The hydrogen couple is extremely electronegative, meaning that H_2 is an excellent electron donor in energy metabolism and can couple to virtually any conceivable electron acceptor. Hence, the ability to conserve energy by H_2 oxidation is found widely in the tree of life (Figure 14.1). Examples of diverse hydrogen-oxidizing phototrophs (Sections 14.4–14.7) and anaerobic chemotrophs (Sections 14.9, 14.10 and 14.14) are discussed throughout this chapter. In addition, H_2 oxidation occurs in virtually every genus of anaerobic *Archaea* (Chapter 16). Here we consider the diversity of autotrophic and aerobic hydrogen-oxidizing chemolithotrophic *Bacteria*.

Many bacteria can grow with H_2 as the sole electron donor and O_2 as the electron acceptor in their energy metabolism:

Most of these organisms, known collectively as the “hydrogen bacteria,” can also grow autotrophically (using reactions of the Calvin cycle to incorporate CO_2). All hydrogen bacteria contain one or more *hydrogenase* enzymes that function to bind H_2 and use it either to produce ATP (► Section 13.7) or for reducing power for autotrophic growth.

Different hydrogen-oxidizing *Proteobacteria* are scattered among the *Alpha*, *Beta*, and *Gamma* subclasses. These organisms should be distinguished from the many strictly anaerobic prokaryotes that oxidize H₂ in anaerobic respirations; for example, acetogens, methanogens, and sulfate-reducing bacteria (☞ Sections 13.17–13.20). Both gram-positive and gram-negative hydrogen bacteria are known, with the best-studied representatives classified in the genera *Ralstonia* (Figure 14.37), *Pseudomonas*, and *Paracoccus*. *Paracoccus denitrificans* can also oxidize H₂ anaerobically by denitrification and has been particularly well studied for its bioenergetics of electron transport and generation of a proton motive force.

Physiology and Ecology of Hydrogen Bacteria

When growing chemolithotrophically on H₂, most hydrogen bacteria grow best under microaerophilic (5–10% O₂) conditions because hydrogenases are typically oxygen-sensitive enzymes. The element nickel (Ni²⁺) must be present in the medium for chemolithotrophic growth of hydrogen bacteria because virtually all hydrogenases contain Ni²⁺ as a key metal cofactor. A few hydrogen bacteria also fix nitrogen (☞ Section 3.17), making possible their culture in a mineral salts medium containing only gases—H₂, O₂, CO₂, and N₂—as energy, carbon, and nitrogen sources. Virtually all hydrogen bacteria are facultative chemolithotrophs, meaning that they can also grow chemoorganotrophically with organic compounds as energy sources.

CO Oxidation

Some hydrogen bacteria can grow aerobically on carbon monoxide (CO) as electron donor. CO-oxidizing bacteria, called *carboxydrotrophic* bacteria, grow autotrophically using the Calvin cycle (☞ Section 13.5) to fix CO₂ generated from the oxidation of CO. Electrons from the oxidation of CO to CO₂ by the enzyme carbon monoxide dehydrogenase travel through an electron transport chain that forms a proton motive force. Interestingly, CO

is a potent inhibitor of many cytochromes, acting as a respiratory poison. However, carboxydrotrophic bacteria get around this problem by synthesizing CO-resistant cytochromes and are thus immune to any toxic effects of CO. Like the hydrogen bacteria, virtually all carboxydrotrophic bacteria also grow chemoorganotrophically by oxidizing organic compounds, a likely indication that CO levels are quite variable in nature and a backup means of energy metabolism is necessary.

CO consumption by carboxydrotrophic bacteria on a global basis is a significant ecological process. Although much CO is generated from human and other sources, CO levels in air have not risen significantly over many years. Because the most significant releases of CO (primarily from automobile exhaust, incomplete combustion of fossil fuels, and the catabolism of lignin, a plant product) are in oxic environments, carboxydrotrophic bacteria in the upper layers of soil probably represent the most significant sink for CO in nature.

14.17 Methanotrophic and Methylotrophic Bacteria

Methylotrophs are organisms that grow using organic compounds lacking C—C bonds as electron donors in energy metabolism and as carbon sources. Methylotrophy occurs in the bacterial phyla *Proteobacteria*, *Firmicutes*, *Actinobacteria*, *Bacteroidetes*, *Verrucomicrobia*, and in the archaeal phylum *Euryarchaeota* (Figure 14.1).

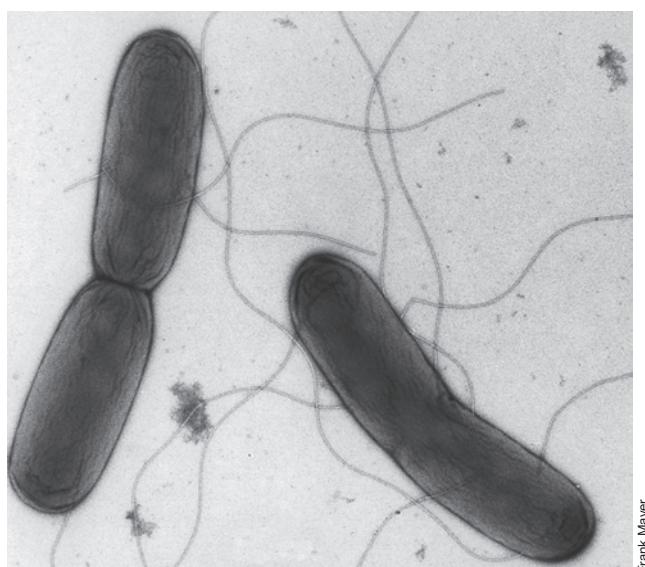

Methanotrophs are a subset of methylotrophs defined by their ability to use methane as a substrate for growth. We discussed the physiology of methanotrophy in Sections 13.23 and 13.24.

Aerobic methylotrophs are common in soil and aquatic environments where O₂ is present. Anaerobic methylotrophs are common in anoxic environments, particularly in marine sediments. Many anaerobic methylotrophs are methanogenic *Archaea*. In addition, a consortium of methanogenic *Archaea* and sulfate-reducing bacteria combine to oxidize methane from gas hydrates found in deep-sea sediments (☞ Section 13.24). We consider here only the aerobic methylotrophs.

Aerobic Facultative Methylotrophs

Key Genera: *Hyphomicrobium*, *Methylobacterium*

Aerobic facultative methylotrophs are unable to use methane but can use many other methylated compounds. They are species of *Alpha*-, *Beta*-, and *Gamma**proteobacteria*, *Actinobacteria*, and *Firmicutes*. Facultative methylotrophs are metabolically diverse and, in addition to methylated substrates, most species can grow aerobically using other organic compounds, such as organic acids, ethanol, and sugars. When growing as methylotrophs, most species can grow aerobically with methanol and some can also metabolize methylated amines, methylated sulfur compounds, and halomethanes. Most are obligate aerobes, though some species are capable of denitrification.

Frank Mayer

The genus *Hyphomicrobium* provides an example of the metabolic versatility of the aerobic facultative methylotrophs. Certain species of *Hyphomicrobium* can grow as aerobic methylotrophs using methanol, methylamine, or dimethylsulfide. Species of *Hyphomicrobium* can also grow as anaerobic methylotrophs using methanol as an electron donor coupled to denitrification. Finally, *Hyphomicrobium* can grow aerobically on a range of C₂ and C₄ compounds.

Aerobic Methanotrophs

Key Genera: *Methylomonas*, *Methylosinus*

Aerobic methanotrophs are methylotrophs that can use methane as an electron donor and typically can use it as a carbon source as well. Table 14.2 gives a taxonomic overview of the methanotrophs. Most species of methanotrophs are *Proteobacteria* and are classified into two major groups based on their internal cell structure, phylogeny, and carbon assimilation pathway. *Type I methanotrophs* assimilate one-carbon compounds via the ribulose monophosphate cycle and are *Gammaproteobacteria*. By contrast, *type II methanotrophs* assimilate C₁ intermediates via the serine pathway and are *Alphaproteobacteria* (Table 14.2). We discussed the biochemical details of these pathways in Section 13.23. Most methanotrophs are metabolically specialized for aerobic growth on methane, though some can grow on either methane or methanol. Methanotrophs are typically obligate methylotrophs; however, the methanotrophic genus *Methylocella* contains species that can also grow using multicarbon substrates.

In addition to the proteobacterial methanotrophs described above, the phylum *Verrucomicrobia* contains the bacterium *Methylacidiphilum*. Genome analysis has shown that species of *Methylacidiphilum* lack key enzymes of both the ribulose monophosphate and serine pathways. Instead, *Methylacidiphilum* uses the Calvin cycle to assimilate carbon from CO₂.

Physiology

Methanotrophs possess a key enzyme, *methane monooxygenase*, which catalyzes the incorporation of an atom of oxygen from O₂ into CH₄, forming methanol (CH₃OH, ↗ Section 13.23). The

requirement for O₂ as a reactant in the initial oxygenation of CH₄ explains why these methanotrophs are obligate aerobes. Methane monooxygenase is located in extensive internal membrane systems that are the site of methane oxidation. Membranes in type I methanotrophs are arranged as bundles of disc-shaped vesicles distributed throughout the cell (Figure 14.38b). Type II species possess paired membranes running along the periphery of the cell (Figure 14.38a). Verrucomicrobial methanotrophs possess membrane vesicles. Methylotrophs unable to use methane lack these internal membrane arrays.

Methanotrophs are virtually unique among bacteria in possessing relatively large amounts of sterols. Sterols are rigid planar molecules found in the cytoplasmic and other membranes of eukaryotes but are absent from most bacteria. Sterols may be an essential part of the complex internal membrane system for methane oxidation (see Figure 14.38). The only other group of bacteria in which sterols are widely distributed is the mycoplasmas, bacteria that lack cell walls and thus probably require a tougher cytoplasmic membrane (↗ Section 15.9). Many methylotrophs contain various carotenoid pigments and high levels of cytochromes in their membranes, and these features often render colonies of aerobic methylotrophs pink.

Ecology

Aerobic methylotrophs are found in the open ocean, soils, in association with plant roots and leaf surfaces, and at the oxic interface of many anoxic environments (↗ Section 13.23). Methanol is produced during the breakdown of plant pectin and this is likely an important substrate for methylotrophs in terrestrial ecosystems. In addition, soils contain aerobic methanotrophs that consume atmospheric methane and are an important biological sink for atmospheric methane. Aerobic methanotrophs are also common at the oxic interface of anoxic environments found in lakes, sediments, and wetlands where methanogens provide a constant source of methane. These methanotrophs play an important role in the global carbon cycle by oxidizing CH₄ and converting it into cell material and CO₂ before it reaches the atmosphere (CH₄ is a strong greenhouse gas).

Methanotrophs also form a variety of symbioses with eukaryotic organisms. For example, some marine mussels live in the vicinity of hydrocarbon seeps on the seafloor, places where CH_4 is released in substantial amounts. Methanotrophic symbionts reside within the animal's gill tissue (Figure 14.39), which ensures effective gas exchange with seawater. Assimilated CH_4 is distributed throughout the animal by the excretion of organic compounds by the methanotrophs. These methanotrophic symbioses are therefore conceptually similar to those that develop between sulfide-oxidizing chemolithotrophs and hydrothermal vent tube worms and giant clams (Section 22.12).

Cells of the methanotrophs are about 1 μm in diameter. Compare with Figure 14.38b.

Methyloirabilis oxyfera is a methanotroph isolated from anoxic waters in the Black Sea, and was the first isolate obtained from the unique bacterial phylum NC-10 (see page 433). *M. oxyfera* is an obligate anaerobe; however, it uses the O_2 -dependent enzyme of aerobic methanotrophs (methane monooxygenase) to oxidize methane to CO_2 . *M. oxyfera* accomplishes this by reducing nitrite to nitric oxide (NO), which is then dismutated to N_2 and O_2 ($2 \text{NO} \rightarrow \text{N}_2 + \text{O}_2$). The O_2 produced by this pathway is then consumed by methane monooxygenase during the oxidation of CH_4 (Section 13.24). As for the methanotroph *Methylacidiphilum*, *M. oxyfera* assimilates C_1 units as CO_2 , probably by the Calvin cycle.

14.18 Acetic Acid Bacteria and Acetogens

A variety of microorganisms produce *acetate* as a by-product of metabolism (e.g., fermentative microorganisms (Sections 13.11–13.15), incomplete sulfate-reducers (Section 14.9), and incomplete iron-reducers (Section 14.14). Here, we consider those organisms for which acetate is the primary product of metabolism. These include the **acetic acid bacteria**, obligate aerobes used in the industrial production of acetic acid (vinegar) from sugars or alcohols. We also consider the **acetogens**, obligate anaerobes that use the acetyl-CoA pathway (Section 13.19) to produce acetate from C_1 compounds. We will see that acetate production in these two groups occurs through quite different metabolic pathways and that acetic acid bacteria and acetogens differ in both their physiology and ecology.

Acetic Acid Bacteria

Key Genera: *Acetobacter*, *Gluconobacter*

The acetic acid bacteria comprise gram-negative, obligately aerobic, motile rods that carry out the incomplete oxidation of

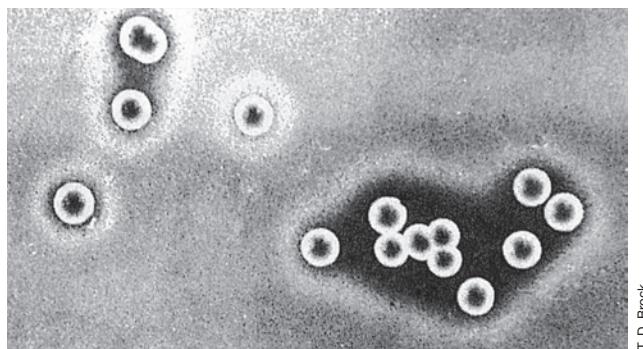

Figure 14.40 Colonies of *Acetobacter aceti* on calcium carbonate (CaCO_3) agar containing ethanol as electron donor. Note the clearing around the colonies due to the dissolution of CaCO_3 by the acetic acid produced.

alcohols and sugars, leading to the accumulation of organic acids as end products. With ethanol ($\text{C}_2\text{H}_5\text{OH}$) as a substrate, acetic acid ($\text{C}_2\text{H}_4\text{O}_2$) is produced, which gives the acetic acid bacteria their name. As one would expect, acetic acid bacteria are tolerant of acidic conditions; most strains can grow well at pH values lower than 5. The acetic acid bacteria are a heterogeneous assemblage of *Alphaproteobacteria*, comprising both peritrichously flagellated (*Acetobacter*) and polarly flagellated (*Gluconobacter*) organisms.

The acetic acid bacteria are commonly found in fermenting fruit juices, such as hard cider or wine, or in beer. Colonies of acetic acid bacteria can be recognized on calcium carbonate (CaCO_3) agar plates containing ethanol because the acetic acid they produce dissolves and causes a clearing of the otherwise insoluble CaCO_3 (Figure 14.40). Cultures of acetic acid bacteria are used in the commercial production of vinegar. In addition to ethanol, acetic acid bacteria carry out an incomplete oxidation of some higher alcohols and sugars. For example, glucose is oxidized to gluconic acid and sorbitol is oxidized to sorbose. This property of “underoxidation” is exploited in the industrial manufacture of ascorbic acid (vitamin C), where sorbose is used as a precursor for the synthesis of ascorbic acid.

Another interesting property of some acetic acid bacteria is their ability to synthesize cellulose that is chemically similar to the cellulose found in plants. Cellulose from acetic acid bacteria is formed as a matrix outside the cell wall and causes cells to become embedded in a tangled mass of cellulose microfibrils. When these species of acetic acid bacteria grow in an unshaken vessel, they form a surface pellicle of cellulose in which the bacteria develop, probably to gain access to air.

Acetogens

Key Genera: *Acetobacterium*, *Clostridium*

Acetogens are obligate anaerobes that produce acetate as the primary product of metabolism. The greatest diversity of acetogens is found in the phylum *Firmicutes*, but acetogens have also been described in the *Spirochaetes* and the *Acidobacteria* (Figure 14.1). True acetogens use the reductive acetyl-CoA pathway to conserve energy and assimilate carbon for growth (➡ Section 13.19).

Many acetogens grow using simple organic compounds such as sugars, alcohols, and organic acids, by first oxidizing these molecules to acetate plus CO_2 and then conserving energy and assimilating carbon through the acetyl-CoA pathway. Use of this pathway also allows most acetogens to grow using C_1 compounds as a sole source of carbon and energy. Many acetogens can grow autotrophically using H_2 , CO , or methanol as an electron donor. Acetogens are often called *homoacetogens* when acetate is the sole product of their metabolism. While acetate is generally the main product of acetogenic metabolism, some acetogens can use the acetyl-CoA pathway to produce products other than acetate (e.g., butyrate or ethanol).

Acetogens are common in anaerobic sediments and waterlogged soils where they play a role in organic matter degradation. Hydrogen-utilizing acetogens are of particular importance in gut communities where they compete for H_2 with methanogens. Acetate is readily assimilated by the gut wall and contributes to the nutrition of the host. Acetogenesis is a dominant process in the overall carbohydrate metabolism of the human gut microbiota. In addition, termites receive more than one-third of their energy from the acetate produced by acetogenic *Spirochaetes* in their hindgut communities.

14.19 Predatory Bacteria

Key Genera: *Bdellovibrio*, *Myxococcus*

Some bacteria are predators that consume other bacteria. Known bacteria predators reside among several classes of *Proteobacteria*

(a) Electron micrograph of a cell of *Bdellovibrio bacteriovorus*; note the thick flagellum A cell is 0.3 μm wide. (b) Events in predation. Following primary contact with a gram-negative bacterium, the highly motile *Bdellovibrio* cell attaches to and penetrates into the prey periplasmic space. Once inside the periplasmic space, *Bdellovibrio* cells elongate and within 4 h progeny cells are released. The number of progeny cells released varies with the size of the prey; 5–6 *bdellovibrios* are released from *Escherichia coli* and 20–30 for a larger prey cell, such as *Aquaspirillum*.

