g., *Desulfovibrio*, *Chromatium*) and in the archaeal phylum *Euryarchaeota* (e.g., *Methanosaeca*). *Desulfovibrio* occur in anoxic salt marsh sediments dominated by *Spartina* grass, and their N_2 fixation is an important nitrogen source to plants that live in this ecosystem.

Other simple mechanisms for protecting nitrogenase from oxygen include fixing N_2 only at times when oxygen is absent or present in low concentration. For example, facultative aerobes will often fix N_2 only while growing anaerobically (e.g., *Klebsiella*). Some aerobic nitrogen-fixers are *microaerophiles*; these organisms fix nitrogen only in environments where oxygen is present at low concentration (typically less than 2%). However, some organisms have evolved more complex mechanisms for protecting nitrogenase from oxygen and are able to grow in the presence of air.

Obligately aerobic free-living diazotrophs include the *Cyanobacteria*, which have evolved a variety of mechanisms of protecting nitrogenase from oxygen (Section 14.3), as well as a variety of unicellular free-living chemoorganotrophic bacteria. Obligately aerobic free-living diazotrophs include *Azotobacter*, *Azospirillum*, and *Beijerinckia*. *Azotobacter* cells are large rods or cocci

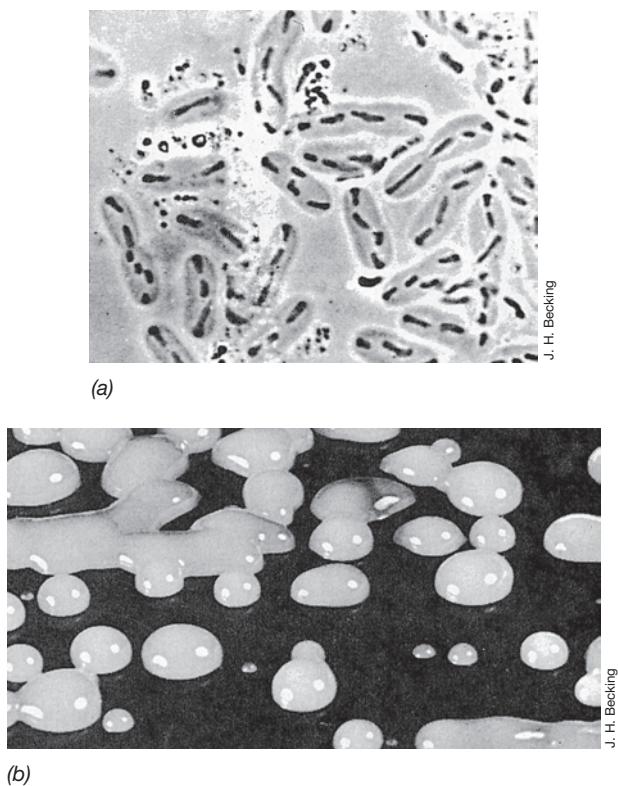

Figure 14.31 Examples of slime production by free-living N_2 -fixing bacteria. (a) Cells of *Derxia gummosa* encased in slime. Cells are about 1–1.2 μm wide. (b) Colonies of *Beijerinckia* species growing on a carbohydrate-containing medium. Note the raised, glistening appearance of the colonies due to abundant capsular slime.

with diameters of 2–4 μm or more. When they are growing on N_2 as a nitrogen source, extensive capsules or slime layers are typically produced (Figure 14.31) (Figure 3.32a). It is thought that the high respiratory rate characteristic of *Azotobacter* cells and the abundant capsular slime they produce help protect nitrogenase from O_2 . *Azotobacter* is able to grow on many different carbohydrates, alcohols, and organic acids, and metabolism is strictly oxidative.

Azotobacter can form resting structures called *cysts* (Figure 14.32b). Like bacterial endospores, *Azotobacter* cysts show negligible endogenous respiration and are resistant to desiccation, mechanical disintegration, and ultraviolet and ionizing radiation. In contrast to endospores, however, cysts are not very heat-resistant, and they are not completely dormant because they rapidly oxidize carbon sources if supplied.