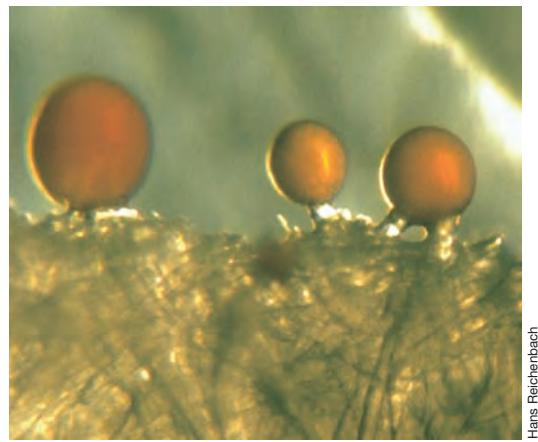

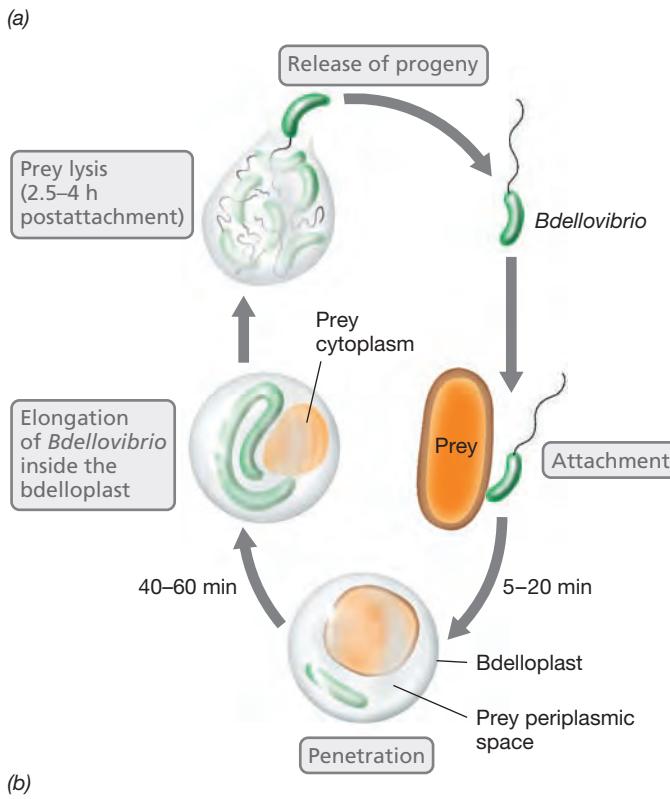

and in the *Bacteroidetes*. Several different methods of predation have been observed. Some predators, such as *Vampirococcus* (phylogeny unknown) and *Micavibrio* (*Alphaproteobacteria*), are *epibiotic predators*; they attach to the surface of their prey and acquire nutrients from its cytoplasm or periplasm. Other predators, such as *Daptobacter* (*Epsilonproteobacteria*), are *cytoplasmic predators*, as they invade their host cells and replicate in the cytoplasm, consuming their prey from the inside out. *Bdellovibrio* have a similar lifestyle as *periplasmic predators*; they invade and replicate within the periplasmic space of their prey cells. Finally, predators such as *Lysobacter* (*Gammaproteobacteria*) and *Myxococcus* (*Deltaproteobacteria*) are *social predators*. These gliding bacteria use swarming behavior to find prey, which they lyse and feed upon collectively. *Bdellovibrio* and *Myxococcus* are the most thoroughly described genera of bacterial predators.

Bdellovibrio

Bdellovibrio are small, highly motile and curved bacteria that prey on other bacteria, using the cytoplasmic constituents of their hosts as nutrients (*bdello* is a prefix meaning “leech”). After attachment of a *Bdellovibrio* cell to its prey, the predator penetrates the cell wall of the prey and replicates in the periplasmic space, eventually forming a spherical structure called a *bdelloplast*. Two stages of penetration are shown in electron micrographs in Figure 14.41 and diagrammatically in Figure 14.42. A wide variety of gram-negative prey bacteria can be attacked by *Bdellovibrio*, but gram-positive cells are not attacked.

Aggregation assembles vegetative cells that then undergo fruiting body formation, within which some vegetative cells undergo morphogenesis to form resting cells called myxospores. Bdellovibrio is an obligate aerobe, obtaining its energy from the oxidation of amino acids and acetate. In addition, *Bdellovibrio* assimilates nucleotides, fatty acids, peptides, and even some intact proteins directly from its host without first hydrolyzing them. Prey-independent derivatives of *Bdellovibrio* can be isolated and grown on complex media, however, showing that predation is not an obligatory lifestyle.

Phylogenetically, bdellovibrions are *Delta*proteobacteria, and they are widespread in aquatic habitats. Procedures for their

isolation are similar to those used to isolate bacterial viruses (Section 8.4). Prey bacteria are spread on the surface of an agar plate forming a lawn, and the surface is inoculated with a small amount of soil suspension that has been filtered through a membrane filter; the filter retains most bacteria but allows the small *Bdellovibrio* cells to pass. On incubation of the agar plate, plaques analogous to bacteriophage plaques (Figure 8.8b) are formed at locations where *Bdellovibrio* cells are multiplying. Pure cultures of *Bdellovibrio* can then be isolated from these plaques. *Bdellovibrio* are widely distributed, as cultures have been obtained from many soils and from sewage.

Myxobacteria

Myxobacteria exhibit the most complex behavioral patterns of all known bacteria. The life cycle of myxobacteria results in the formation of multicellular structures called *fruiting bodies*. The fruiting bodies are often strikingly colored and morphologically

elaborate (Figure 14.43), and these can often be seen with a hand lens on moist pieces of decaying wood or plant material. The fruiting myxobacteria are classified on morphological grounds using characteristics of the vegetative cells, the myxospores, and fruiting body structure.

The life cycle of a typical myxobacterium is shown in Figure 14.44. The vegetative cells of the myxobacteria are simple, non-flagellated, gram-negative rods (Figure 14.45) that glide across surfaces and obtain their nutrients primarily by using extracellular enzymes to lyse other bacteria and use the released nutrients. A vegetative cell excretes slime, and as it moves across a solid surface, it leaves behind a slime trail (Figure 14.46). The vegetative cells form a swarm that exhibits self-organizing behavior, and this allows them to behave as a single coordinated entity in response to environmental cues.

Upon nutrient exhaustion, vegetative cells of myxobacteria begin to migrate toward each other, aggregating together in mounds or heaps (Figure 14.47). Aggregation is likely mediated by chemotactic or quorum-sensing responses (Sections 7.8 and 7.9). As the cell masses become higher, they begin to differentiate into fruiting bodies containing *myxospores*. Myxospores are specialized cells that are resistant to drying, ultraviolet radiation, and heat, but the degree of heat resistance is much less than that of the bacterial endospore (Section 2.16). Fruiting bodies can be simple, consisting of masses of myxospores embedded in slime, or complex, consisting of a stalk and heads (Figure 14.48). The fruiting body stalk is composed of slime within which a few cells are trapped. The majority of the cells migrate to the fruiting body head, where they undergo differentiation into myxospores (Figure 14.44).

VI • Morphological Diversity of *Bacteria*

14.20 Spirochetes and Spirilla

Key Genera: *Spirochaeta*, *Treponema*, *Cristispira*, *Leptospira*, *Borrelia*

Spirochetes are morphologically unique bacteria found only within the bacterial phylum *Spirochaetes*. Spirochetes are gram-negative, motile, tightly coiled *Bacteria*, typically slender and flexuous in shape (Figure 14.49). Spirochetes are widespread in aquatic sediments and in animals. Some cause diseases, including syphilis, an important human sexually transmitted disease (🔗 Section 29.12). Spirochetes are classified into eight genera (Table 14.3) primarily on the basis of habitat, pathogenicity, phylogeny, and morphological and physiological characteristics.

Spirochetes have an unusual mode of motility conveyed by their unusual morphology. Spirochetes contain *endoflagella*, which resemble normal flagella but are found in the cell periplasm (Figure 14.50). The endoflagella are anchored at the cell poles and extend back along the length of the cell. Both the endoflagella and the protoplasmic cylinder are surrounded by a flexible membrane called the *outer sheath* (Figure 14.50b). Endoflagella rotate, as do typical bacterial flagella. However, when both endoflagella rotate in the same direction, the protoplasmic cylinder rotates in the opposite direction, placing torsion on the cell (Figure 14.50b). This torsion causes the spirochete cell to flex, resulting in a corkscrew-like motion that allows cells to burrow through viscous materials or tissues (Figure 14.50b).

Spirochetes are often confused with spirilla. **Spirilla** are helically curved rod-shaped cells, usually motile by means of polar flagella (Figure 14.51). The word *spirillum* refers to a type of cell shape that is widespread among *Bacteria* and *Archaea*. The number of helical turns in a single spirillum may vary from less than

one complete turn (in which case the organism looks like a vibrio) to many turns. In addition, spirilla that divide terminally, such as the cyanobacterium *Spirulina* (Figure 14.5), can form long helical filaments that superficially resemble spirochetes. Spirilla, however, lack the outer sheath, endoflagella, and corkscrew-like motility of spirochetes. In addition, spirilla are typically fairly rigid cells while spirochetes are highly flexible and quite thin (<0.5 µm).

Spirochaeta and *Cristispira*

The genus *Spirochaeta* includes free-living, anaerobic, and facultatively aerobic spirochetes. These organisms, of which several species are known, are common in aquatic environments such as freshwater and sediments, and also in the oceans. *Spirochaeta plicatilis* (Figure 14.49b) is a large spirochete found in sulfidic freshwater and marine habitats. The 20 or so endoflagella inserted at each pole of *S. plicatilis* are arranged in a bundle that winds around the coiled protoplasmic cylinder. Another species, *Spirochaeta stenostrepta* (Figure 14.49a), is an obligate anaerobe commonly found in H₂S-rich black muds. It ferments sugars to ethanol, acetate, lactate, CO₂, and H₂.

Cristispira (Figure 14.52) is a unique spirochete found in nature only in the crystalline style of certain molluscs, such as clams and oysters. The crystalline style is a flexible, semisolid rod seated in a sac and rotated against a hard surface of the digestive tract, thereby mixing and grinding the small particles of food taken in by the animal. *Cristispira* lives in both freshwater and marine molluscs, but not all species of molluscs possess this organism. Unfortunately, *Cristispira* has not been cultured, and so the physiological rationale for its restriction to this unique habitat is unknown.

Treponema and Borrelia

Anaerobic or microaerophilic host-associated spirochetes that are commensals or pathogens of humans and animals reside in the genus *Treponema*. *T. pallidum*, the causal agent of syphilis (☞ Section 29.12), is the best-known species of *Treponema*. It differs in morphology from other spirochetes in that the *Treponema* cell is not helical but flat and wavy. The *T. pallidum* cell is remarkably thin, measuring only 0.2 µm in diameter. Because of this, dark-field microscopy has long been used to examine exudates from suspected syphilitic lesions (☞ Figure 29.37).

Other species of *Treponema* are also often found as commensals in humans and other animals. For example, *Treponema denticola* is common in the human oral cavity and is associated with gum disease. It ferments amino acids such as cysteine and serine, forming acetate as the major fermentation acid, as well as CO₂, NH₃, and H₂S. Spirochetes are also common in the rumen, the digestive organ of ruminant animals (☞ Section 22.7). For instance, *Treponema saccharophilum* (Figure 14.53) is a large, pectinolytic spirochete found in the bovine rumen where it ferments pectin, starch, inulin, and other plant polysaccharides. *Treponema primitia* can be found in the hindgut of certain termites. In

the termite gut, fermentation of cellulose causes production of H₂ and CO₂. *T. primitia* is an acetogen (☞ Section 13.19) that grows on H₂ plus CO₂, forming acetate, which is an important component of the insect's nutrition. *Treponema azotonutricium* is also found in the termite hindgut and is capable of nitrogen fixation (☞ Section 3.17).

The majority of species of *Borrelia* are animal or human pathogens. *Borrelia burgdorferi* (Figure 14.53b) is the causative agent

of the tickborne *Lyme disease*, which infects humans and animals (► Section 30.4). *B. burgdorferi* is also of interest because it is one of the few known bacteria that has a linear (as opposed to a circular) chromosome (► Sections 4.3 and 6.4). Other species of *Borrelia* are primarily of veterinary importance, causing diseases in cattle, sheep, horses, and birds. In most cases, the bacterium is transmitted to the animal host from the bite of a tick.

Leptospira and Leptonema

The genera *Leptospira* and *Leptonema* contain strictly aerobic spirochetes that oxidize long-chain fatty acids (for example, the C₁₈ fatty acid oleic acid) as electron donors and carbon sources. With few exceptions, these are the only substrates utilized for growth. Leptospiros are thin, finely coiled, and usually bent at

each end into a semicircular hook. At present, several species are recognized in this group, some free-living and many parasitic. Two major species of *Leptospira* are *L. interrogans* (parasitic) and *L. biflexa* (free-living). Strains of *L. interrogans* are parasitic for humans and animals. Rodents are the natural hosts of most leptospiros, although dogs and pigs are also important carriers of certain strains.

In humans the most common leptospiral syndrome is *leptospirosis*, a disorder in which the organism localizes in the kidneys and can cause renal failure or even death. Leptospiros ordinarily enter the body through the mucous membranes or through breaks in the skin during contact with an infected animal. After a transient multiplication in various parts of the body, the organism localizes in the kidneys and liver, causing nephritis and jaundice. Domestic animals such as dogs are vaccinated against leptospirosis with a killed virulent strain in the combined distemper-leptospira-hepatitis vaccine.

14.21 Budding and Prosthecate/ Stalked Bacteria

Key Genera: *Hyphomicrobium*, *Caulobacter*

The growth of most bacteria is coupled to cell division by the well-known process of binary fission (► Section 5.1). In this section, we consider organisms that grow and divide in different ways, including budding and the formation of appendages. Budding and appendaged species often have life cycles that are distinct among bacteria.

Budding Division

Budding bacteria divide as a result of unequal cell growth. In contrast to binary fission that forms two equivalent cells (► Figure 5.1), cell division in stalked and budding bacteria forms a totally new daughter cell, with the mother cell retaining its original identity (Figure 14.54).

A fundamental difference between budding bacteria and bacteria that divide by binary fission is the formation of new cell wall material from a single point (polar growth) rather than throughout the whole cell (intercalary growth) as in binary fission (► Sections 5.1–5.4). Several genera not normally considered to be budding bacteria show polar growth without differentiation of cell size (Figure 14.54). An important consequence of polar growth is that internal structures, such as membrane complexes, are not partitioned in the cell division process and must be formed *de novo*. However, this has an advantage in that more complex internal structures can be formed in budding cells than in cells that divide by binary fission, since the latter cells would have to partition these structures between the two daughter cells. Not coincidentally, many budding bacteria, particularly phototrophic and chemolithotrophic species, contain extensive internal membrane systems.

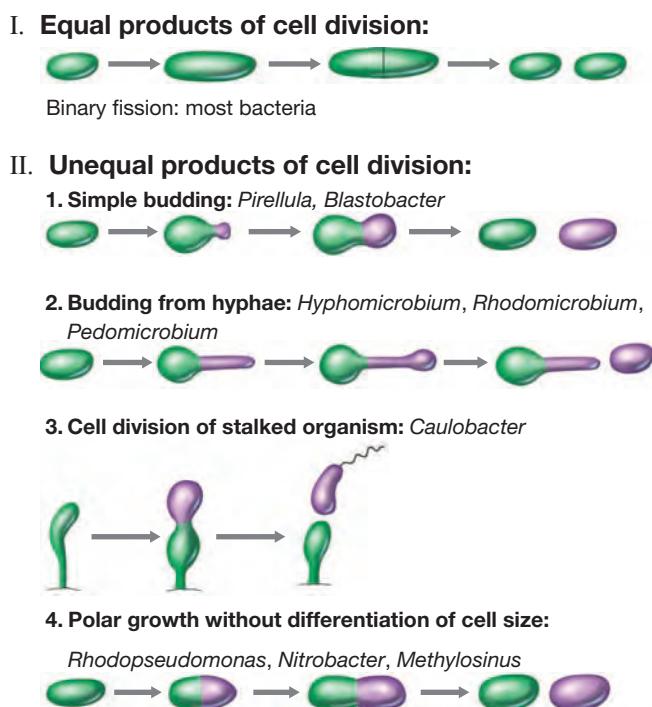

Figure 14.54 Cell division in different bacteria. Contrast between cell division in conventional bacteria and in various budding and stalked bacteria.

Budding Bacteria: *Hypomicrobium*

Two well-studied budding bacteria are closely related *Alphaproteobacteria*: *Hypomicrobium*, which is chemoorganotrophic, and *Rhodomicrobium*, which is phototrophic. These organisms release buds from the ends of long, thin hyphae. The hypha is a direct cellular extension and contains cell wall, cytoplasmic membrane, and ribosomes, and can contain DNA.

Figure 14.55 shows the life cycle of *Hypomicrobium*. The mother cell, which is often attached by its base to a solid substrate, forms a thin outgrowth that lengthens to become a hypha. At the end of the hypha, a bud forms. This bud enlarges, forms a flagellum, breaks loose from the mother cell, and swims away. Later, the daughter cell loses its flagellum and after a period of maturation forms a hypha and buds. More buds can also form at the hyphal tip of the mother cell, leading to arrays of cells connected by hyphae. In some cases, a bud begins to form directly from the mother cell without the intervening formation of a hypha, whereas in other cases a single cell forms hyphae from each end (Figure 14.56). Nucleoid replication events occur before the bud emerges, and then once a bud has formed, a copy of the chromosome moves down the hypha and into the bud. A cross-septum then forms, separating the still-developing bud from the hypha and mother cell (Figure 14.55).

Physiologically, *Hypomicrobium* is a methylotrophic bacterium (Section 14.17), and it is widespread in freshwater, marine, and terrestrial habitats. Preferred carbon sources are C₁ compounds such as methanol (CH₃OH), methylamine (CH₃NH₂), formaldehyde (CH₂O), and formate (HCOO⁻). A fairly specific enrichment procedure for *Hypomicrobium* is to use CH₃OH as an electron donor with nitrate (NO₃⁻) as an electron acceptor in a

dilute medium incubated under anoxic conditions. The only rapidly growing denitrifying bacterium known that uses CH₃OH as an electron donor is *Hypomicrobium*, and so this procedure can select this organism out of a wide variety of environments.

Prosthecate and Stalked Bacteria

A variety of bacteria are able to produce cytoplasmic extrusions including *stalks* (Figure 14.57), *hyphae*, and *appendages* (Table 14.4). Extrusions of these kinds, which are smaller in diameter than the mature cell and contain cytoplasm and a cell wall, are collectively called **prosthecae** (Figure 14.58). Prosthecae allow organisms to attach to particulate matter, plant material, or other microorganisms in aquatic habitats. In addition, prosthecae can be used to increase the ratio of surface area to cell volume. Recall that the high surface-to-volume ratio of prokaryotic cells in general confers an increased ability to take up nutrients and expel wastes (Section 2.6). The unusual morphology of appendaged

bacteria (Figure 14.58) carries this theme to an extreme, and may be an evolutionary adaptation to life in oligotrophic (nutrient-poor) waters where these organisms are most commonly found.

Prosthecae may also function to reduce cell sinking. Because these organisms are aquatic and their metabolism is typically aerobic, prosthecae may keep cells from sinking into anoxic zones in their aquatic environments where they would be unable to respire.

Caulobacter

Two common stalked bacteria are *Caulobacter* (Figure 14.57) and *Gallionella* (Figure 14.36). The former is a chemoorganotroph that produces a cytoplasm-filled stalk, that is, a prostheca, while the latter is a chemolithotrophic iron-oxidizing bacterium whose stalk is composed of ferric hydroxide $[Fe(OH)_3]$ (Section 14.15). *Caulobacter* cells are often seen on surfaces in aquatic environments with the stalks of several cells attached to form rosettes (Figure 14.57a). At the end of the stalk is a structure called a *holdfast* by which the stalk anchors the cell to a surface.

The *Caulobacter* cell division cycle (Figure 14.59; ↗ Section 7.12 and Figure 7.26) is unique because cells undergo unequal binary fission. A stalked cell of *Caulobacter* divides by elongation of the cell followed by binary fission, and a single flagellum forms at the pole opposite the stalk. The flagellated cell so formed, called a *swarmer*, separates from the nonflagellated mother cell and eventually attaches to a new surface, forming a new stalk at

the flagellated pole; the flagellum is then lost. Stalk formation is a necessary precursor of cell division and is coordinated with DNA synthesis (Figure 14.59). The cell division cycle in *Caulobacter* is thus more complex than simple binary fission or budding division because the stalked and swarmer cells are structurally different and the growth cycle must include both forms.

14.22 Sheathed Bacteria

Key Genera: *Sphaerotilus*, *Leptothrix*

Bacteria in many phyla form sheaths made of polysaccharide or protein that encase one or many cells. Sheaths often function to bind cells together into long multicellular filaments (Sections 14.3, 14.11). Sheathed bacteria such as *Sphaerotilus* and *Leptothrix* are *Betaproteobacteria* that have a unique life cycle. *Sphaerotilus* and *Leptothrix* are filamentous bacteria that grow within a sheath. Under favorable conditions, the cells grow vegetatively, leading to the formation of long, cell-packed sheaths. Flagellated swarmer cells form within the sheath and under unfavorable growth conditions; the swarmer cells break out and are dispersed to new environments, leaving behind the empty sheath.

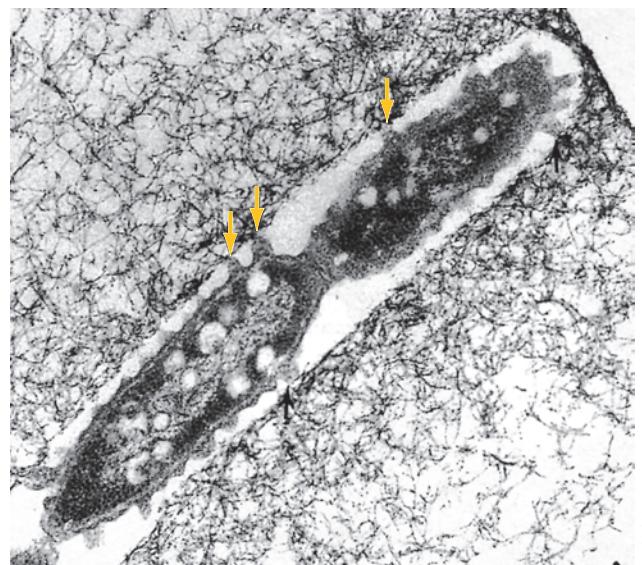

Sphaerotilus and *Leptothrix* are common in freshwater habitats that are rich in organic matter, such as wastewaters and polluted streams. Because they are typically found in flowing waters, they are also abundant in trickling filters and activated sludge digesters in sewage treatment plants (☞ Section 21.6). In habitats in which reduced iron (Fe^{2+}) or manganese (Mn^{2+}) is present, the sheaths may become coated with ferric hydroxide [Fe(OH)_3] or manganese oxides from the oxidation of these metals.

Leptothrix

The ability of *Sphaerotilus* and *Leptothrix* to precipitate iron oxides on their sheaths is well established, and when sheaths become iron encrusted, as occurs in iron-rich waters, they can frequently be seen microscopically (Figure 14.60). Iron precipitates form when ferrous iron (Fe^{2+}), chelated to organic materials such as humic or tannic acids, is oxidized. These chemoorganotrophic bacteria use the organic materials as a carbon or energy source and, when no longer chelated, the ferrous iron becomes oxidized and precipitates on the sheath. Iron oxidation is fortuitous and though these organisms are closely related to dissimilative iron-oxidizers (Section 14.15), the organism does not gain energy from iron oxidation. In a similar way, *Leptothrix* can also oxidize manganese.

Sphaerotilus

The *Sphaerotilus* filament is composed of a chain of rod-shaped cells enclosed in a closely fitting sheath. This thin, transparent structure is difficult to see when it is filled with cells, but when it is partially empty, the sheath can more easily be resolved (Figure 14.61a). Individual cells are $1\text{--}2 \times 3\text{--}8 \mu\text{m}$ and stain gram-negatively. The cells within the sheath (Figure 14.61b) divide by binary fission, and the new cells synthesize new sheath material at the tips of the filaments. Eventually, motile swarmer cells are liberated from the sheaths (Figure 14.61c) and then migrate, attach to a solid surface, and begin to grow, with each swarmer being the forerunner of a new filament. The sheath, which is devoid of peptidoglycan, consists of protein and polysaccharide.

A single cell measures about $0.9 \mu\text{m}$ in diameter. Note the protuberances of the cell envelope that contact the sheath (arrows).

Sphaerotilus cultures are nutritionally versatile and use simple organic compounds as carbon and energy sources. Befitting its habitat in flowing waters, *Sphaerotilus* is an obligate aerobe. Large masses (blooms) of *Sphaerotilus* often occur in the fall of the year in streams and brooks when leaf litter causes a temporary increase in the organic content of the water. In addition, its filaments are the main component of a microbial complex that wastewater engineers call “sewage fungus,” a filamentous slime found on the rocks in streams receiving sewage pollution. In activated sludge of sewage treatment plants (☞ Section 21.6), *Sphaerotilus* is often responsible for a condition called *bulking*, where the tangled masses of *Sphaerotilus* filaments so increase the bulk of the sludge that it remains suspended and does not settle as it should. This has a negative effect on the oxidation of organic matter and the recycling of inorganic nutrients and leads to treatment plant discharges with high nitrogen and carbon loads.

14.23 Magnetic Bacteria

Key Genera: *Magnetospirillum*

Magnetic bacteria demonstrate a dramatic directed movement in a magnetic field called *magnetotaxis*. Within these cells are structures called *magnetosomes*, which consist of chains of magnetic particles made of magnetite (Fe_3O_4) or greigite (Fe_3S_4). Magnetosomes are localized within invaginations of the cell membrane that are organized in a linear conformation by a protein scaffold (☞ Section 2.14 and Figure 2.38). Magnetic bacteria orient along the north–south magnetic moment of a magnetic field, aligning

parallel to the field lines in much the same manner as a compass needle. Magnetic bacteria are typically microaerophilic or anaerobic and are most often found near the oxic-anoxic interface in sediments or stratified lakes. The magnetosomes of aerobic species typically contain the mineral magnetite while those of anaerobes contain exclusively greigite.

Although the ecological role of bacterial magnets is unclear, the ability to orient in a magnetic field may be of selective advantage in maintaining these organisms in zones of low O_2 concentration. Generally, the concentration of O_2 decreases with depth through sediments or the water column of stratified lakes. Since Earth is spherical, its magnetic field lines have a strong vertical component in the Northern and Southern Hemispheres. Thus, bacteria that orient along these field lines can preferentially swim down and away from O_2 . The magnetosome functions like a compass needle to “point” the bacterium in the right direction; rotation of

the flagellum, by contrast, is controlled by a chemotactic response to O_2 (Section 2.19).

Magnetic bacteria display one of two magnetic polarities depending on the orientation of magnetosomes within the cell. Cells in the Northern Hemisphere have the north-seeking pole of their magnetosomes forward with respect to their flagella and thus move in a northward direction (which in the Northern Hemisphere is downward). Cells in the Southern Hemisphere have the opposite polarity and move southward.

Most of the magnetic bacteria that have been described are species of *Alphaproteobacteria*, but species have also been observed in the *Gammaproteobacteria*, the *Deltaproteobacteria*, and the *Nitrospira* group. The best-characterized species is *Magnetospirillum magnetotacticum* (Figure 14.62), which is a chemoorganotrophic microaerophile that can also grow anaerobically by reducing NO_3^- or N_2O . In contrast, the species *Desulfovibrio magneticus* is a sulfate reducer and an obligate anaerobe. In addition, magnetosomes have been observed in a few species of sulfur oxidizers and purple nonsulfur bacteria. Multicellular magnetotactic bacteria are also known. These are *Deltaproteobacteria* that form multicellular aggregates of 10–20 cells organized as a hollow sphere. While multicellular magnetotactic bacteria are obligate anaerobes, the basis of their metabolism has not yet been determined.

14.24 Bacterial Bioluminescence

Key Genera: *Vibrio*, *Aliivibrio*, *Photobacterium*

Several species of bacteria can emit light, a process called **bioluminescence** (Figure 14.63). Most bioluminescent bacteria are classified in the genera *Photobacterium*, *Aliivibrio*, and *Vibrio*, but a few species reside in *Shewanella*, a genus of primarily marine bacteria, and in *Photorhabdus* (☞ Chapter 7 opener), a genus of terrestrial bacteria (all *Gammaproteobacteria*).

Most bioluminescent bacteria inhabit the marine environment, and some species colonize specialized *light organs* of certain marine fishes and squids, producing light that the animal uses for signaling, avoiding predators, and attracting prey (Figure 14.63c–f and ☞ Section 22.11). When living symbiotically in light organs of fish and squids, or saprophytically, for example on the skin of a dead fish, or parasitically in the body of a crustacean, luminous bacteria can be recognized by the light they produce.

Mechanism and Ecology of Bioluminescence

Although *Photobacterium*, *Aliivibrio*, and *Vibrio* isolates are facultative aerobes, they are bioluminescent only when O₂ is present. Luminescence in bacteria requires the genes *luxCDABE* (☞ Section 7.9) and is catalyzed by the enzyme *luciferase*, which uses O₂, a long-chain aliphatic aldehyde (RCHO) such as tetradecanal, and reduced flavin mononucleotide (FMNH₂) as substrates:

The light-generating system constitutes a metabolic route for shunting electrons from FMNH₂ to O₂ directly, without employing other electron carriers such as quinones and cytochromes.

Luminescence in many luminous bacteria only occurs at high population density. The enzyme luciferase and other proteins of the bacterial luminescence system exhibit a population density-responsive induction, called **autoinduction**, in which transcription of the *luxCDABE* genes is controlled by a regulatory protein, LuxR, and an inducer molecule, acyl homoserine lactone (AHL, ☞ Section 7.9 and Figure 7.20). During growth, cells produce AHL, which can rapidly cross the cytoplasmic membrane in either direction, diffusing in and out of cells. Under conditions in which a high local population density of cells of a given species is attained, as in a test tube, a colony on a plate (☞ Figure 1.1), or in the light organ of a fish or squid (☞ Section 22.11), AHL accumulates. Only when it reaches a certain concentration in the cell is AHL bound by LuxR, forming a complex that activates transcription of *luxCDABE*; cells then become luminous (Figure 14.58b). This gene regulatory mechanism is also called *quorum sensing* because of the population density-dependent nature of the phenomenon (☞ Section 7.9).

In saprophytic, parasitic, and symbiotic habitats, the strategy for population density-responsive induction of luminescence is to ensure that luminescence develops only when sufficiently high population densities are reached to allow the light produced to be visible to animals. The bacterial light can then attract animals to

feed on the luminous material, thereby bringing the bacteria into the animal's nutrient-rich gut for further growth. Alternatively, the luminous material may function as a light source in symbiotic, light organ associations.

Quorum sensing is a form of regulation that has also been found in many different nonluminous bacteria, including several animal and plant pathogens. Quorum sensing in these bacteria controls activities such as the production of extracellular enzymes and expression of virulence factors for which a

high population density is beneficial if the bacteria are to have a biological effect.

BIG IDEAS

14.1 • Phylogenetic diversity is that component of microbial diversity that deals with evolutionary relationships between microorganisms. By contrast, functional diversity deals with diversity in form and function as it relates to microbial physiology and ecology. Incongruence between phylogeny and the functional traits of microorganisms can result from patterns of gene loss, horizontal gene transfer, and/or convergent evolution.

14.2 • Anoxygenic phototrophs, which do not produce oxygen, were the first phototrophic organisms to evolve. The evolution of photosynthesis has been impacted strongly by patterns of horizontal gene transfer.

14.3 • *Cyanobacteria* is the only bacterial phylum that contains oxygenic phototrophs. All species of cyanobacteria can fix CO₂ and many can fix N₂, making these organisms important primary producers in many ecosystems.

14.4 • Purple sulfur bacteria are anoxygenic phototrophic *Gammaproteobacteria*. Purple sulfur bacteria use H₂S and S⁰ as electron donors and fix CO₂ by the Calvin cycle. These phototrophs have bacteriochlorophylls *a* or *b* and use a type II photosystem.

14.5 • Purple nonsulfur bacteria are anoxygenic phototrophic *Alpha-* and *Betaproteobacteria*. Purple nonsulfur bacteria are metabolically diverse, growing best as photoheterotrophs, and can also grow in darkness. These phototrophs have bacteriochlorophylls *a* or *b* and use a type II photosystem. Aerobic anoxygenic phototrophs have a type II photosystem but only possess bacteriochlorophyll *a*.

14.6 • Green sulfur bacteria are anoxygenic phototrophs of the phylum *Chlorobi*. Green sulfur bacteria use H₂S or S⁰ as electron donors and fix CO₂ by the reverse citric acid cycle. These phototrophs contain bacteriochlorophylls *c*, *d*, or *e* (localized in their chlorosomes) as well as bacteriochlorophyll *a* in their reaction centers and use a type I photosystem.

14.7 • Green nonsulfur bacteria are anoxygenic phototrophs of the phylum *Chloroflexi* and grow best as photoheterotrophs. These phototrophs contain bacteriochlorophyll *c* in chlorosomes (as in green sulfur bacteria) and bacteriochlorophyll *a* and a type II photosystem (as in phototrophic purple bacteria).

14.8 • Heliobacteria are anoxygenic phototrophic *Firmicutes* that grow as photoheterotrophs or in darkness as chemotrophs. Heliobacteria produce bacteriochlorophyll *g* and have a type I photosystem. *Chloracidobacterium thermophilum* is an anoxygenic phototrophic acidobacterium that grows photoheterotrophically, possesses bacteriochlorophyll *a* and *c* as well as chlorosomes, and has a type I photosystem.

14.9 • Dissimilative sulfate-reducers are obligate anaerobes that grow by reducing SO₄²⁻ with H₂ or simple organic compounds as electron donors. Most sulfate reducers are *Deltaproteobacteria*. Two physiological classes of sulfate-reducing bacteria are known: complete oxidizers, which oxidize acetate to CO₂, and incomplete oxidizers, which cannot.

14.10 • Dissimilative sulfur-reducers are metabolically and phylogenetically diverse organisms that grow by reducing S⁰ and other oxidized sulfur compounds as electron acceptors but are unable to reduce SO₄²⁻.

14.11 • Sulfur chemolithotrophs, most of which are *Proteobacteria*, oxidize H₂S and other reduced sulfur compounds for energy metabolism with O₂ or NO₃⁻ as electron acceptors and use either CO₂ or organic compounds as carbon sources. Sulfur chemolithotrophs use a variety of ecological strategies to conserve energy from H₂S and O₂, substances that otherwise react together spontaneously.

14.12 • Diazotrophs are bacteria that assimilate N₂ through activity of the enzyme nitrogenase. Diazotrophs are metabolically and phylogenetically diverse and employ various adaptations to protect nitrogenase from oxygen inactivation.

14.13 • Nitrifying bacteria are aerobic chemolithotrophs that oxidize NH_3 to NO_2^- (prefix *Nitroso-*) or NO_2^- to NO_3^- (prefix *Nitro-*). Ammonia oxidizers are *Proteobacteria* or *Thaumarchaeota*, while nitrite oxidizers are *Proteobacteria* or *Nitrospira*. Denitrifiers are metabolically and phylogenetically diverse facultative aerobes and chemoorganotrophs that reduce NO_3^- to the gaseous products NO , N_2O , and N_2 .

14.14 • Dissimilative iron-reducers reduce insoluble electron acceptors in anaerobic respirations. Most species can grow anaerobically by reducing ferric iron using H_2 or simple organic compounds as electron donor. The best-characterized genera include *Geobacter*, which contains exclusively obligate anaerobes, and *Shewanella*, which contains facultative aerobes.

14.15 • Dissimilative iron-oxidizers conserve energy from the aerobic oxidation of ferrous iron. These organisms use several ecological strategies to cope with the chemical instability of ferrous iron in oxic habitats at neutral pH. Iron oxidizers are found in four physiological groups: aerobic acidophiles, aerobic neutrophiles, anaerobic chemotrophs, and anaerobic phototrophs.

14.16 • Hydrogen bacteria oxidize H_2 with O_2 as electron acceptor and fix CO_2 by the Calvin cycle. Some hydrogen bacteria, the carboxydobacteria, oxidize carbon monoxide (CO). Most of these bacteria can also grow on organic compounds.

14.17 • Methylotrophs grow on organic compounds that lack carbon–carbon bonds. Some methylotrophs are also methanotrophs, organisms able to catabolize methane. Most methanotrophs are *Proteobacteria* that contain extensive internal membranes and incorporate carbon by either the serine or ribulose monophosphate pathways.

14.18 • The acetic acid bacteria *Acetobacter* and *Gluconobacter* are obligate aerobes that produce acetate from the oxidation of ethanol, and these acid-tolerant bacteria are

often found in the fermenting fluids of alcoholic beverages. Acetogens are obligate anaerobes that use the acetyl-CoA pathway to conserve energy and produce acetate.

14.19 • Bacterial predators such as *Bdellovibrio* and *Myxococcus* consume other microorganisms. Myxobacteria have a complex developmental cycle that involves the formation of fruiting bodies that contain myxospores.

14.20 • The phylum *Spirochaetes* contains helically shaped bacteria that show a novel form of motility that allows them to “corkscrew” through viscous materials. These organisms are common in anoxic habitats and are the cause of many well-known human diseases, such as syphilis.

14.21 • Budding and prosthecate bacteria are appendaged cells that form stalks or prosthecae used for attachment or nutrient absorption, and are primarily aquatic. *Hyphomicrobium*, *Caulobacter*, and *Gallionella* are major genera and are all *Proteobacteria*.

14.22 • Sheathed bacteria are filamentous *Proteobacteria* in which individual cells form chains within an outer layer called the sheath. *Sphaerotilus* and *Leptothrix* are major genera of sheathed bacteria and can oxidize metals, such as Fe^{2+} and Mn^{2+} .

14.23 • Magnetosomes are specialized magnetic structures present in magnetotactic bacteria. Magnetosomes orient cells along the magnetic field lines of Earth, and this allows cells to use their normal chemotactic response to move vertically in a directed fashion in sediments or stratified aquatic systems.