***Azotobacter* and Alternative Nitrogenases**

We considered the important process of biological N_2 fixation in Section 3.17 and discussed the central importance of the metals molybdenum (Mo) and iron (Fe) to the enzyme nitrogenase. The species *Azotobacter chroococcum* was the first nitrogen-fixing bacterium shown capable of growth on N_2 in the absence of molybdenum. It was shown in *A. chroococcum* that either of two “alternative nitrogenases” are formed when Mo limitation prevents the normal MoFe nitrogenase from being synthesized. These nitrogenases are less efficient than the MoFe nitrogenase

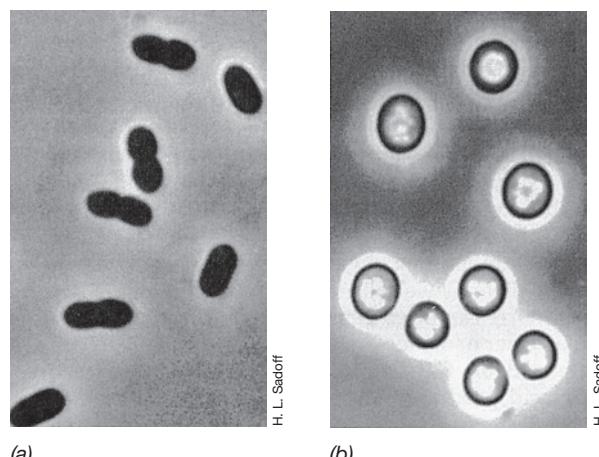

Figure 14.32 *Azotobacter vinelandii*. (a) Vegetative cells and (b) cysts visualized by phase-contrast microscopy. A cell measures about 2 μm in diameter and a cyst about 3 μm .

and contain either vanadium (V) or Fe in place of Mo. The three different types of nitrogenase (MoFe, VFe, and FeFe) are encoded by paralogous genes, and these three related enzyme types arose as a result of gene duplication events (Section 12.6). Subsequent investigations of other nitrogen-fixing bacteria have shown that these genetically distinct “backup” nitrogenases are widely distributed among nitrogen-fixing bacteria, in particular in the *Cyanobacteria* and *Archaea*.

MINIQUIZ

- What mechanisms do free-living diazotrophs use to protect nitrogenase from oxygen?
- Where might you expect to find nitrogen-fixing bacteria?

14.13 Diversity of Nitrifying and Denitrifying Bacteria and Archaea

Microorganisms that grow by the anaerobic respiration of inorganic nitrogen (NO_3^- , NO_2^-) to the gaseous products NO , N_2O , and N_2 are called **denitrifiers** (Section 13.17). These organisms are typically facultative aerobes and chemoorganotrophs that use organic carbon as both carbon source and electron donor.

Microorganisms able to grow chemolithotrophically at the expense of reduced inorganic nitrogen compounds (NH_3 , NO_2^-) are called **nitrifiers** (Figure 14.33) (Section 13.10). These organisms are typically obligate aerobes that can also grow autotrophically; most species fix CO_2 by the Calvin cycle. A few species have also been shown to grow mixotrophically by assimilating organic carbon in addition to CO_2 .

Physiology of Nitrifying Bacteria and Archaea

No chemolithotroph is known that carries out the complete oxidation of NH_3 to nitrate (NO_3^-). Thus, nitrification results from the sequential activities of two physiological groups of organisms, the *ammonia oxidizers* (which oxidize NH_3 to

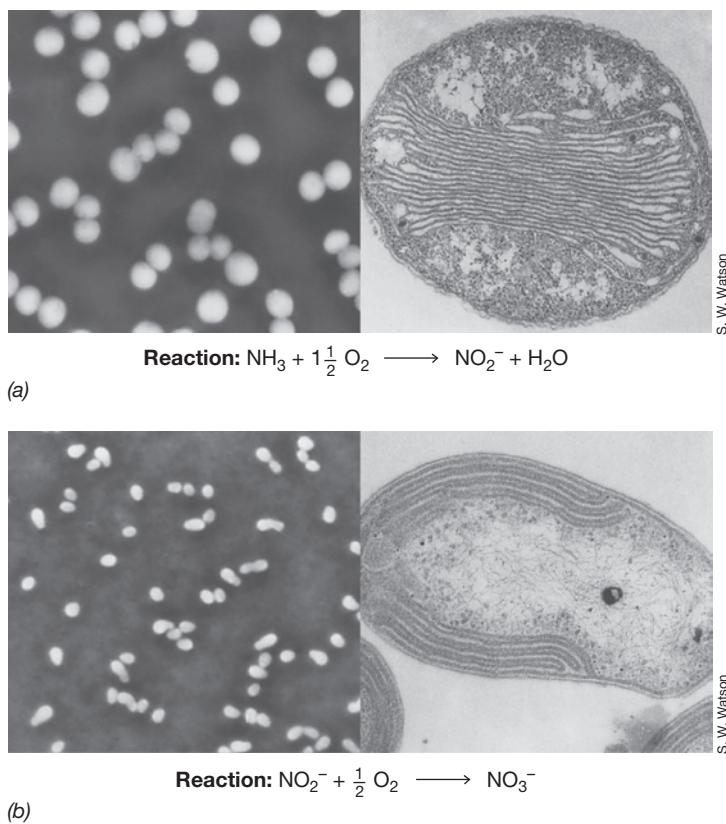

Figure 14.33 Nitrifying bacteria. (a) Phase-contrast photomicrograph (left) and electron micrograph (right) of the ammonia-oxidizing bacterium *Nitrosococcus oceani*. A single cell is about 2 μm in diameter. (b) Phase-contrast photomicrograph (left) and electron micrograph (right) of the nitrite-oxidizing bacterium *Nitrobacter winogradskyi*. A cell is about 0.7 μm in diameter. Beneath each panel is the chemolithotrophic reaction that each organism catalyzes. The distinct internal membranes of each species are sites of key enzymes of nitrification.

nitrite, NO_2^-) (Figure 14.33a), and the *nitrite oxidizers*, the actual nitrate-producing microorganisms, which oxidize NO_2^- to NO_3^- (Figure 14.33b). Ammonia oxidizers typically have genus names beginning in *Nitroso-*, whereas genus names of nitrate producers begin with *Nitro-*.

Many species of nitrifiers have internal membrane stacks (Figure 14.33) that closely resemble the photosynthetic membranes found in their close phylogenetic relatives, the purple phototrophic bacteria (Section 14.4) and the methane-oxidizing (methanotrophic) bacteria (Section 14.17). The membranes are the location of key enzymes in nitrification: *ammonia monooxygenase*, which oxidizes NH_3 to hydroxylamine (NH_2OH), and *nitrite oxidoreductase*, which oxidizes NO_2^- to NO_3^- (Section 13.10).

Enrichment cultures of nitrifying bacteria can be achieved using mineral salts media containing NH_3 or NO_2^- as electron donors and bicarbonate (HCO_3^-) as the sole carbon source. Because these organisms produce very little ATP from their electron donors (Section 13.10), visible turbidity may not develop in cultures even after extensive nitrification has occurred. An easy means of monitoring growth is thus to assay for the production of NO_2^- (with NH_3 as electron donor) or NO_3^- (with NO_2^- as electron donor).

Nitrifying Bacteria and Archaea: Ammonia Oxidizers

Key Genera: *Nitrosomonas*, *Nitrosospira*, *Nitrosopumilus*

Ammonia oxidizers are found in the Beta- (e.g., *Nitrosomonas*, *Nitrosospira*, *Nitrosolobus*, *Nitrovibrio*) and Gammaproteobacteria (*Nitrosococcus*), and in the archaeal phylum Thaumarchaeota (*Nitrosopumilus*, *Nitrosocaldus*, *Nitrosoarchaeum*, *Nitrososphaera*).

Ammonia oxidizers are widespread in soil and water. Bacterial ammonia-oxidizers are present in highest numbers in habitats where NH_3 is abundant, such as sites with extensive protein decomposition (ammonification), and also in sewage treatment facilities (Section 21.6). Nitrifying bacteria develop especially well in lakes and streams that receive inputs of sewage or other wastewaters because these are frequently high in NH_3 . *Nitrosomonas* is often observed in the activated sludge present in aerobic wastewater treatment facilities. Bacterial ammonia-oxidizers are also common in soils (e.g., *Nitrosospira*, *Nitrovibrio*) and in the oceans (e.g., *Nitrosococcus*).