14.24 • *Vibrio*, *Aliivibrio*, and *Photobacterium* species are marine bacteria, some of which are pathogenic and bioluminescent. Bioluminescence, catalyzed by the enzyme luciferase, is controlled by a quorum-sensing mechanism that ensures that light is not emitted until a large cell population has been attained.

REVIEW OF KEY TERMS

Acetic acid bacteria obligately aerobic organisms that produce acetate from alcohols; used for making vinegar

Acetogen an obligately anaerobic organism that produces acetate by use of the reductive acetyl-CoA cycle

Aerobic anoxygenic phototroph an organism that is an aerobic heterotroph that uses anoxygenic photosynthesis as a supplemental source of energy

Autoinduction a gene regulatory mechanism involving small, diffusible signal molecules that are produced in larger amounts as population size increases

Bioluminescence the enzymatic production of visible light by living organisms

Carboxysome a polyhedral cellular inclusion of crystalline ribulose bisphosphate carboxylase (RubisCO), the key enzyme of the Calvin cycle

Chemolithotroph an organism able to oxidize inorganic compounds (such as H_2 , Fe^{2+} , S^0 , or NH_4^+) as energy sources (electron donors)

Chlorosome a cigar-shaped structure bounded by a nonunit membrane and containing the light-harvesting bacteriochlorophyll (*c*, *d*, or *e*) in green sulfur bacteria and *Chloroflexus*

Consortium a two- or more-membered association of bacteria, usually living in an intimate symbiotic fashion

Convergent evolution a circumstance where a trait or set of traits that are similar in form and/or function between two organisms are not inherited from a shared ancestor (i.e., traits that are similar but not homologous)

Cyanobacteria prokaryotic oxygenic phototrophs containing chlorophyll *a* and phycobilins

Denitrifier an organism that carries out anaerobic respiration with NO_3^- , reducing it to the gaseous products NO , N_2O , and N_2

Diazotroph an organism that can assimilate N_2 into biomass by activity of the enzyme nitrogenase

Dissimilative sulfate-reducer an anaerobic microorganism that conserves energy through the reduction of SO_4^{2-}

Dissimilative sulfur-reducer an anaerobic microorganism that conserves energy through the reduction of S^0 but cannot reduce SO_4^{2-}

Dissimilative sulfur-oxidizer a microorganism that gains energy for growth through oxidation of reduced sulfur compounds

Functional diversity the component of biological diversity that deals with the forms and functions of organisms as they relate to differences in physiology and ecology

Green nonsulfur bacteria anoxygenic phototrophs containing chlorosomes, a type II photosystem, bacteriochlorophylls *a* and *c* as light-harvesting chlorophyll, and typically growing best as photoheterotrophs

Green sulfur bacteria anoxygenic phototrophs containing chlorosomes, type I photosystem, bacteriochlorophylls *c*, *d*, or *e* as light-harvesting chlorophyll, and typically growing with H_2S as an electron donor

Heliobacteria anoxygenic phototrophs containing bacteriochlorophyll *g*

Horizontal gene transfer a unidirectional transfer of genes between unrelated organisms; can cause homologous genes to be dispersed in a phylogeny

Methanotroph an organism capable of oxidizing methane (CH_4) as an electron donor in energy metabolism

Methylotroph an organism capable of oxidizing organic compounds that do not contain carbon–carbon bonds; if able to oxidize CH_4 , also a methanotroph

Mixotroph an organism that conserves energy from the oxidation of inorganic compounds but requires organic compounds as a carbon source

Nitrifier a chemolithotroph capable of carrying out the transformation $NH_3 \rightarrow NO_2^-$, or $NO_2^- \rightarrow NO_3^-$

Phycobilin a protein containing the pigment phycocyanin or phycoerythrin that functions as a photosynthetic accessory pigment in cyanobacteria

Prochlorophyte a bacterial oxygenic phototroph that contains chlorophylls *a* and *b* but lacks phycobilins

Prosthecae extrusion of cytoplasm, often forming distinct appendages, bounded by the cell wall

Purple nonsulfur bacteria a group of phototrophic bacteria containing bacteriochlorophyll *a* or *b* and a type II photosystem and that grow best as photoheterotrophs

Purple sulfur bacteria a group of phototrophic bacteria containing bacteriochlorophylls *a* or *b* and type II photosystem and that can oxidize H_2S to sulfur

Spirilla (singular, spirillum) spiral-shaped cells

Spirochete a slender, tightly coiled, gram-negative bacterium of the phylum Spirochaetes characterized by possession of endoflagella used for motility

Discovering Novel Microbial Phyla

Many plants and animals cannot be kept in captivity because they live in unique habitats or require complex biological interactions that cannot be replicated in a zoo or botanical garden. Many microorganisms are hard to get or keep in captivity as well, because of intimate connections to their environments. These noncultivated microorganisms were largely unknown before the development of molecular techniques for studying microbial diversity. Only 12 phyla of *Bacteria* were known in 1987, but as a result of sequencing 16S ribosomal RNA genes from environmental samples, we now know of more than 80 bacterial phyla, most of which lack cultured representatives.

A recent culturing success story occurred with phylum OP10, named after a 16S ribosomal RNA gene sequence originally recovered from Obsidian Pool, a geothermal spring in Yellowstone National Park (USA).¹ Following its discovery, 16S gene sequences from the OP10 phylum were observed in various thermal environments around the world, but a culture was never obtained. However, with persistence and improvements in culturing techniques, microbiologists were finally successful in cultivating species of OP10, now renamed as the phylum *Armatimonadetes*.¹

One of the first cultured species of *Armatimonadetes* was the bacterium *Chthonomonas calidirosea*, isolated from geothermally heated soil at Hell's Gate, New Zealand (photo). *C. calidirosea* is a thermophile that grows best at 68°C and degrades cellulose and xylan aerobically. Strains with these characteristics often produce enzymes that are useful in industrial processes which transform plant biomass into energy or other useful products.

In the last chapter we examined microbial diversity with respect to *functional* diversity. In this and the next two chapters we shift our focus to *phylogenetic* diversity. We examine the major lineages of *Bacteria* (Figure 15.1a) in this chapter and the *Archaea* and microbial *Eukarya* in Chapters 16 and 17, respectively.

Including phyla of *Bacteria* known only from 16S ribosomal RNA (rRNA) gene sequences retrieved from the environment (Section 22.6), over 80 phyla can be distinguished. However, fewer than half of these contain species that have been characterized in laboratory culture (Figure 15.1b). Remarkably, more than

90% of characterized genera and species of *Bacteria* originate in only four phyla: *Proteobacteria*, *Actinobacteria*, *Firmicutes*, and *Bacteroidetes* (Figure 15.1b).

With more than ten thousand species of bacteria described, we obviously cannot consider them all. Therefore, using phylogenetic trees to focus our discussion, we will explore some of the best-known species from a broad diversity of phyla. In this chapter we will consider species from more than 20 bacterial phyla, focusing on those with the largest numbers of characterized species. We begin our tour of the *Bacteria* with the phylum *Proteobacteria*.

(a) Major phyla of *Bacteria*

Figure 15.1 Some major phyla of *Bacteria* based on 16S ribosomal RNA gene sequence comparisons. (a) Depicted are the major phyla of *Bacteria* that have cultivated species. Analyses of 16S rRNA gene sequences from natural environments suggest there are

more than 80 bacterial phyla. (b) Numbers of cultured and characterized species (green bars) and known 16S rRNA gene sequences (phylotypes, red bars) for each of the 29 major bacterial phyla that have at least one characterized species in pure culture. Also shown are

related data for the different classes of *Proteobacteria*. Differences between the size of the red and green bars indicate the degree to which members of each group are common in natural environments but difficult to cultivate in isolation. Note that the abscissa is a log scale.

I • *Proteobacteria*

The *Proteobacteria* are by far the largest and most metabolically diverse phylum of *Bacteria* (Figure 15.2). More than a third of characterized species of *Bacteria* originate within this group (Figure 15.1b), and *Proteobacteria* constitute the majority of known bacteria of medical, industrial, and agricultural significance.

As a group, the *Proteobacteria* are all gram-negative bacteria. They show an exceptionally wide diversity of energy-generating mechanisms, with chemolithotrophic, chemoorganotrophic, and phototrophic species (Figure 15.2). Indeed, we have already seen the great diversity of energy metabolisms used by various

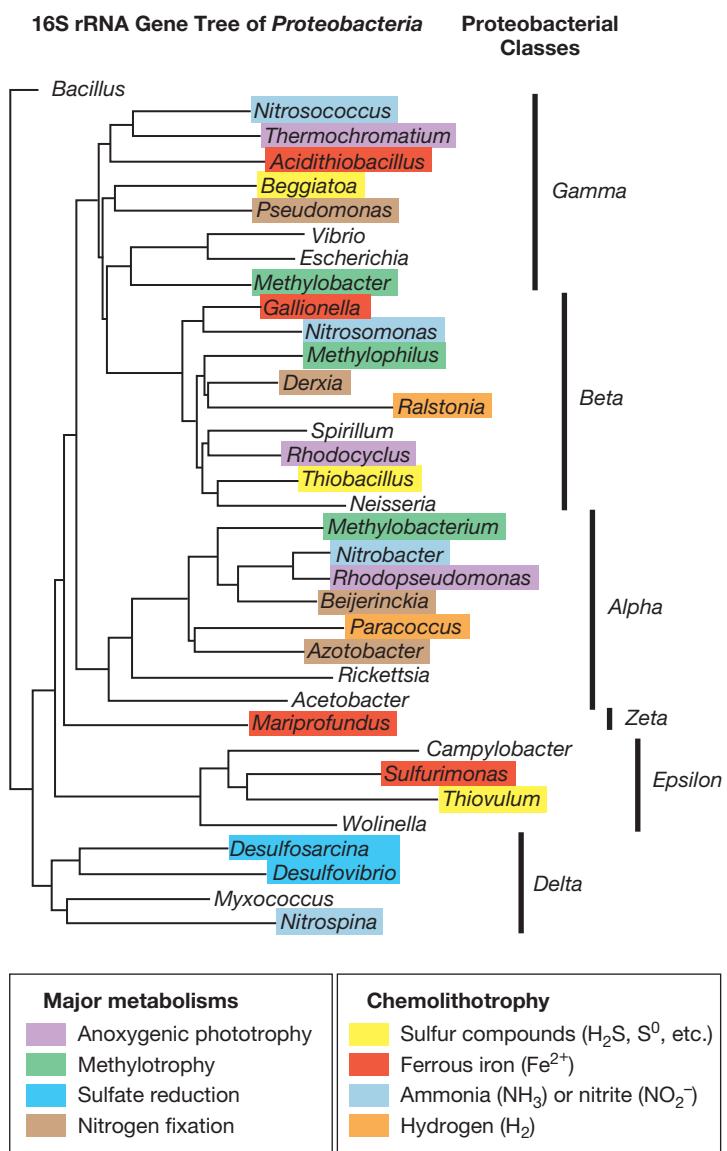

Figure 15.2 Phylogenetic tree and metabolic links of some key genera of *Proteobacteria*. Phylogeny of representative genera of *Proteobacteria* as revealed by analysis of 16S rRNA gene sequences. Note how identical metabolisms are often distributed in phylogenetically distinct genera, suggesting that horizontal gene flow has been extensive in the *Proteobacteria*. Some organisms listed may have multiple properties; for example, some sulfur chemolithotrophs are also iron or hydrogen chemolithotrophs, and several of the organisms listed can fix nitrogen. Phylogenetic analyses were performed and the phylogenetic tree constructed by Marie Asao, Ohio State University.

representatives of this group in Chapter 13. The *Proteobacteria* are equally diverse in terms of their relationship to oxygen (O_2), with anaerobic, microaerophilic, and facultatively aerobic species known. Morphologically, they also exhibit a wide range of cell shapes, including straight and curved rods, cocci, spirilla, filamentous, budding, and appendaged forms.

Based on 16S rRNA gene sequences, the phylum *Proteobacteria* can be divided into six classes: *Alpha*-, *Beta*-, *Gamma*-, *Delta*-, *Epsilon*-, and *Zetaproteobacteria*. Each class contains many genera with the exception of the *Zetaproteobacteria*, which is composed of a single species, the marine iron-oxidizing

bacterium *Mariprofundus ferrooxydans* (☞ Section 14.15). Despite the phylogenetic breadth of the *Proteobacteria*, species in different classes often have similar metabolisms. For example, phototrophy and methylotrophy occur in three different classes of *Proteobacteria*, and nitrifying bacteria span four classes of *Proteobacteria* (☞ Figure 14.1). This suggests that horizontal gene flow (☞ Section 6.12) has played a major role in shaping the metabolic diversity of the *Proteobacteria*. The sharing of metabolic traits in the different classes of *Proteobacteria* is also a good reminder that phenotype and phylogeny often provide different views of prokaryotic diversity (☞ Section 14.1).

15.1 Alphaproteobacteria

With nearly one thousand described species, the *Alphaproteobacteria* are the second largest class of *Proteobacteria* (Figure 15.1b). The *Alphaproteobacteria* contain extensive functional diversity (Figure 15.2, ☞ Figure 14.1) and many genera in this group have already been considered in Chapter 14. Most species are obligate aerobes or facultative aerobes and many are **oligotrophic**, preferring to grow in environments that have low nutrient concentration. A total of 10 orders have been described within the *Alphaproteobacteria*, but the vast majority of species fall within the *Rhizobiales*, *Rickettsiales*, *Rhodobacterales*, *Rhodospirillales*, *Caulobacterales*, and *Sphingomonadales* (Figure 15.3, Table 15.1).

Family	Genus	Notable characteristics
Caulobacterales	Caulobacter	Asymmetric cell division and formation of prosthecae
Rickettsiales	Rickettsia	Obligate intracellular parasites, transmitted by arthropods
	Wolbachia	Live within arthropods and impact their reproduction
Rhizobiales	Bartonella	Obligate intracellular parasites, transmitted by arthropods
	Bradyrhizobium	Form root nodules with soybean and other legumes
	Brucella	Facultative intracellular parasites of animals, zoonotic pathogen
	Hypomicrobium	Stalked cells, metabolically versatile
	Mesorhizobium	Form root nodules with bird's-foot trefoil and other legumes
	Methylobacterium	Methylotroph found on plants and in soil
	Nitrobacter	Nitrifying bacterium that oxidizes NO_2^- to NO_3^-
	Pelagibacter	Oligotrophic chemoorganotroph; high abundance in ocean surface
	Rhodopseudomonas	Metabolically versatile purple nonsulfur bacterium
Rhodobacterales	Paracoccus	Species used as a model for studying denitrification
	Rhodobacter	Metabolically versatile purple nonsulfur bacteria
	Roseobacter	Aerobic anoxygenic phototroph
Rhodospirillales	Acetobacter	Used industrially for producing acetic acid
	Azospirillum	Obligately aerobic diazotroph
	Gluconobacter	Used industrially for producing acetic acid
	Magnetospirillum	Magnetotactic bacterium
Sphingomonadales	Sphingomonas	Aerobic degradation of aromatic organics, biodegradation
	Zymomonas	Ferments sugars into ethanol, potential for biofuel production

Rhizobiales

Key Genera: *Bartonella*, *Methylobacterium*, *Pelagibacter*, *Rhizobium*, *Agrobacterium*

The Rhizobiales (Figure 15.3) are the largest and most metabolically diverse order of *Alphaproteobacteria* and contain phototrophs (e.g., *Rhodopseudomonas*), chemolithotrophs (e.g., *Nitrobacter*),

symbionts (e.g., rhizobia), free-living nitrogen-fixing bacteria (e.g., *Beijerinckia*), a few pathogens of plants and animals, and diverse chemoorganotrophs. The group gets its name from the *rhizobia*, a polyphyletic collection of genera that form root nodules and fix nitrogen in symbiotic association with leguminous plants (► Section 22.3).

Among the Rhizobiales are nine genera that contain rhizobia: *Bradyrhizobium*, *Ochrobactrum*, *Azorhizobium*, *Devosia*, *Methylobacterium*, *Mesorhizobium*, *Phyllobacterium*, *Sinorhizobium*, and *Rhizobium*. These are typically chemoorganotrophs and obligate aerobes, and the genes that convey the ability to form root nodules have clearly been distributed among these genera by horizontal gene transfer. Each rhizobial genus has a distinct range of plant hosts that can be colonized (► Table 22.1). Rhizobia can be isolated by crushing nodules and spreading their contents on nutrient-rich solid media; colonies typically produce copious amounts of exopolysaccharide slime (Figure 15.4).

The organism *Agrobacterium tumefaciens* (also called *Rhizobium radiobacter*) is closely related to root nodule *Rhizobium* species but is a plant pathogen that causes crown gall disease (► Section 22.4). *A. tumefaciens* is unable to form root nodules, and the genes that encode gall formation are unrelated to those that mediate nodule formation.

The genus *Methylobacterium* is one of the largest in the Rhizobiales. These species are often called “pink-pigmented facultative methylotrophs” (► Section 14.17) due to the pink color of their colonies grown on methanol. Species are commonly found on the surface of plants and in soils and freshwater systems. These organisms are also commonly encountered in toilets and baths where their growth on shower curtains, caulk, and in toilet bowls results in the formation of pink-pigmented biofilms. Species of *Methylobacterium* are readily isolated by pressing the surface of a plant leaf onto an agar Petri plate containing methanol as the sole source of carbon.

Bartonella is another notable genus of Rhizobiales. These organisms, once classified with the Rickettsiales, are intracellular pathogens of humans. Species of *Bartonella* can cause a variety of diseases in humans and other vertebrate animals. *Bartonella quintana* is the causative agent of trench fever, a disease that decimated troops in World War I. Other species of *Bartonella* can cause bartonellosis, cat scratch disease, and a variety of inflammatory diseases. Disease transmission is mediated by arthropod vectors including fleas, lice, and sand flies. Species of *Bartonella* are fastidious and difficult to cultivate, and isolation is most commonly achieved using blood agar. When growing in tissue culture,

Odile Barge

cells of *Bartonella* grow on the outside surface of the eukaryotic host cells rather than within the cytoplasm or the nucleus.

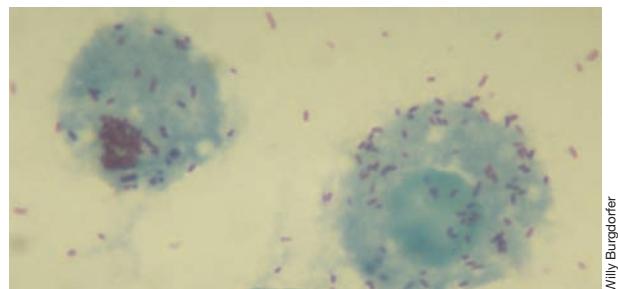

Finally, the genus *Pelagibacter* also belongs to the *Rhizobiales*. *Pelagibacter ubique* is an oligotroph and an obligately aerobic chemoorganotroph that inhabits the photic zone of Earth's oceans. This organism can make up 25% of the bacterial cells found at the ocean's surface, and its numbers can reach 50% of cells in temperate waters in the summer; as a consequence, *Pelagibacter ubique* is likely the most abundant bacterial species on Earth (☞ Section 19.11).