Archaeal ammonia-oxidizers (Section 16.6) appear to be most common in habitats where NH_3 is present in low concentration. These organisms are thought to be the dominant ammonia oxidizers in the oceans where ammonia levels are very low (Sections 19.9 and 19.11). Archaeal ammonia-oxidizers are also common in soils, and in some soils they outnumber bacterial ammonia-oxidizers by several orders of magnitude. The availability of NH_3 relative to NH_4^+ declines with pH, and thus acid soils ($\text{pH} < 6.5$), which are common, may favor organisms able to grow at low NH_3 concentration.

Nitrifying Bacteria: Nitrite Oxidizers

Key Genera: *Nitrospira*, *Nitrobacter*

Nitrite oxidizers are found in the classes Alpha- (*Nitrobacter*), Beta- (*Nitrotoga*), Gamma- (*Nitrococcus*), and Deltaproteobacteria (*Nitrospina*), as well as in the phylum *Nitrospira* (Section 15.21).

Like nitrite-oxidizing Proteobacteria, *Nitrospira* oxidizes nitrite (NO_2^-) to nitrate (NO_3^-) and grows autotrophically (Figure 14.34). However, *Nitrospira* lacks the extensive internal membranes

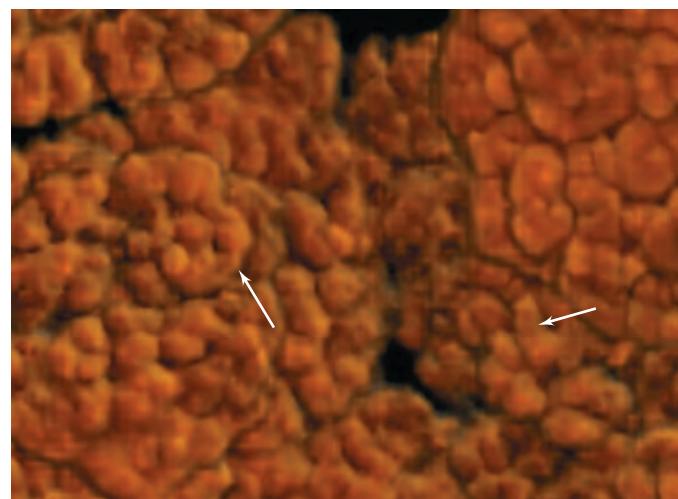

Figure 14.34 The nitrifying bacterium *Nitrospira*. An aggregate of *Nitrospira* cells enriched from activated sludge from a wastewater treatment facility. Individual cells are curved (arrows) and group into tetrads in the aggregate. A single cell of *Nitrospira* is about $0.3 \times 1\text{--}2 \mu\text{m}$.

found in species of nitrifying *Proteobacteria*. Nevertheless, *Nitrospira* inhabits many of the same environments as nitrite-oxidizing *Proteobacteria* such as *Nitrobacter*, so it has been suggested that its capacity for NO_2^- oxidation may have been acquired by horizontal gene flow from nitrifying *Proteobacteria* (or vice versa). As we know, this mechanism for acquiring physiological traits has been widely exploited in the bacterial world (☞ Sections 6.12 and 12.5). However, environmental surveys for the presence of nitrifying bacteria in nature have shown *Nitrospira* to be much more abundant than *Nitrobacter*; thus most of the NO_2^- oxidized in natural environments is probably due to the activities of *Nitrospira*.

Denitrifying Bacteria and Archaea

Key Genera: *Paracoccus*, *Pseudomonas*

Denitrifiers are capable of growth by the anaerobic respiration of NO_3^- or NO_2^- to the gaseous products NO , N_2O , and N_2 (☞ Section 13.17). Nearly all denitrifiers are chemoorganotrophs that use organic carbon as both carbon source and electron donor. Exceptions include the denitrifying sulfur-oxidizers discussed in Section 14.11. Denitrifiers are typically facultative aerobes and in nearly all cases will grow preferentially as aerobes if O_2 is present.