Rickettsiales

Key Genera: *Rickettsia*, *Wolbachia*

Rickettsiales (Figure 15.3) are all obligate intracellular parasites or mutualists of animals. Species in this order have not yet been cultivated in the absence of host cells (Figure 15.5) and must be grown in chicken eggs or in host cell tissue culture. Typically, *Rickettsiales* are closely associated with arthropods. Those genera that cause disease such as *Rickettsia* and *Ehrlichia* are transmitted by arthropod bites; other genera such as *Wolbachia* are obligate parasites or mutualists of insects and other arthropods.

Species of the genus *Rickettsia* are the causative agents of several human diseases, including typhus (*Rickettsia prowazekii*), and spotted fever rickettsiosis, commonly called Rocky Mountain spotted fever (*Rickettsia rickettsii*) (☞ Section 30.3). These organisms are closely associated with arthropod vectors

(b) Electron micrograph of cells of *Rickettsiella popilliae* within a blood cell of its host, the beetle *Melolontha melolontha*. The bacteria grow inside a vacuole within the host cell.

and can be transmitted by ticks, fleas, lice and mites. Most rickettsias are metabolically specialized, able to oxidize only the amino acids glutamate or glutamine and unable to oxidize glucose or organic acids. Rickettsias are unable to synthesize certain metabolites and must instead obtain them from host cells. Rickettsias do not survive long outside their hosts, and this may explain why they must be transmitted from animal to animal by arthropod vectors.

Electron micrographs of thin sections of rickettsial cells show a typical prokaryotic morphology including a cell wall (Figure 15.5b). The penetration of a host cell by a rickettsial cell is an active process, requiring both host and parasite to be viable and metabolically active. Once inside the host cell, the bacteria multiply primarily in the cytoplasm and continue replicating until the host cell is loaded with parasites (Figure 15.5; ☞ Figure 30.6). The host cell then bursts and liberates the bacterial cells.

The genus *Wolbachia* contains intracellular parasites of many insects (Figure 15.6), a huge group that constitutes 70% of all known arthropod species. *Wolbachia* species can have any of several effects on their insect hosts. These include inducing parthenogenesis (development of unfertilized eggs), the killing of males, and feminization (the conversion of male insects into females).

Wolbachia pipiensis is the best-studied species in the genus. Cells of *W. pipiensis* colonize the insect egg (Figure 15.6), where they multiply in vacuoles of host cells surrounded by a membrane of host origin. Cells of *W. pipiensis* are passed from an infected female to her offspring through this egg infection. *Wolbachia*-induced parthenogenesis occurs in a number of species of wasps. In these insects, males normally arise from unfertilized eggs (which contain only one set of chromosomes), while females arise from fertilized eggs (which contain two sets of chromosomes). However, in unfertilized eggs infected with *Wolbachia*, the organism somehow triggers a doubling of the chromosome number, thus yielding only females. Predictably, if female insects are fed antibiotics that kill *Wolbachia*, parthenogenesis ceases.

Other Orders of Alphaproteobacteria

Key Genera: *Rhodobacter*, *Acetobacter*, *Caulobacter*, and *Sphingomonas*

The families *Rhodobacterales* and *Rhodospirillales* (Figure 15.3) contain metabolically diverse organisms that have been discussed previously, including purple nonsulfur bacteria (*Rhodobacter* and *Rhodospirillum*, ↗ Section 14.5), aerobic anoxygenic phototrophs (*Roseobacter*, ↗ Section 14.5), nitrogen-fixing bacteria (*Azospirillum*, ↗ Section 14.12), denitrifiers (*Paracoccus*, ↗ Section 14.13), methylotrophs (*Methylobacterium*, ↗ Section 14.17), acetic acid bacteria (*Acetobacter* and *Gluconobacter*, ↗ Section 14.18), and magnetotactic bacteria (*Magnetospirillum*, ↗ Section 14.23), among others.

The *Caulobacterales* are typically oligotrophic and strictly aerobic chemoorganotrophs. Species typically form prosthecae or stalks (↗ Section 14.21), and many species display asymmetric forms of cell division. The characteristic genus is *Caulobacter*, which has a characteristic life cycle that we have discussed previously (↗ Sections 7.12 and 14.21).

The *Sphingomonadales* include diverse aerobic and facultatively aerobic chemoorganotrophs as well as species of aerobic anoxygenic phototrophs (*Erythrobacter*), and a few obligate anaerobes. The characteristic genus is *Sphingomonas*, which consists of obligately aerobic and nutritionally versatile species. Sphingomonads are widespread in aquatic and terrestrial environments and are notable for their ability to metabolize a wide range of organic compounds including many aromatic compounds that are common environmental contaminants (e.g., toluene, nonylphenol, dibenzo-*p*-dioxin, naphthalene, and anthracene, among others). As a consequence, sphingomonads have been widely studied as potential agents of bioremediation (↗ Section 21.5). These organisms are typically easy to cultivate and grow well on a variety of complex culture media.

15.2 Betaproteobacteria

With nearly 500 described species, the *Betaproteobacteria* are the third largest class of *Proteobacteria* (Figure 15.7). The *Betaproteobacteria* contain an immense amount of functional diversity (Figure 15.2 and ↗ Figure 14.1), and many species in this group have already been considered in Chapter 14. A total of six orders of *Betaproteobacteria* have many characterized species: *Burkholderiales*, *Hydrogenophilales*, *Methylophilales*, *Neisseriales*, *Nitrosonomadales*, and *Rhodocyclales*, and we focus on these here.

Burkholderiales

Key Genera: *Burkholderia*

The *Burkholderiales* contain species with a wide range of metabolic and ecological characteristics. Species include strictly aerobic, facultatively aerobic, and obligately anaerobic chemoorganotrophs, anoxygenic phototrophs, obligate and facultative

Betaproteobacteria

chemolithotrophs, free-living nitrogen fixers, and pathogens of plants, animals, and humans.

Burkholderia is the type genus for the *Burkholderiales*. The genus *Burkholderia* includes diverse species of chemoorganotrophs with strictly respiratory metabolism. All species can grow aerobically, some also grow anaerobically with nitrate as the electron acceptor, and many strains are able to fix N₂. The metabolic versatility of *Burkholderia* species with respect to organic compounds, and aromatic compounds in particular, has led to interest in their use in bioremediation (↗ Section 21.5). Certain strains of *Burkholderia* have also been shown to promote plant growth. However, many species are potentially pathogenic for plant or animals. One of the best-known of the pathogenic species is *Burkholderia cepacia*.

B. cepacia is primarily a soil bacterium but also an opportunistic pathogen (Figure 15.8). *B. cepacia* is often found in the rhizosphere of plants. *B. cepacia* can produce both anti-fungal and

Figure 15.8 Colonies of *Burkholderia*. Photograph of colonies of *Burkholderia cepacia* on an agar plate.

anti-nematodal compounds and thus its ability to colonize plant roots can provide disease protection and promote plant growth. However, *B. cepacia* is also known as a plant pathogen in certain circumstances, and it is a major cause of soft rot in onions. *B. cepacia* has also emerged as an opportunistic hospital-acquired infection in humans, as it is a hardy organism that is difficult to eradicate from the clinical setting. *B. cepacia* can form secondary lung infections in patients who are immunocompromised or have pneumonia or cystic fibrosis. Its ability to form biofilms in the lung and its natural resistance to many antibiotics has made this organism particularly dangerous for patients with cystic fibrosis (Section 19.4).

Rhodocyclales

Key Genera: *Rhodococcus*, *Zoogloea*

Like the *Burkholderiales*, the order *Rhodocyclales* contains species with diverse metabolic and ecological characteristics. The type genus for the *Rhodocyclales* is *Rhodococcus*, a purple nonsulfur bacterium (Section 14.5). Like most purple nonsulfur bacteria, *Rhodococcus* species grow best as a photoheterotrophs but most can also grow as photoautotrophs with H₂ as electron acceptor. Species can also grow by respiration in darkness, but they are typically found in illuminated anoxic environments where organic matter is present.

Zoogloea is another important genus of the *Rhodocyclales*. *Zoogloea* species are aerobic chemoorganotrophs that are distinctive for producing a thick gelatinous capsule which binds cells together into a complex matrix with branching, fingerlike projections. This gelatinous matrix can cause *flocculation*, the formation of macroscopic particles that settle out of solution. *Zoogloea ramigera* is of particular importance in aerobic wastewater treatment (Section 21.6), where it degrades much of the organic carbon in the waste stream and promotes flocculation and settling, crucial steps in water purification.

Neisseriales

Key Genera: *Chromobacterium*, *Neisseria*

The order *Neisseriales* contains at least 29 genera of diverse chemoorganotrophs. The most well-characterized species are in the genera *Neisseria* and *Chromobacterium*. Species of *Neisseria* are commonly isolated from animals, and some of them are pathogenic. *Neisseria* species are always cocci (Figure 15.9a). Some

Neisseria are free-living saprophytes and reside in the oral cavity and other moist areas on the animal body. Others are serious pathogens, such as *Neisseria meningitidis*, which can cause a potentially fatal inflammation of the membranes lining the brain (meningitis, Section 29.5). We discuss the clinical microbiology of *Neisseria gonorrhoeae*—the causative agent of the disease gonorrhea—in Section 27.3, and the pathogenesis of gonorrhea itself in Section 29.12.

Chromobacterium is a close phylogenetic relative of *Neisseria* but is rod-shaped in morphology. The best-known *Chromobacterium* species is *C. violaceum*, a purple-pigmented organism (Figure 15.9b) found in soil and water and occasionally in pus-forming wounds of humans and other animals. *C. violaceum* and a few other chromobacteria produce the purple pigment *violacein* (Figure 15.9b), a water-insoluble pigment with both antimicrobial and antioxidant properties. *Chromobacterium* is a facultative aerobe, growing fermentatively on sugars and aerobically on various carbon sources.

Hydrogenophilales, Methylophilales, and Nitrosomonadales

Key Genera: *Hydrogenophilus*, *Thiobacillus*, *Methylophilus*, *Nitrosomonas* These three orders contain organisms that have fairly specialized metabolic capabilities including chemolithotrophs and methylotrophs; most species are obligate aerobes and many are autotrophic. *Hydrogenophilus thermoluteolus* is an obligate aerobe that can grow as a chemolithotroph using H₂ as an electron donor for respiration (Sections 13.7 and 14.16) and the Calvin cycle to fix CO₂. This species is a facultative chemolithotroph, and can also grow as a chemoorganotroph on simple carbon sources. *Thiobacillus* is another important genus of *Hydrogenophilales*. Species of *Thiobacillus* can be chemoorganotrophs or chemolithotrophs. Chemolithotrophic species of *Thiobacillus* are sulfur bacteria (Sections 13.8 and 14.11) that oxidize reduced sulfur compounds as electron donors and grow by aerobic respiration or denitrification (Sections 13.17 and 14.13). Species of *Thiobacillus* can also fix CO₂ using the Calvin cycle and are commonly found in soils, sulfur springs, marine habitats, and other locales where reduced sulfur compounds are available.

The *Methylophilales* and *Nitrosomonadales* contain metabolically specialized organisms. *Methylophilus* species are obligate and facultative methylotrophs (Section 14.17) that grow on methanol and other C₁ compounds, but not on CH₄. Facultative species can grow as chemoorganotrophs through aerobic respiration of simple sugars. The order *Nitrosomonadales* contains obligately chemolithotrophic ammonia-oxidizing bacteria, the key genera being *Nitrosomonas* and *Nitrosospira* (Section 14.13).

15.3 Gammaproteobacteria—Enterobacteriales

Key Genera: *Enterobacter, Escherichia, Klebsiella, Proteus, Salmonella, Serratia, Shigella*

The *Gammaproteobacteria* are the largest and most diverse class of *Proteobacteria*, containing nearly half of the characterized species in the phylum. The class contains more than 1500 characterized species among its 15 orders (Figure 15.10, Figure 15.1b). Its species have diverse metabolic and ecological characteristics (Figure 15.2 and Figure 14.1) and include many well-known human pathogens. Species can be phototrophic (including the purple sulfur bacteria, Section 14.4), chemoorganotrophic, or chemolithotrophic, and can have either respiratory or fermentative metabolism. Members of this group often develop quickly in laboratory media and can be isolated from a wide diversity of habitats. In this section we consider the *Enterobacteriales*, one of the largest and most well-known orders within the *Gammaproteobacteria*.

The *Enterobacteriales*, commonly called the **enteric bacteria**, comprise a relatively homogeneous phylogenetic group within

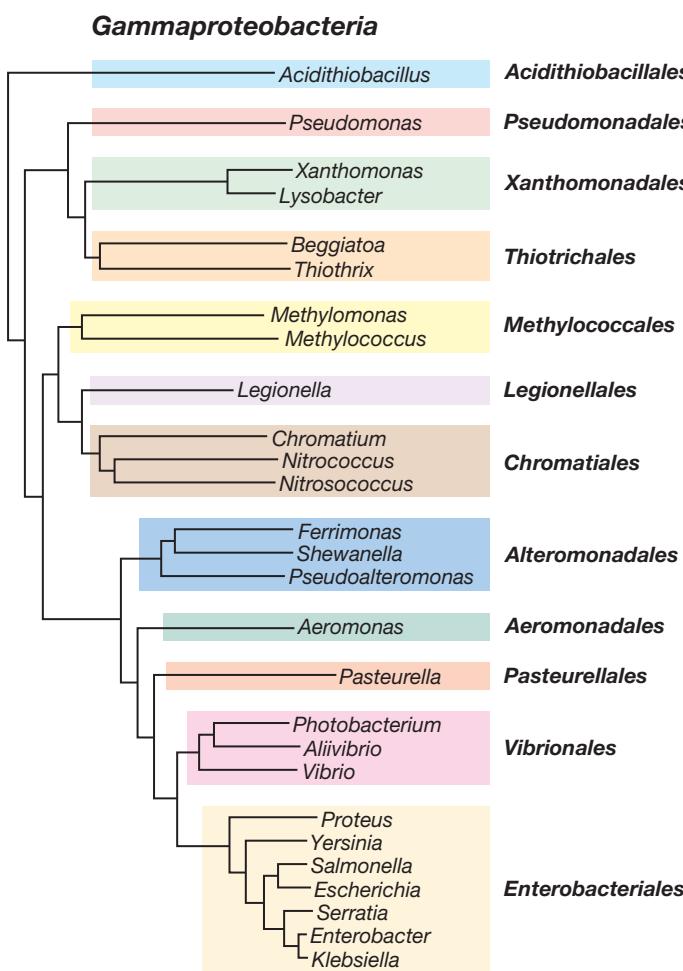

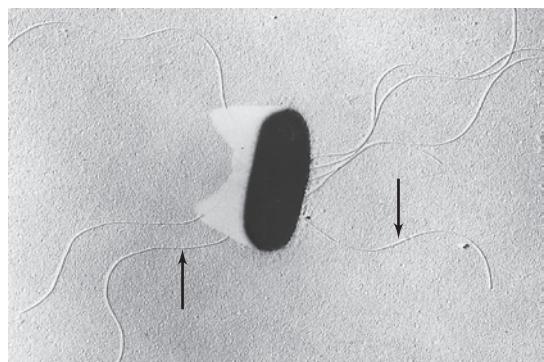

Figure 15.10 Major orders of *Proteobacteria* in the class *Gammaproteobacteria*.
The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera of *Gammaproteobacteria*. Order names are shown in bold.

the *Gammaproteobacteria* and consist of facultatively aerobic, gram-negative, nonsporulating rods that are either nonmotile or motile by peritrichous flagella (Figure 15.11). The *oxidase test* and the *catalase test* are common assays used to characterize bacteria (Section 27.3) and these tests can be used to discriminate enteric bacteria from many other *Gammaproteobacteria*. The oxidase test is an assay for the presence of cytochrome *c* oxidase, an enzyme present in many respiring bacteria. The catalase test assays for the enzyme catalase, which detoxifies hydrogen peroxide and is commonly found in bacteria able to grow in the presence of oxygen (Section 5.16 and Figure 5.31). Enteric bacteria are oxidase-negative and catalase-positive. They also produce acid from glucose and reduce nitrate but only to nitrite. Enteric bacteria have relatively simple nutritional requirements and ferment sugars to a variety of end products.

Among the enteric bacteria are many species pathogenic to humans, other animals, or plants, as well as other species of industrial importance. *Escherichia coli*, the best known of all organisms, is the classic enteric bacterium. Because of the medical importance of many enteric bacteria, an extremely large number have been characterized, and numerous genera and species have been defined, largely for ease in identification purposes in clinical microbiology. However, because enteric bacteria are genetically very closely related, their positive identification often presents considerable difficulty. In clinical laboratories, identification is typically based on the combined analysis of a large number of diagnostic tests carried out using miniaturized rapid diagnostic media kits along with immunological and genomic analyses to identify signature proteins or genes of particular species (Chapter 27).

Fermentation Patterns in Enteric Bacteria

One major taxonomic characteristic separating the various genera of enteric bacteria is the type and proportion of fermentation products generated from the fermentation of glucose. Two broad patterns are recognized, the *mixed-acid fermentation* and the *2,3-butanediol fermentation* (Figure 15.12).