Denitrifiers are of great importance in agricultural soils where they cause the loss of nitrogen fertilizers and the production of N_2O , which is a dominant component of greenhouse gases produced by agricultural soils (☞ Section 20.8).

Denitrifiers are phylogenetically and metabolically diverse and include two archaeal phyla and six bacterial phyla, including five classes of *Proteobacteria* (Figure 14.1). One of the best-characterized denitrifiers is *Paracoccus denitrificans* (*Alphaproteobacteria*). Denitrification of NO_3^- to N_2 requires several key enzymatic steps (☞ Section 13.17), and the genes that encode these enzymes are present throughout the tree of life. Many nitrate reducers possess only part of the denitrification pathway, and are thus unable to reduce NO_3^- completely to N_2 . The phylogenetic distribution of the genes that encode denitrification has been strongly influenced by horizontal gene exchange.

MINIQUIZ

- Under what conditions would you expect microorganisms to grow as a result of denitrification?
- What traits are shared among ammonia and nitrite oxidizers?

V • Diversity of Other Distinctive Chemotrophic Bacteria

We continue our focus on functional groups whose physiological and ecological traits span different phyla as a result of convergent evolution or horizontal gene transfer. From a physiological standpoint, all groups here are chemotrophs—either chemolithotrophs or chemoorganotrophs—that contribute to specific steps in the carbon cycle or that metabolize hydrogen or metals.

14.14 Dissimilative Iron-Reducing Bacteria

Key Genera: *Geobacter*, *Shewanella*

Dissimilative iron-reducers couple the reduction of oxidized metals or metalloids to cellular growth. These organisms need to overcome the fundamental obstacle of using an insoluble solid material as an electron acceptor in respiration. A variety of microorganisms are able to enzymatically reduce metals as a consequence of either fermentation reactions or sulfur or sulfate reduction, but such organisms do not conserve energy from metal reduction. In contrast, dissimilative iron-reducers carry out metal respiration by coupling the oxidation of H_2 or organic compounds to the reduction of ferric iron (Fe^{3+}) or manganese (Mn^{6+}) (Figure 14.35a).

Dissimilative iron-reducers are phylogenetically diverse (Figure 14.1). Bacterial genera are found in the *Proteobacteria* (*Geobacter*, *Shewanella*), *Acidobacteria* (*Geothrix*), *Deferribacteres* (*Geobrio*), *Deinococcus–Thermus* (*Thermus*), *Thermotogae* (*Thermotoga*), and *Firmicutes* (*Bacillus*, *Thiobacillus*), while archaeal genera are found in the *Crenarchaeota* (*Pyrobaculum*). Iron respiration likely evolved early in the history of life and its wide distribution may be due to its presence in the universal ancestor coupled with subsequent gene loss in some lineages and horizontal gene transfer to others.

Physiology

Dissimilative iron-reducers specialize in insoluble external electron acceptors, and these organisms are typically extremely versatile at anaerobic respiration. Dissimilative iron-reducers are unusual in that they possess outer membrane cytochromes that facilitate electron transfer with insoluble minerals. Most species are able to use either iron oxides or manganese oxides as electron acceptors and various species are also able to use nitrate, fumarate, inorganic sulfur compounds, cobalt, chromium, uranium, selenium, arsenic, and humic compounds (☞ Section 13.21). Most genera of iron-reducing bacteria are obligate anaerobes, but some, such as *Shewanella* and relatives, are facultative aerobes. Electron donors are typically organic compounds such as fatty acids, alcohols, sugars, and in certain cases, even aromatic compounds. Many species are also able to use H_2 as an electron donor, but they are generally unable to grow autotrophically, requiring a source of organic carbon to support growth.