In the mixed-acid fermentation, three acids are formed in significant amounts: acetic, lactic, and succinic. Ethanol, CO₂, and H₂ are also formed, but not butanediol. In the butanediol fermentation, smaller amounts of acids are formed, and butanediol,

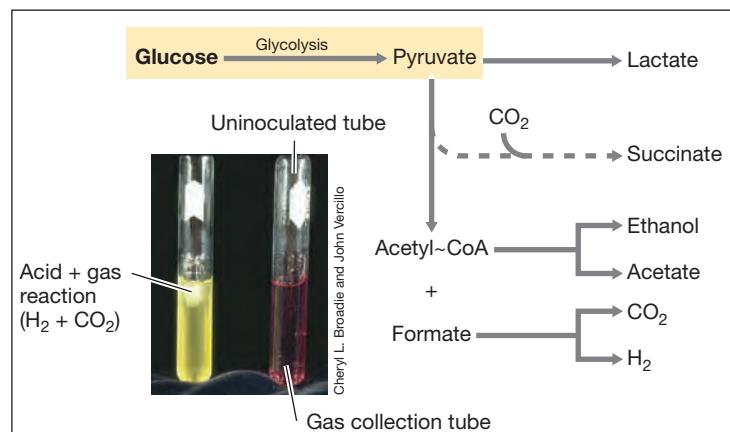

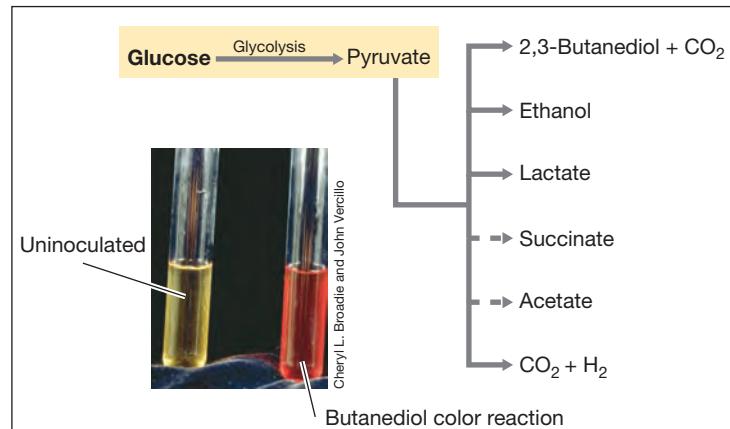

(a) Mixed-acid fermentation (for example, *Escherichia coli*)(b) Butanediol fermentation (for example, *Enterobacter aerogenes*)

Figure 15.12 Enteric fermentations. Distinction between (a) mixed-acid and (b) butanediol fermentation in enteric bacteria (☞ Figure 13.32). The solid arrows indicate reactions leading to major products. Dashed arrows indicate minor products. (a) The photo shows the production of acid (yellow) and gas (in the inverted Durham tube) in a culture of *Escherichia coli* carrying out a mixed-acid fermentation (purple tube was uninoculated). (b) The photo shows the pink-red color in the Voges-Proskauer (VP) test, which indicates butanediol production, following growth of *Enterobacter aerogenes*. The left (yellow) tube was not inoculated. Note that the mixed-acid fermentation produces less CO_2 but more acid products from glucose than does the butanediol fermentation.

ethanol, CO_2 , and H_2 are the main products (☞ Figure 13.32). As a result of mixed-acid fermentation, equal amounts of CO_2 and H_2 are produced, whereas in the butanediol fermentation, considerably more CO_2 than H_2 is produced. This is because mixed-acid fermenters produce CO_2 only from formic acid by means of the enzyme formate hydrogenlyase:

This reaction results in equal amounts of CO_2 and H_2 . The butanediol fermenters also produce CO_2 and H_2 from formic acid, but they produce two additional molecules of CO_2 during the formation of each molecule of butanediol (Figure 15.12b). Butanediol fermentation is characteristic of *Enterobacter*, *Klebsiella*, *Erwinia*, and *Serratia*, whereas mixed-acid fermentation is observed in *Escherichia*, *Salmonella*, *Shigella*, *Citrobacter*, *Proteus*, and *Yersinia*.

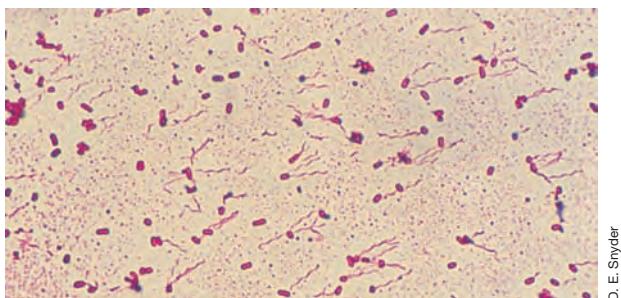

Mixed-Acid Fermenters: *Escherichia*, *Salmonella*, *Shigella*, and *Proteus*

Species of *Escherichia* are almost universal inhabitants of the intestinal tract of humans and other warm-blooded animals, although they are by no means the dominant organisms in this habitat. *Escherichia* may play a nutritional role in the intestinal tract by synthesizing vitamins, particularly vitamin K. As a facultative aerobe, this organism probably also helps consume O_2 , thus rendering the large intestine anoxic. Wild-type *Escherichia* strains rarely show any growth-factor requirements and are able to grow on a wide variety of carbon and energy sources such as sugars, amino acids, organic acids, and so on.

Some strains of *Escherichia* are pathogenic and have been implicated in diarrheal diseases, especially in infants; diarrheal diseases are a major public health problem in developing countries. (☞ Section 31.11). *Escherichia* is also a major cause of urinary tract infections in women. Enteropathogenic *E. coli* strains are becoming more frequently implicated in gastrointestinal infections and generalized fevers. Some strains, such as enterohemorrhagic *E. coli*, an important representative of which is strain O157:H7, can cause sporadic outbreaks of severe foodborne disease. Infection occurs primarily through consumption of contaminated foods, such as raw or undercooked ground beef, unpasteurized milk, or contaminated water. In a small percentage of cases, *E. coli* O157:H7 causes a life-threatening complication related to its production of a very potent enterotoxin.

Salmonella and *Escherichia* are quite closely related. However, in contrast to *Escherichia*, species of *Salmonella* are almost always pathogenic, either to humans or to other warm-blooded animals (*Salmonella* is also found in the intestines of cold-blooded animals, such as turtles and lizards). In humans the most common diseases caused by salmonellas are typhoid fever and gastroenteritis (☞ Sections 31.5 and 31.10). The shigellas are also genetically very closely related to *Escherichia*. Genomic analyses strongly suggest that *Shigella* and *Escherichia* have exchanged a significant number of genes by horizontal gene flow. In contrast to most *Escherichia*, however, species of *Shigella* are typically pathogenic to humans, causing a rather severe gastroenteritis called *bacillary dysentery*. *Shigella dysenteriae*, transmitted by food- and water-borne routes, is a good example of this. The bacterium, which contains endotoxin, invades intestinal epithelial cells, where it excretes a neurotoxin that causes acute gastrointestinal distress.

The genus *Proteus* typically contains highly motile cells (Figure 15.13) that produce the enzyme *urease*. Unlike *Salmonella* and *Shigella*, *Proteus* shows only a distant relationship to *E. coli*. *Proteus* is a frequent cause of urinary tract infections in humans and probably benefits in this regard from its ready ability to degrade urea by urease. Because of the rapid motility of *Proteus* cells, colonies growing on agar plates often exhibit a characteristic swarming phenotype (Figure 15.13b). Cells at the edge of the growing colony are more rapidly motile than those in the center of the colony. The former move a short distance away from the colony in a mass and then undergo a reduction in motility, settle down, and divide, forming a new population of motile cells that again swarm. As a result, the mature colony appears as a series of concentric rings, with higher concentrations of cells alternating with lower concentrations (Figure 15.13b).

Butanediol Fermenters: *Enterobacter*, *Klebsiella*, and *Serratia*

The butanediol fermenters are genetically more closely related to each other than to the mixed-acid fermenters, a finding that is in agreement with the observed physiological differences (Figure 15.12). *Enterobacter aerogenes* is a common species in water and sewage as well as the intestinal tract of warm-blooded animals and is an occasional cause of urinary tract infections. One species of *Klebsiella*, *K. pneumoniae*, occasionally causes pneumonia in humans, but klebsiellas are most commonly found in soil and water. Most *Klebsiella* strains also fix nitrogen (► Section 3.17), a property not characteristic of other enteric bacteria.

The genus *Serratia* forms a series of red pyrrole-containing pigments called *prodigiosins* (Figure 15.14). Prodigiosin is produced in stationary phase as a secondary metabolite and is of interest because it contains the pyrrole ring also found in the pigments for energy transfer: porphyrins, chlorophylls, bacteriochlorophylls, and phycobilins (► Sections 13.1–13.3). However, it is unclear if prodigiosin plays any role in energy transfer, and its exact function is unknown. Species of *Serratia* can be isolated from water and soil as well as from the gut of various insects and vertebrates and occasionally from the intestines of humans. *Serratia marcescens*

is also a human pathogen that can cause infections in many body sites. It has been implicated in infections caused by some invasive medical procedures and is an occasional contaminant in intravenous fluids.

15.4 Gammaproteobacteria— *Pseudomonadales* and *Vibrionales*

Key Genera: *Aliivibrio*, *Pseudomonas*, *Vibrio*

The phylogenetic and metabolic diversity of the *Gammaproteobacteria* makes it difficult to select the many notable species in this class of *Proteobacteria*. We focus here on the *Pseudomonadales* and *Vibrionales*, since these groups (along with the *Enterobacterales*) represent three of the most abundant and most commonly encountered orders of *Gammaproteobacteria* (Figure 15.10).

Pseudomonadales

The *Pseudomonadales* contain exclusively chemoorganotrophs that carry out respiratory metabolism. All species can grow as aerobes and are typically oxidase- and catalase-positive, but some are also capable of anaerobic respiration with nitrate as the electron acceptor. Most species are able to use a wide diversity of organic compounds as sources of carbon and energy for growth. These organisms are ubiquitous in soil and aquatic systems, and many species cause diseases of plants and animals, including humans. The type genus is *Pseudomonas*, and key species are defined on the basis of phylogeny and various physiological and other phenotypic characteristics, as outlined in Table 15.2. The term **pseudomonad** is often used to describe any gram-negative, polarly flagellated, aerobic rod that is able to use diverse carbon sources. Pseudomonads can be found in several different groups of *Proteobacteria*, but here we consider only those organisms in the order *Pseudomonadales*.

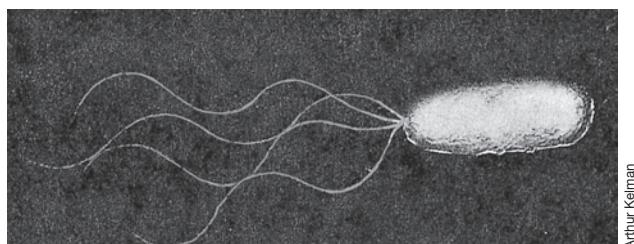

Table 15.2 Characteristics of some key *Pseudomonas* species

Species	Characteristics
<i>Pseudomonas aeruginosa</i>	Pyocyanin production; growth at up to 43°C; single polar flagellum; capable of denitrification; primarily a soil organism, but also common in hospital-acquired (nosocomial) infections
<i>Pseudomonas fluorescens</i>	Does not produce pyocyanin or grow at 43°C; tuft of polar flagella; primarily a soil organism, rarely pathogenic
<i>Pseudomonas marginalis</i>	Degradates pectin, causes soft rot of various plants
<i>Pseudomonas putida</i>	Similar to <i>P. fluorescens</i> , but does not liquefy gelatin and does grow on benzylamine
<i>Pseudomonas syringae</i>	Lacks arginine dihydrolase; oxidase-negative; plant pathogen causing chlorosis and necrotic lesions on leaves
<i>Pseudomonas stutzeri</i>	Soil saprophyte; strong denitrifier and nonfluorescent

Several species of *Pseudomonas* are pathogenic (Table 15.2). Among these, *Pseudomonas aeruginosa* (Figure 15.15) is frequently associated with infections of the urinary and respiratory tracts in humans. *P. aeruginosa* is not an obligate pathogen. Instead, the organism is an opportunist, initiating infections in individuals with weakened immune systems. *P. aeruginosa* is a common cause of hospital-acquired (nosocomial) infections from catheterizations, tracheostomies, lumbar punctures, and intravenous infusions, and often emerges in patients given prolonged treatment with immunosuppressive agents. *P. aeruginosa* is also a common pathogen in patients receiving treatment for severe burns or other traumatic skin damage and in people suffering from cystic fibrosis. In addition to localized infections, *P. aeruginosa* can also cause systemic infections, usually in individuals who have experienced extensive skin damage.

P. aeruginosa is naturally resistant to many widely used antibiotics, so treatment of infections is often difficult. Resistance is typically due to a resistance transfer plasmid (R plasmid) (☞ Sections 4.3 and 27.17), which is a plasmid whose genes encode proteins that detoxify various antibiotics or pump them out of the cell. Polymyxin, an antibiotic not ordinarily used in human therapy because of its toxicity, is effective against *P. aeruginosa* and is used in critical medical situations.

Certain species of *Pseudomonas* are well-known plant pathogens (phytopathogens) (Table 15.2). Phytopathogens frequently

Arthur Kelman

Figure 15.15 Cell morphology of pseudomonads. Shadow-cast transmission electron micrograph of a *Pseudomonas* cell. The cell measures about 1 µm in diameter.

inhabit nonhost plants (in which disease symptoms are inapparent) and from there become transmitted to host plants and initiate infection. Disease symptoms vary considerably, depending on the particular phytopathogen and host plant. The pathogen releases plant toxins, lytic enzymes, plant growth factors, and other substances that destroy or distort plant tissue, releasing nutrients for use by the bacterium. In many cases the disease symptoms help identify the phytopathogen. Thus, *Pseudomonas syringae* is typically isolated from leaves showing chlorotic (yellowing) lesions, whereas *Pseudomonas marginalis*, a “soft-rot” pathogen, infects stems and shoots but rarely leaves.

Vibrionales

The *Vibrionales* contain facultatively aerobic rods and curved rods that employ a fermentative metabolism. One key difference between the *Vibrio* group and enteric bacteria is that *Vibrio* are oxidase-positive whereas enteric bacteria are oxidase-negative. Although *Pseudomonas* species are also oxidase-positive, they are not fermentative and so are clearly distinct from *Vibrio* species. The best-known genera in this group are *Vibrio*, *Aliivibrio*, and *Photobacterium*, which contain several species that are bioluminescent (☞ Section 14.24).

Most vibrios and related bacteria are aquatic, found in marine, brackish, or freshwater habitats. *Vibrio cholerae* is the cause of the disease cholera in humans (☞ Sections 28.10 and 31.3); the organism does not normally cause disease in other hosts. Cholera is one of the most common human infectious diseases in developing countries and is transmitted almost exclusively via water.

Vibrio parahaemolyticus inhabits the marine environment and is a major cause of gastroenteritis in Japan, where raw fish is widely consumed; the organism has also been implicated in outbreaks of gastroenteritis in other parts of the world, including the United States. *V. parahaemolyticus* can be isolated from seawater itself or from shellfish and crustaceans, and its primary habitat is probably marine animals, with humans being an accidental host.

15.5 Deltaproteobacteria and Epsilonproteobacteria

These classes of *Proteobacteria* contain fewer species and less functional diversity than we have encountered in the *Alpha*-, *Beta*-, and *Gammaproteobacteria* (Figure 15.2 and ☞ Figure 14.1). The *Deltaproteobacteria* are primarily sulfate- and sulfur-reducing bacteria (☞ Sections 14.9 and 14.10), dissimilative iron-reducers (☞ Section 14.14), and bacterial predators (☞ Section 14.19). *Epsilonproteobacteria*, by contrast, contain many species that oxidize the H₂S produced by the sulfate and sulfur reducers. The final class of *Proteobacteria*, the *Zetaproteobacteria*, contains only one characterized species (the iron oxidizer *Mariprofundus ferrooxydans*) and was considered earlier (☞ Section 14.15).

Deltaproteobacteria

Key Genera: *Bdellovibrio*, *Myxococcus*, *Desulfovibrio*, *Geobacter*, *Syntrophobacter*

Eight orders have been characterized within the *Deltaproteobacteria* (Figure 15.16). The largest and most common order containing sulfate reducers is the *Desulfobacterales*. These organisms are readily cultivated from marine sediments and nutrient-rich anoxic environments that contain sulfate. Species of *Desulfovibrionales* are typically incomplete oxidizers (☞ Section 14.9). All use sulfate as the terminal electron acceptor, and all require small organic compounds such as lactate as a source of carbon and energy for growth. Species within the orders *Desulfobacterales* and *Desulfarculales* also typically reduce sulfate; however, in contrast to the *Desulfobacterales*, these species can be complete or incomplete acetate oxidizers (☞ Section 14.9). In addition to sulfate, some species in these three orders can also reduce sulfite, thiosulfate, or nitrate, and some are capable of certain fermentations.

The final order containing sulfate reducers is the *Syntrophobacterales*. Some but not all species of the *Syntrophobacterales* are able to reduce sulfate. In nature, however, species of *Syntrophobacterales* primarily interact with H₂-consuming bacteria in a metabolic partnership called *syntrophy* (☞ Sections 13.15 and 20.2). For example, syntrophic species such as *Syntrophobacter wolinii* oxidize propionate, producing acetate, CO₂, and H₂. However, such growth is only possible when a H₂-consuming partner is present. If sulfate is present, *S. wolinii* can grow as a sulfate reducer without the need for a partner. *S. wolinii* can also grow without a partner organism by fermenting pyruvate, fumarate, or malate.

Epsilonproteobacteria

Key Genera: *Campylobacter*, *Helicobacter*

The *Epsilonproteobacteria* (Figure 15.16) were initially defined by only a few pathogenic bacteria; in particular, by species of

Epsilonproteobacteria

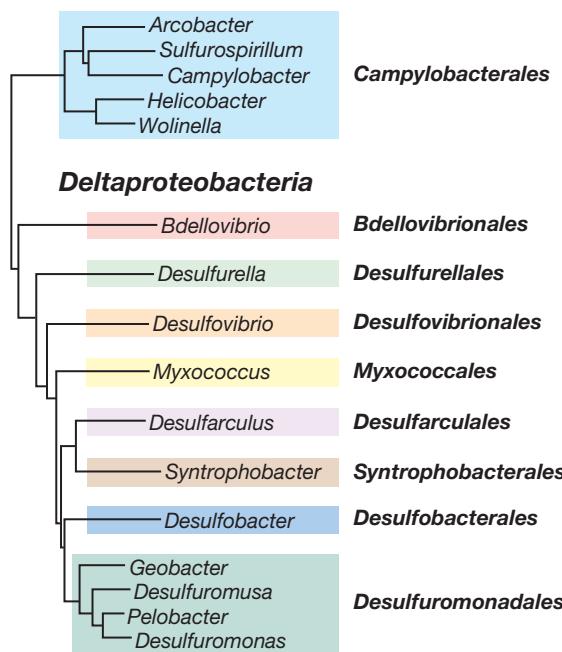

Figure 15.16 Major orders of *Proteobacteria* in the classes

Deltaproteobacteria and Epsilonproteobacteria. The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera in the Delta- and Epsilonproteobacteria. Order names are shown in bold.

Campylobacter and *Helicobacter*. However, environmental studies of marine and terrestrial microbial habitats have shown that a diversity of *Epsilonproteobacteria* exist in nature, and their numbers and metabolic capabilities suggest they play important ecological roles (Table 15.3). Species of *Epsilonproteobacteria* are especially abundant at oxic–anoxic interfaces in sulfur-rich environments, and play major roles in the oxidation of sulfur compounds in nature.

Table 15.3 Characteristics of key genera of *Epsilonproteobacteria*

Genus	Habitat	Descriptive characters	Physiology and metabolism
<i>Campylobacter</i>	Reproductive organs, oral cavity, and intestinal tract of humans and other animals; pathogenic	Slender, spirally curved rods; corkscrew-like motility by single polar flagellum	Microaerophilic; chemoorganotrophic
<i>Arcobacter</i>	Diverse habitats (freshwater, sewage, saline environments, animal reproductive tract, plants); some species pathogenic for humans and other animals	Slender, curved rods; motile by single polar flagellum	Microaerophilic; aerotolerant or aerobic; chemoorganotrophic; oxidation of sulfide to elemental sulfur (S ⁰) by some species; nitrogen fixation in one species
<i>Helicobacter</i>	Intestinal tract and oral cavity of humans and other animals; pathogenic	Rods to tight spiral; some species with tightly coiled periplasmic fibers	Microaerophilic, chemoorganotrophic; produce high levels of urease (nitrogen assimilation)
<i>Sulfurospirillum</i>	Freshwater and marine habitats containing sulfur	Vibrioid to spiral-shaped cells; motile by polar flagella	Microaerophilic; reduces elemental sulfur (S ⁰)
<i>Thiovulum</i>	Freshwater and marine habitats containing sulfur; not yet in pure culture (☞ Figure 14.29)	Cells contain orthorhombic S ⁰ granules; rapid motility by peritrichous flagella	Microaerophilic; chemolithotrophic oxidizing H ₂ S
<i>Wolinella</i>	Bovine rumen	Rapidly motile by polar flagellum; single species known: <i>W. succinogenes</i>	Anaerobe; anaerobic respiration using fumarate, nitrate, or other compounds as terminal electron acceptor, and with H ₂ or formate as electron donor

Campylobacter and Helicobacter

These two genera of *Epsilonproteobacteria* share a number of characteristics. *Campylobacter* and *Helicobacter* species are gram-negative, oxidase- and catalase-positive, motile spirilla, and most species are pathogenic to humans or other animals (Table 15.3). These organisms are also microaerophilic (☞ Section 5.16) and must therefore be cultured from clinical specimens at low (3–15%) O₂ and high (3–10%) CO₂.

Campylobacter species, over a dozen of which have been described, cause acute gastroenteritis that typically results in a bloody diarrhea. Pathogenesis is due to several factors, including an enterotoxin that is related to cholera toxin. *Helicobacter pylori*, also a pathogen, causes both chronic and acute gastritis, leading to the formation of peptic ulcers. We consider these diseases, including their modes of transmission and clinical symptoms, in more detail in Sections 29.10 and 31.12.

Sulfurospirillum and Wolinella

Species of *Sulfurospirillum*, a *Campylobacter* relative, are non-pathogenic, free-living microaerophiles found in freshwater and marine habitats (Table 15.3). These bacteria also carry out anaerobic respirations using elemental sulfur (S⁰), selenate, or arsenate as electron acceptors (☞ Sections 13.18 and 13.21).

Wolinella is an anaerobic bacterium isolated from the bovine rumen (Table 15.3; ☞ Section 22.7). Unlike other *Epsilonproteobacteria*, the single known species, *W. succinogenes*, grows best as an anaerobe and can catalyze anaerobic respirations using fumarate or nitrate as electron acceptors with H₂ or formate as electron donors. Although *W. succinogenes* has thus far been found only in the rumen, its genome shows significant homologies to both the *Campylobacter* and *Helicobacter* genomes and contains

additional genes that encode nitrogen fixation, extensive cell signaling mechanisms, and virtually complete metabolic pathways, absent from closely related genomes. This suggests that *Wolinella* inhabits diverse environments outside of the rumen.

Environmental *Epsilonproteobacteria*

In addition to cultured representatives of the genera mentioned above, and many additional species and genera not considered here, there are large groups within this class that are known only from 16S ribosomal RNA gene sequences obtained from the environment (☞ Section 18.5). Through environmental sequencing studies and ongoing cultivation efforts, species of *Epsilonproteobacteria* are now becoming recognized as ubiquitous in marine and terrestrial environments where sulfur-cycling activities are ongoing, particularly in deep-sea hydrothermal vent habitats where sulfide-rich and oxygenated waters mix (☞ Section 19.13). Also, living attached to the surface of animals such as the tube worm *Alvinella* and the shrimp *Rimicaris* that reside near hydrothermal vents, a large variety of uncultured *Epsilonproteobacteria* may, through their sulfur metabolism, detoxify H₂S that would otherwise be deleterious to their animal hosts, allowing the animals to thrive in a chemically hostile environment (☞ Section 22.12). Further exploration of the phylogeny, metabolic activities, and ecological roles of *Epsilonproteobacteria* will likely uncover exciting new aspects of prokaryotic diversity.

II • Firmicutes, Tenericutes, and Actinobacteria

We continue our tour of phylogenetic bacterial diversity with the gram-positive bacteria of the phyla *Actinobacteria* and *Firmicutes*, and the closely-related phylum *Tenericutes* (Figure 15.17). These three phyla contain nearly half of all characterized species of *Bacteria* (Figure 15.1b).

The *Actinobacteria* include the actinomycetes, a huge group of primarily filamentous soil bacteria. One distinguishing feature of the *Actinobacteria* is that they typically have genomes of high GC content and as a result are also called the **high GC gram-positive bacteria**. The *Tenericutes* include cells that lack a cell wall, and the *Firmicutes* include the endospore-forming bacteria, lactic acid bacteria, and several other groups. In contrast to the *Actinobacteria*, the genomes of *Firmicutes* generally have a low GC content, and as a result, they are also called the **low GC gram-positive bacteria**.

We begin by examining *Firmicutes* that do not form endospores.

15.6 Firmicutes—Lactobacillales

Key Genera: *Lactobacillus*, *Streptococcus*

The order *Lactobacillales* contains the **lactic acid bacteria**, fermentative organisms that produce lactic acid as a major end product of metabolism. These organisms are used widely in food

production and preservation. Lactic acid bacteria are nonsporulating, oxidase- and catalase-negative rods or cocci that show an exclusively fermentative metabolism. All lactic acid bacteria produce lactic acid as a major or sole fermentation product. Members of this group lack porphyrins and cytochromes, do not carry out oxidative phosphorylation, and hence obtain energy only by substrate-level phosphorylation. Unlike many anaerobes, however, most lactic acid bacteria are not sensitive to oxygen (O₂) and can grow in its presence; thus they are called **aerotolerant anaerobes**.

Most lactic acid bacteria obtain energy only from the metabolism of sugars and therefore are usually restricted to habitats in which sugars are present. They typically have limited biosynthetic abilities, and their complex nutritional requirements include needs for amino acids, vitamins, purines, and pyrimidines (for example, ☞ Table 3.2 for *Leuconostoc mesenteroides*). One important difference between subgroups of the lactic acid bacteria lies in the pattern of products formed from the fermentation of sugars. One group, called **homofermentative**, produces a single fermentation product, *lactic acid*. The other group, called **heterofermentative**, produces other products, mainly ethanol and CO₂, as well as lactate (☞ Section 13.12 provides additional coverage of homofermentative and heterofermentative pathways).

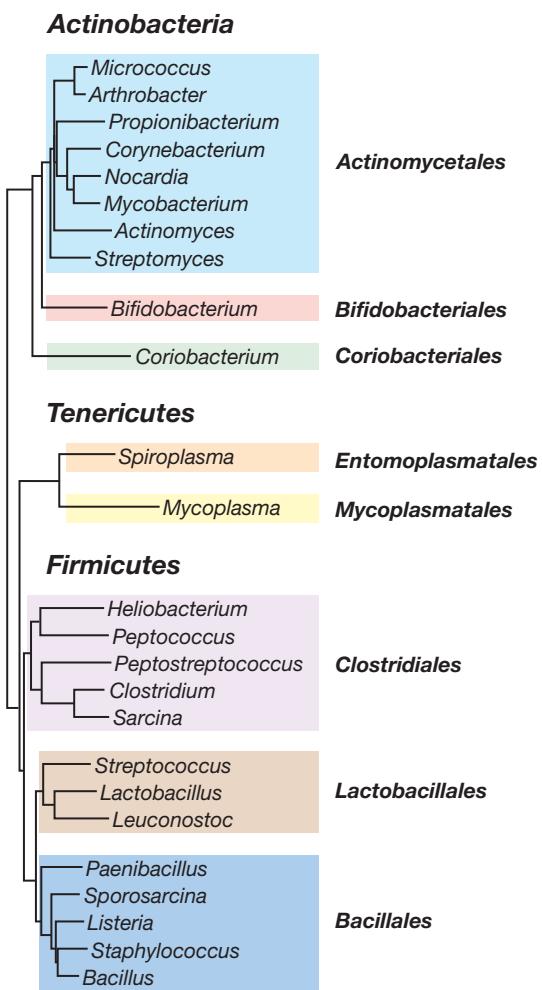

Figure 15.17 Major orders of gram-positive bacteria and relatives.

The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Actinobacteria*, *Firmicutes*, and *Tenericutes*. Order names are shown in bold.

Lactobacillus

Lactobacilli are typically rod-shaped and grow in chains, varying from long and slender to short, bent rods (Figure 15.18), and most are homofermentative. Lactobacilli are common in dairy products, and some strains are used in the preparation of fermented milk products. For instance, *Lactobacillus acidophilus* (Figure 15.18a) is used in the production of acidophilus milk; *Lactobacillus delbrueckii* (Figure 15.18c) is used in the preparation of yogurt; and other species are used in the production of sauerkraut, silage, and pickles (Section 31.6).

Lactobacilli are typically more resistant to acidic conditions than are other lactic acid bacteria and are able to grow well at pH values as low as 4. Because of this, they can be selectively enriched from dairy products and fermenting plant material on acidic carbohydrate-containing media. The acid resistance of the lactobacilli enables them to continue growing during natural lactic fermentations, even when the pH value has dropped too low for other lactic acid bacteria to grow. The lactobacilli are therefore typically responsible for the final stages of most lactic acid fermentations. They are rarely, if ever, pathogenic.

Cells measure about 0.8 × 2 µm. (c) *Lactobacillus delbrueckii*, scanning electron micrograph. Cells are about 0.7 µm in diameter.

Streptococcus and Other Coccis

The genera *Lactococcus* and *Streptococcus* (Figure 15.19) contain homofermentative species of coccoid-shaped lactic acid bacteria with quite distinct habitats and activities that are of considerable practical importance to humans. Some species are pathogenic to humans and animals (Section 29.2). *Streptococcus* species (Figure 15.19a) have a characteristic cell morphology forming cocci in chains or tetrads and so are readily resolved from the rod-shaped lactobacilli. As producers of lactic acid, other streptococci play important roles in the production of buttermilk, silage, and other fermented products (Section 31.6), and certain species play a major role in the formation of dental caries (Section 23.3).

There are several other genera of homofermentative coccis. The genus *Lactococcus* (Figure 15.19b) contains those streptococci of dairy significance, whereas the genus *Enterococcus* includes streptococci that are primarily of fecal origin and can be human pathogens. Species of the genera *Peptococcus* and *Peptostreptococcus* are obligate anaerobes that ferment proteins rather than sugars.

Streptococci have been divided into two groups of related species: the *pyogenes* subgroup, characterized by *Streptococcus pyogenes*, the cause of strep throat (Section 29.2), and the *viridans* subgroup, characterized by *Streptococcus mutans*, the cause of dental caries (Section 23.3). Hemolysis on blood agar is

of considerable importance in the subdivision of the genus into species. For example, species that produce the virulence factors streptolysin O or S form colonies surrounded by a large zone of complete red blood cell hemolysis when plated on blood agar, a condition called β -hemolysis (Figure 23.18a). β -hemolysis is diagnostic for streptococci in the pyogenes subgroup. In contrast, streptococci in the viridans subgroup cause incomplete hemolysis on blood agar, a condition that leads to greening of the agar under colonies. Streptococci are also divided into immunological groups (designated by the letters A, B, C, F, G), based on the presence of specific carbohydrate antigens (antigens are substances that elicit an immune response). Those β -hemolytic streptococci found in humans usually contain the group A antigen, whereas enterococci contain the group D antigen.

Heterofermentative lactococci reside in the genus *Leuconostoc*. Strains of *Leuconostoc* also produce the flavoring ingredients diacetyl and acetoin from the catabolism of citrate; they have been used as starter cultures in dairy fermentations. Some strains of *Leuconostoc* produce large amounts of glucose or fructose polysaccharide slimes, especially when cultured on sucrose as the carbon and energy source (Figure 15.19c), and some of these polymers have found medical use as plasma extenders in blood transfusions.

15.7 Firmicutes—Nonsporulating Bacillales and Clostridiales

Key Genera: *Listeria*, *Staphylococcus*, *Sarcina*

Firmicutes that form endospores reside in the orders *Bacillales* and *Clostridiales*. However, numerous *Bacillales* and *Clostridiales* are unable to form endospores, and we consider some of these here.

Listeria

The order *Bacillales* typically contains aerobic and facultatively aerobic chemoorganotrophs. Few human pathogens are found within this group, but the genus *Listeria* is a notable exception. *Listeria* are gram-positive, catalase-positive, and obligately aerobic coccobacilli that tend to form chains of three to five cells (Figure 31.16). Although several species of *Listeria* are known, the species *Listeria monocytogenes* is most noteworthy because it causes a major foodborne illness, *listeriosis* (Section 31.13). The organism is transmitted in contaminated, usually ready-to-eat foods, such as cheese and sausages, and can cause anything from a mild illness to a fatal form of meningitis. Species of *Listeria* often grow well at low temperatures, allowing growth in refrigerated foods.

Staphylococcus

Staphylococcus (Figure 15.20) is a facultative aerobe that shows a typical respiratory metabolism but can also grow fermentatively. Cells typically grow in clusters and produce acid from glucose both aerobically and anaerobically. *Staphylococcus* species are catalase-positive, and this permits their distinction from *Streptococcus* and some other genera of lactic acid bacteria. *Staphylococci* are relatively resistant to reduced water potential and tolerate drying and high salt (NaCl) fairly well. Their ability to grow in media containing salt provides a selective means for isolation. For example, if an appropriate inoculum such as a skin swab, dry soil, or room dust is spread on a rich-medium agar plate containing 7.5% NaCl and the plate is incubated aerobically, gram-positive cocci often form the predominant colonies. Many species are pigmented, and this provides an additional aid in selecting gram-positive cocci.

Staphylococci are common commensals and parasites of humans and animals, and they occasionally cause serious infections. In humans, there are two major species, *Staphylococcus epidermidis*, a nonpigmented, nonpathogenic organism usually found on the skin or mucous membranes, and *Staphylococcus aureus* (Figure 15.20), a yellow-pigmented species that is most commonly associated with pathological conditions including boils, pimples, pneumonia, osteomyelitis, meningitis, and arthritis. We discuss the pathogenesis of *S. aureus* in Section 23.2 and staphylococcal diseases in Sections 29.9 and 31.8.

Sarcina

The genus *Sarcina* groups obligate anaerobes that are catalase-negative within the order *Clostridiales*. *Sarcina* species divide in three perpendicular planes to yield packets of eight or more cells and are notable for this morphology (Figure 15.21). *Sarcina* are also extremely acid-tolerant, being able to ferment sugars and grow in environments at a pH as low as 2. Cells of one species, *Sarcina ventriculi*, contain a thick, fibrous layer of cellulose surrounding the cell wall (Figure 15.21b). The cellulose layers of adjacent cells

become attached, and this functions as a cementing material to hold together packets of *S. ventriculi* cells.

Sarcina species can be isolated from soil, mud, feces, and stomach contents. Because of its extreme acid tolerance, *S. ventriculi* is one of only a few bacteria that can inhabit and grow in the stomach of humans and other monogastric animals. Rapid growth of *S. ventriculi* is observed in the stomach of humans suffering from certain gastrointestinal disorders, such as pyloric ulcerations. These pathological conditions retard the flow of food to the intestine and often require surgery to correct.

15.8 Firmicutes—Sporulating *Bacillales* and *Clostridiales*

Key Genera: *Bacillus*, *Clostridium*, *Sporosarcina*

All endospore-forming bacteria are gram-positive species of *Bacillales* or *Clostridiales*. The ability to form endospores evolved only once in a common ancestor of the *Bacillales*, *Clostridiales*, and *Lactobacillales* (Figure 15.17). However, many *Bacillales* and *Clostridiales* and the entire order *Lactobacillales* are unable to form endospores. The capacity to make endospores requires many genes (Sections 2.16 and 7.11) and has not been acquired by horizontal gene transfer. It thus appears that the phylogenetic distribution of endospores has seen many cases where the capacity to form endospores has been lost during the course of evolution.

Endospore-forming bacteria (Table 15.4) are distinguished on the basis of cell morphology, shape and cellular position of the endospore (Figure 15.22), relationship to O₂, and energy metabolism. The two genera about which most is known are *Bacillus*, species of which are aerobic or facultatively aerobic, and *Clostridium*, which contains species that are obligately anaerobic and fermentative. All endospore-forming bacteria are ecologically related because they are found in nature primarily in soil. Even those species that are pathogenic to humans or other animals

are primarily saprophytic soil organisms and infect animals only incidentally. Indeed, the ability to produce endospores should be advantageous for a soil microorganism because soil is a highly variable environment in terms of nutrient levels, temperature, and water activity.

Endospore-forming bacteria can be selectively isolated from soil, food, dust, and other materials by heating the sample to 80°C for 10 min, a treatment that effectively kills vegetative cells while any endospores present remain viable. Streaking such heat-treated samples on plates of the appropriate medium and incubating either aerobically or anaerobically selectively yields species of *Bacillus* or *Clostridium*, respectively.

Bacillus and *Paenibacillus*

A list of representatives in the *Bacillus* group is shown in Table 15.5. Species of *Bacillus* and *Paenibacillus* grow well on defined media containing any of a number of carbon sources. Many bacilli produce extracellular hydrolytic enzymes that break down complex polymers such as polysaccharides, nucleic acids, and lipids, permitting the organisms to use these products as carbon sources and electron donors. Many bacilli produce antibiotics, including bacitracin, polymyxin, tyrocidine, gramicidin, and cireculin. In most cases the antibiotics are released when the culture enters the stationary phase of growth and is committed to sporulation.

Several bacilli, most notably *Paenibacillus popilliae* and *Bacillus thuringiensis*, produce toxic insecticidal proteins. *P. popilliae* causes a fatal condition called milky disease in Japanese beetle larvae and larvae of closely related beetles of the family *Scarabaeidae*. *B. thuringiensis* causes a fatal disease of many different groups of insects. Both of these insect pathogens form a crystalline protein during sporulation called the *parasporal body*, which

is deposited within the sporangium but outside the endospore proper (Figure 15.23). In *B. thuringiensis*, the parasporal body is a protoxin that is converted to a toxin in the insect gut. The toxin binds to specific receptors in the intestinal epithelial cells of certain insects and induces pore formation that causes leakage of the host cell cytoplasm followed by lysis. Diverse strains of *B. thuringiensis* can make different types of toxin that have specificity for different groups of insects. Endospore preparations derived from *B. thuringiensis* and *P. popilliae* are commercially available as biological insecticides.

The *cry* genes that encode crystal proteins have been isolated from several *B. thuringiensis* strains. The genes for the *B. thuringiensis* crystal protein (known commercially as “Bt toxin”) have been introduced into genetically modified crops (e.g., maize, soybeans, and cotton) to render the plants resistant to insects. These genetically modified “Bt crops” are used widely around the world. Genetically altered Bt toxins have also been developed by genetic engineering to help increase toxicity and reduce resistance (Section 11.13).