The family *Geobacteraceae* in the *Delta proteobacteria* contains four genera of dissimilative iron-reducing bacteria (*Geobacter*, *Desulfuromonas*, *Desulfuromusa*, *Pelobacter*) that aptly demonstrate the physiological diversity of the obligately anaerobic metal reducers. *Geobacter*, *Desulfuromonas*, and *Desulfuromusa* can all use acetate as an electron donor as well as a diversity of other small organics, and they oxidize these substrates completely to CO_2 . These genera typically specialize in anaerobic respiration. *Geobacter* in particular can use a wide range of electron donors and acceptors. *Geobacter* produce pili (Figure 14.35b) that contain cytochromes (Figure 14.35c), and these pili facilitate electron transfer to the surface of iron oxide minerals (for how this might occur, see the opening page of Chapter 20). *Pelobacter*, in contrast, are primarily fermentative organisms having a more limited

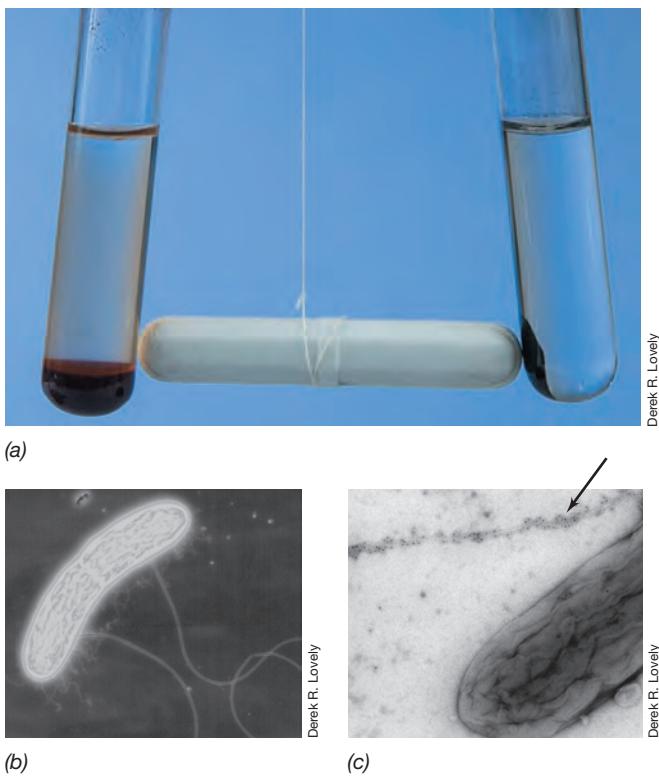

Figure 14.35 The dissimilative iron-reducing bacterium *Geobacter*.
 (a) The uninoculated tube (left) contains an anoxic medium that includes acetate and ferrihydrite, a poorly magnetic iron oxide. Following growth of *Geobacter* (right tube) the ferrihydrite is reduced to magnetite, which is magnetic. (b) Transmission electron micrograph of *Geobacter sulfurreducens* showing flagella and pili. The cell is about $0.7 \times 3.5 \mu\text{m}$. (c) Transmission electron micrograph of *G. sulfurreducens* showing immunogold labeling of cytochrome OmcS on the pili (arrow).

respiratory capacity. For example, *Pelobacter carbinolicus* can only use lactate as the electron donor and can only use ferric iron or S^0 as the electron acceptors. *Pelobacter* are unable to oxidize their carbon substrates completely to CO_2 .

Shewanella and its relatives *Ferrimonas* and *Aeromonas* in the *Gammaproteobacteria* are facultative aerobes and will grow aerobically when O_2 is available. *Shewanella* are able to use a wide diversity of electron donors and acceptors in addition to ferric iron and manganese. However, like *Pelobacter*, they are unable to oxidize their carbon substrates completely to CO_2 and are unable to oxidize acetate as an electron donor for anaerobic respiration.

Ecology

Dissimilative iron-reducers are common in anoxic freshwater and marine sediments. These organisms are thought to play an important role in organic matter oxidation in many anoxic habitats. Dissimilative iron-reducers are also common in the deep subsurface, found both in shallow aquifers as well in the deep subsurface environment (► Section 19.7). In addition, several thermophilic and hyperthermophilic iron-reducing species are known (e.g., *Thermus*, *Thermotoga*) and are often found in hot springs and other geothermally heated systems, including the deep subsurface.

MINIQUIZ

- In what phylogenetic groups are *Geobacter* and *Shewanella* to be found?
- Which genera of dissimilative iron-reducers contain facultative aerobes?

14.15 Dissimilative Iron-Oxidizing Bacteria

Key Genera: *Acidithiobacillus*, *Gallionella*

The ability to couple the oxidation of ferrous iron (Fe^{2+}) to cell growth is widespread in the tree of life and thought to be a trait that evolved early in Earth's history. Genera capable of using ferrous iron as an electron donor to support growth are spread across five bacterial and two archaeal phyla (Figure 14.1).

Aerobic iron-oxidizer diversity and distribution are influenced strongly by pH and O_2 . Ferrous iron oxidizes spontaneously to form insoluble precipitates in the presence of O_2 at neutral to alkaline pH ($\text{pH} > 7$) but is stable either under anoxic conditions or aerobically at acidic pH ($\text{pH} < 4$). Iron oxidizers can be divided into four functional groups on the basis of their basic physiology: acidophilic aerobic iron-oxidizers, neutrophilic aerobic iron-oxidizers, anaerobic chemotrophic iron-oxidizers, and anaerobic phototrophic iron-oxidizers.

Acidophilic Aerobic Iron-Oxidizing Bacteria

The growth of iron-oxidizing bacteria is favored in iron-rich acidic environments where soluble ferrous iron is present. Aerobic iron-oxidizers are often abundant in acid mine drainage generated from abandoned coal or iron mines or from mine tailings (► Sections 21.1 and 21.2). Acidophilic aerobic iron-oxidizers also inhabit iron-rich acidic springs in volcanic areas. In these environments, sulfur is often present along with ferrous iron, and many acidophilic aerobic iron-oxidizers are able to oxidize both elemental sulfur and ferrous iron. Species can be either autotrophic or heterotrophic, and commonly observed genera include *Acidithiobacillus* (*Gammaproteobacteria*), *Leptospirillum* (*Nitrospirae*), and *Ferroplasma* (*Euryarchaeota*). Other acidophilic aerobic iron-oxidizers can be found in the *Actinobacteria* and *Firmicutes*.

Neutrophilic Aerobic Iron-Oxidizing Bacteria

Neutrophilic aerobic iron-oxidizers are organisms adapted to a specialized niche (► Section 13.9). This is because ferrous iron is relatively insoluble at neutral pH and its chemical oxidation is spontaneous and rapid in the presence of air. Furthermore, at neutral pH, iron oxidation at the cell surface causes the formation of an iron oxide crust that can effectively entomb growing cells. Neutrophilic aerobic iron-oxidizers therefore thrive where iron-rich anoxic waters are exposed to air. Such habitats are common near wetlands or soils where anoxic groundwater forms a spring, but iron oxidizers also inhabit the rhizosphere of wetland plants and certain submarine hydrothermal systems.

Few genera of neutrophilic aerobic iron-oxidizers have been described and they all belong to the *Proteobacteria*. Those species found in freshwater habitats belong to a set of closely related genera in the *Betaproteobacteria*, while species found in marine

habitats belong to the *Zetaproteobacteria*. The metabolism of these organisms is fairly narrow. Species are typically micro-aerophiles and obligate chemolithotrophs, though in certain cases mixotrophy has been observed. The genera *Leptothrix* and *Sphaerotilus* are an exception (Section 14.22). *Leptothrix* and *Sphaerotilus* are common in freshwater environments containing neutrophilic aerobic iron-oxidizers. They catalyze the oxidation of both iron and manganese but do not appear to conserve energy from these reactions, conserving energy instead from the oxidation of organic matter.

Characteristic species of neutrophilic aerobic iron-oxidizers are found in the genus *Gallionella* (freshwater) and the marine genus *Mariprofundus* (marine). Species of *Gallionella* and *Mariprofundus* each form a twisted stalklike structure containing Fe(OH)_3 from the oxidation of ferrous iron (Figure 14.36). The iron-encrusted stalk contains an organic matrix on which Fe(OH)_3 accumulates as it is excreted from the cell surface. Stalk formation is presumably an adaptation that prevents cells from becoming entombed in an iron oxide crust.

Gallionella is common in the waters draining bogs, iron springs, and other habitats where ferrous iron is present. *Mariprofundus* was first isolated from Lō'ihi Seamount, a submarine volcano found near Hawaii. *Gallionella* and *Mariprofundus* are both autotrophic chemolithotrophs containing enzymes of the Calvin cycle (► Section 13.5).

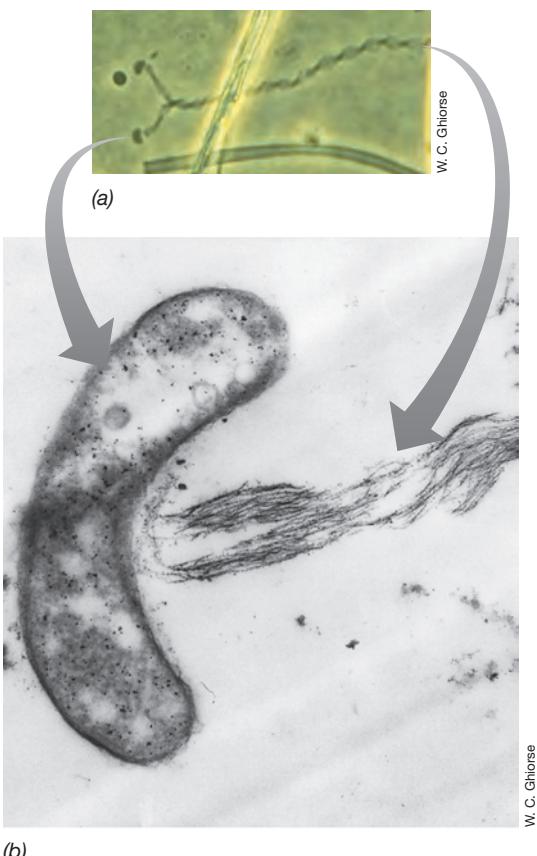

Figure 14.36 The neutrophilic ferrous iron oxidizer, *Gallionella ferruginea*, from an iron seep near Ithaca, New York. (a) Photomicrograph of two bean-shaped cells with stalks that combine to form one twisted mass. (b) Transmission electron micrograph of a thin section of a *Gallionella* cell with stalk. Cells are about 0.6 μm wide.

Anaerobic Iron-Oxidizing Bacteria

Anaerobic ferrous iron oxidation can be mediated by both chemotrophic and phototrophic bacteria. These groups are common in anoxic sediments and wetlands. Anoxic conditions promote the solubility of ferrous iron across a wide range of pH and so, unlike the aerobic iron-oxidizing bacteria, growth of anaerobic iron-oxidizers is not strictly limited to neutral pH. These groups contain organisms that are metabolically diverse and able to grow by using a variety of different electron donors and acceptors.

Phototrophic iron oxidation occurs in select species of purple nonsulfur bacteria of the *Alphaproteobacteria* (e.g., *Rhodopseudomonas palustris*), select species of purple sulfur bacteria of the *Gammaproteobacteria* (► Figure 13.25), and select species of green sulfur bacteria found in the *Chlorobi* (*Chlorobium ferrooxidans*). In all cases ferrous iron is one of several compounds that these organisms can use as an electron donor in photosynthesis.

Anaerobic chemotrophic iron-oxidizers couple the oxidation of ferrous iron to nitrate reduction, producing either NO_2^- or nitrogen gases (denitrification). These organisms are *Alpha*-, *Beta*-, *Gamma*-, or *Deltaproteobacteria*, and most are also able to use various organic electron donors in nitrate reduction; many can also grow aerobically. The bacterial genera *Acidovorax*, *Aquabacterium*, and *Marinobacter* all contain anaerobic iron-oxidizers. While most species are mixotrophs when growing with ferrous iron as electron donor, species such as *Marinobacter aquaeolei* and *Thiobacillus denitrificans* are able to grow autotrophically as iron-oxidizing chemolithotrophs.

MINIQUIZ

- What habitat characteristics govern the diversity and distribution of iron oxidizers?
- How do aerobic neutrophilic iron-oxidizers keep their cells from becoming entombed in a crust of iron?

14.16 Hydrogen-Metabolizing Bacteria

Key Genera: *Ralstonia*, *Paracoccus*