Clostridium

Clostridia lack a respiratory chain, and so unlike *Bacillus* species, they obtain ATP by substrate-level phosphorylation. Many anaerobic energy-yielding mechanisms are known in the clostridia (Section 13.13). Indeed, the separation of the genus *Clostridium* into subgroups is based primarily on these properties and on the fermentable substrate used (Table 15.6). A number of clostridia are *saccharolytic* and ferment sugars, producing butyric acid as a major end product. Some of these also produce acetone and butanol, such as *Clostridium pasteurianum*, which is also a vigorous nitrogen-fixing bacterium.

One group of clostridia including the species *C. thermocellum*, *C. cellulolyticum*, and *C. cellulovorans* ferments cellulose with the formation of acids and alcohols. These species are likely the major organisms decomposing cellulose in anoxic environments such as the rumen and sediments. Cellulolytic clostridia possess *cellulosomes*, a complex multienzyme structure found on the outer surface of the

cell wall. The cellulosome binds insoluble cellulose and degrades it into soluble products that are transported into the cytoplasm and metabolized by the cell. This cellulosome mechanism is common to bacteria that are able to degrade cellulose anaerobically.

Another group of clostridia are *proteolytic* and conserve energy from the fermentation of amino acids. Some species ferment individual amino acids, but others ferment only amino acid pairs. The products of amino acid fermentation are typically acetate, butyrate, CO₂, and H₂. The coupled catabolism of an amino acid pair is called a *Stickland reaction*; for example, *Clostridium sporogenes* ferments glycine plus alanine. In the Stickland reaction, one amino acid functions as the electron donor and is oxidized, whereas the other is the electron acceptor and is reduced (☞ Figure 13.34). Many of the products of amino acid fermentation by clostridia are foul-smelling substances, and the odor that results from putrefaction is mainly the result of clostridial action. In addition to butyric acid, other odoriferous compounds produced are isobutyric acid, isovaleric acid, caproic acid, hydrogen sulfide, methylmercaptan (from sulfur amino acids), cadaverine (from lysine), putrescine (from ornithine), and ammonia.

The main habitat of clostridia is the soil, where they live primarily in “pockets” made anoxic by facultative or obligately aerobic bacteria. In addition, a number of clostridia inhabit the anoxic environment of the mammalian intestinal tract. Several clostridia are capable of causing severe diseases in humans, as will be discussed in Sections 23.9 and 30.9. For example, botulism is caused by *Clostridium botulinum*, tetanus by *Clostridium tetani*, and gas gangrene by *Clostridium perfringens* and a number of other clostridia, both sugar and amino acid fermenters. These pathogenic clostridia seem in no way unusual metabolically but are distinct in that they produce specific toxins or, in those causing gas gangrene, a group of toxins. *C. perfringens* and related species can also cause gastroenteritis in humans and domestic animals (☞ Section 31.9), and botulism outbreaks are not uncommon in birds such as ducks and a variety of other animals.

Sporosarcina

The genus *Sporosarcina* (Figure 15.24) is unique among endospore formers because cells are cocci instead of rods. *Sporosarcina* consists of strictly aerobic spherical to oval cells that divide

in two or three perpendicular planes to form tetrads or packets of eight or more cells. The major species is *Sporosarcina ureae*. This bacterium can be enriched from soil by plating dilutions of a pasteurized soil sample on alkaline nutrient agar supplemented with 8% urea and incubating in air. Most soil bacteria are strongly inhibited by as little as 2% urea. However, *S. ureae* tolerates this, catabolizing urea to CO₂ and ammonia (NH₃), which dramatically raises the pH. *S. ureae* is remarkably alkaline-tolerant and can be grown in media up to pH 10, and this feature can be used to advantage in its enrichment from soil.

15.9 Tenericutes: The Mycoplasmas

Key Genera: *Mycoplasma*, *Spiroplasma*

The *Tenericutes*, which contain the single class *Mollicutes*, are bacteria that lack cell walls (*mollis* is Latin for “soft”) and are some of the smallest organisms known. This group is often called the *mycoplasmas* because *Mycoplasma*, a notable genus containing human pathogens, is the best-characterized genus in the phylum (Table 15.7).

Although they do not stain gram-positively (because they lack cell walls), mycoplasmas are phylogenetically related to the *Firmicutes*. Mycoplasmas typically live in close association with animal and plant hosts and this may eliminate the need for a gram-positive cell wall. These organisms also have small genomes (ranging in size from 600 to 2200 kilobase pairs), a characteristic common to obligate symbionts (☞ Sections 6.5 and 22.9).

Properties of Mycoplasmas

The absence of cell walls in mycoplasmas has been confirmed by electron microscopy and chemical analyses, which show that peptidoglycan is absent. Mycoplasmas resemble protoplasts (bacteria treated to remove their cell walls), but they are more resistant to osmotic lysis and are able to survive conditions under which protoplasts lyse. This ability to resist osmotic lysis is at least partially determined by the presence of sterols, which make the cytoplasmic membranes of mycoplasmas more stable than that of other bacteria. Indeed, some mycoplasmas require sterols in their growth media, and this sterol requirement can aid in the classification of mycoplasmas (Table 15.7).

In addition to sterols, certain mycoplasmas contain compounds called *lipoglycans* (Table 15.7). Lipoglycans are long-chain heteropolysaccharides covalently linked to membrane lipids and embedded in the cytoplasmic membrane of many mycoplasmas. Lipoglycans in some ways resemble the lipopolysaccharides in the outer membrane of gram-negative bacteria, except that they lack the lipid A backbone (☞ Section 2.11). Lipoglycans function to help stabilize the cytoplasmic membrane and have also been identified as facilitating attachment of mycoplasmas to cell surface receptors of animal cells.

Growth of Mycoplasmas

Mycoplasmas can be grown in the laboratory and are small and pleiomorphic cells. A single culture may exhibit small coccoid elements; larger, swollen forms; and filamentous forms, often highly branched (Figure 15.25). The small coccoid elements (0.2–0.3 µm in size) are among the smallest of free-living cells (Section 2.6). The mode of growth of mycoplasmas differs in liquid and agar cultures. On agar the organisms tend to grow so that they become embedded in the medium. These colonies show a characteristic “fried-egg” appearance consisting of a dense central core that penetrates downward into the agar, surrounded by a circular spreading area that is lighter in color (Figure 15.26). As would be expected of cells lacking cell walls, growth of *Mollicutes* is not inhibited by antibiotics that inhibit cell wall synthesis. However,

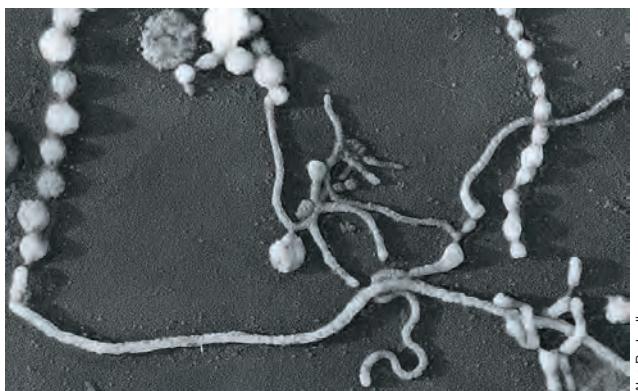

Figure 15.25 *Mycoplasma mycoides*. Metal-shadowed transmission electron micrograph. Note the coccoid and hyphalike elements. The average diameter of cells in chains is about 0.5 µm.

mycoplasmas are as sensitive as most *Bacteria* to antibiotics whose targets are other than the cell wall.

Media for the culture of mycoplasmas are typically quite complex. For many species, growth is poor or absent even in complex yeast extract–peptone–beef heart infusion media. Fresh serum or ascitic fluid (peritoneal fluid) is needed as well to provide unsaturated fatty acids and sterols. Some mycoplasmas can be cultivated on relatively simple culture media, however, and even defined media have been developed for some species. Most mycoplasmas use carbohydrates as carbon and energy sources and require vitamins, amino acids, purines, and pyrimidines as growth factors. The energy metabolism of mycoplasmas is variable; some species are strictly aerobic, whereas others are facultative aerobes or obligate anaerobes (Table 15.7).

Spiroplasma

The genus *Spiroplasma* consists of helical or spiral-shaped *Mollicutes*. Amazingly, although they lack a cell wall and flagella, spiroplasmas are motile by means of a rotary (screw) motion or a slow undulation. Intracellular fibrils that are thought to play a role in motility have been demonstrated. The organism has been isolated from ticks, the hemolymph (Figure 15.27) and gut of insects, vascular plant fluids and insects that feed on these fluids, and the surfaces of flowers and other plant parts. For example, *Spiroplasma citri* has been isolated from the leaves of citrus plants, where it causes a disease called citrus stubborn disease, and from corn plants suffering from corn stunt disease. A number of

other mycoplasma-like organisms have been detected in diseased plants by electron microscopy, which indicates that a large group of plant-associated *Mollicutes* may exist. Some species of *Spiroplasma* are known that cause insect diseases, such as honeybee spiroplasmosis and lethargy disease of the beetle *Melolontha*.

of the cell wall. Localized rupture of this outer layer on only one side of the cell results in a bending of the two cells away from the ruptured side (Figure 15.29) and thus development of V-shaped forms.

The main genera of coryneform bacteria are *Corynebacterium* and *Arthrobacter*. The genus *Corynebacterium* consists of an extremely diverse group of bacteria, including animal and plant pathogens and saprophytes. Some species, such as *Corynebacterium diphtheriae*, are pathogenic (diphtheria, ↗ Section 29.3). The genus *Arthrobacter*, consisting primarily of soil organisms, is distinguished from *Corynebacterium* on the basis of a developmental cycle involving conversion from rod to coccus and back to rod again (Figure 15.30). However, some coryneform bacteria are pleiomorphic and form coccoid cells during growth, and so the distinction between the two genera on the basis of life cycle is not

absolute. The *Corynebacterium* cell frequently has a swollen end, so it has a club-shaped appearance, whereas *Arthrobacter* species are less commonly club-shaped.

Along with the *Acidobacteria* (Section 15.21), species of *Arthrobacter* are among the most common of all soil bacteria. They are remarkably resistant to desiccation and starvation, despite the fact that they do not form spores or other resting cells. Arthrobacters are a heterogeneous group that have considerable nutritional versatility, and strains have been isolated that decompose herbicides, caffeine, nicotine, phenols, and other unusual organic compounds.

Propionic Acid Bacteria

The **propionic acid bacteria** (genus *Propionibacterium*) were first discovered in Swiss (Emmentaler) cheese, where their fermentative production of CO₂ produces the characteristic holes and the propionic acid they produce is at least partly responsible for the unique flavor of the cheese. The bacteria in this group are gram-positive anaerobes that ferment lactic acid, carbohydrates, and polyhydroxy alcohols, producing primarily propionic acid, acetic acid, and CO₂ (Section 13.13).

The fermentation of lactate is of interest because lactate itself is an end product of fermentation for many bacteria (Section 15.6). The starter culture in Swiss cheese manufacture consists of a mixture of homofermentative streptococci and lactobacilli, plus propionic acid bacteria. The homofermentative organisms carry out the initial fermentation of lactose to lactic acid during formation of the curd (protein and fat). After the curd has been drained, the propionic acid bacteria develop rapidly. The eyes (or holes) characteristic of Swiss cheese are formed by the accumulation of CO₂, the gas diffusing through the curd and gathering at weak points. The propionic acid bacteria are thus able to obtain energy anaerobically from a product that other bacteria have produced by fermentation. This metabolic strategy is called a *secondary fermentation*.

Propionate is also formed in the fermentation of succinate by the bacterium *Propionigenium*. This organism is phylogenetically and ecologically unrelated to *Propionibacterium*, but energetic aspects of its fermentation are of considerable interest. We discussed the mechanism of the *Propionigenium* fermentation in Section 13.14.

15.11 Actinobacteria: *Mycobacterium*

Key Genus: *Mycobacterium*

The genus *Mycobacterium* contains several notable human pathogens, chief among them *Mycobacterium tuberculosis*, the cause of tuberculosis (Section 29.4). Species are rod-shaped bacteria that at some stage of their growth cycle possess the distinctive staining property called **acid-fastness**. This property is due to the presence of unique lipids called *mycolic acids*, found only in species of the genus *Mycobacterium*, on the surface of the mycobacterial cell. Mycolic acids are a group of complex branched-chain hydroxylated lipids (Figure 15.31a) covalently bound to peptidoglycan in the cell wall; the complex gives the cell surface a waxy, hydrophobic consistency.

Because of their waxy surface, mycobacteria do not stain well with Gram stain. A mixture of the red dye basic fuchsin and phenol is used in the acid-fast (Ziehl–Neelsen) stain. The stain is driven into the cells by slow heating, and the role of the phenol is to enhance penetration of the fuchsin into the lipids. After washing in distilled water, the preparation is decolorized with acid alcohol and counterstained with methylene blue. Cells of acid-fast organisms stain red, whereas the background and non-acid-fast organisms appear blue (Figure 29.15a).

Mycobacteria are somewhat pleomorphic and may undergo branching or even filamentous growth. However, in contrast to the filaments of the actinomycetes (Section 15.12), the filaments of the mycobacteria do not form a true mycelium. Mycobacteria can be separated into two major groups: slow-growing species (e.g., *M. tuberculosis*, *M. avium*, *M. bovis*, and *M. gordonae*) and fast-growing species (e.g., *M. smegmatis*, *M. phlei*, *M. chelonae*, *M. parafuruitum*). *Mycobacterium tuberculosis* is a typical slow

(b) A colony of virulent *M. tuberculosis* at an early stage, showing the characteristic cordlike growth. Individual cells are about 0.5 μm in diameter. grower, and visible colonies are produced from dilute inoculum only after days to weeks of incubation. When growing on solid media, mycobacteria form tight, compact, often wrinkled colonies (Figure 15.32). This colony morphology is probably due to the high lipid content and hydrophobic nature of the cell surface, which facilitates cells sticking together.

For the most part, mycobacteria have relatively simple nutritional requirements. Most species can grow aerobically in a simple mineral salts medium with ammonium as the nitrogen source and glycerol or acetate as the sole carbon source and electron donor. Growth of *M. tuberculosis* is more difficult and is stimulated by lipids and fatty acids. The virulence of *M. tuberculosis* cultures has been correlated with the formation of long, cordlike structures (Figure 15.32b) that form due to side-to-side aggregation and intertwining of long chains of bacteria. Growth in cords reflects the presence of a characteristic glycolipid, the *cord factor*, on the cell surface (Figure 15.33). The pathogenesis of tuberculosis, along with the related mycobacterial disease leprosy, is discussed in Section 29.4.

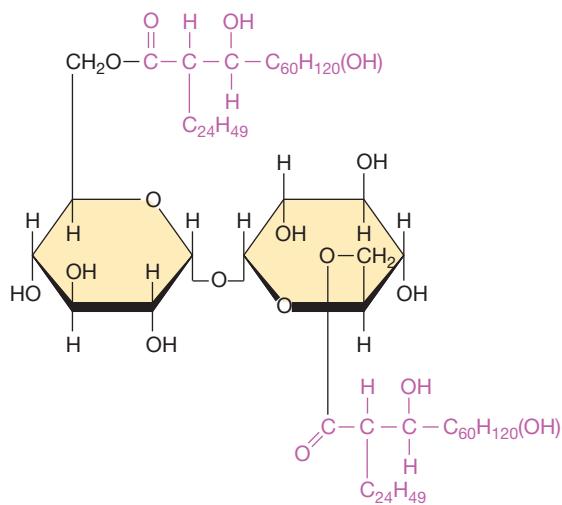

Figure 15.33 Structure of cord factor, a mycobacterial glycolipid: 6,6'-di-O-mycetyl trehalose. The two identical long-chain dialcohol groups are shown in purple.

Some mycobacteria produce yellow carotenoid pigments (Figure 15.32c), and pigmentation can aid in identification. Mycobacteria can either be nonpigmented (e.g., *M. tuberculosis*, *M. bovis*, *M. smegmatis*, *M. chelonae*); or can form pigment only when cultured in light, a property called *photochromogenesis* (e.g., *M. parafuruitum*); or can form pigment even when cultured in the dark, a property called *scotochromogenesis* (e.g., *M. gordonaiae*, *M. phlei*). Photochromogenesis is triggered by the blue region of the visible spectrum and is characterized by the photoinduction of one of the early enzymes in carotenoid biosynthesis. As with other carotenoid-containing bacteria, it is likely that carotenoids protect mycobacteria against oxidative damage from singlet oxygen ([Section 5.16](#)).

15.12 Filamentous Actinobacteria: *Streptomyces* and Relatives

Key Genera: *Streptomyces*, *Actinomyces*, *Nocardia*

The **actinomycetes** are a large group of phylogenetically related, filamentous and aerobic gram-positive *Bacteria* common in soils. Many actinomycetes have a characteristic developmental cycle that culminates in the production of desiccation-resistant spores. Filaments elongate from their ends and form branching *hyphae*. Hyphal growth results in a network of filaments called a *mycelium* (Figure 15.34), analogous to that formed by filamentous fungi ([Section 17.9](#)). When nutrients are depleted, the mycelium forms aerial hyphae that differentiate into spores that allow for survival and dispersal. We focus here on the genus *Streptomyces*, the most important genus in this group.

Streptomyces

Over 500 species of *Streptomyces* are recognized. *Streptomyces* filaments are typically 0.5–1.0 μm in diameter and of indefinite

length, and often lack cross-walls in the vegetative phase. *Streptomyces* grow at the tips of the filaments and may branch often. Thus, the vegetative phase consists of a complex, tightly woven matrix, resulting in a compact, convoluted mycelium and subsequent colony. As the colony ages, characteristic aerial filaments called *sporophores* are formed, which project above the surface of the colony and give rise to spores (Figure 15.35).

Streptomyces spores, called *conidia*, are quite distinct from the endospores of *Bacillus* and *Clostridium*. Unlike the elaborate cellular differentiation that leads to the formation of an endospore, conidia are produced by the formation of cross-walls in the multinucleate

Differences in the shape and arrangement of aerial filaments and spore-bearing structures of various species are among the fundamental features used in classifying the *Streptomyces* species (Figure 15.37). The conidia and sporophores are often pigmented and contribute a characteristic color to the mature

colony (Figure 15.38). The dusty appearance of the mature colony, its compact nature, and its color make detection of *Streptomyces* colonies on agar plates relatively easy (Figure 15.38b).

Ecology and Isolation of *Streptomyces*

Although a few streptomycetes are aquatic, they are primarily soil organisms. In fact, the characteristic earthy odor of soil is caused by the production by streptomycetes of a series of complex metabolites all called *geosmin*. Alkaline to neutral soils are more favorable for the development of *Streptomyces* than are acid soils. Moreover, higher numbers of *Streptomyces* are found in well-drained soils (such as sandy loams or soils covering limestone), where conditions are more likely to be aerobic, than in waterlogged soils, which quickly become anoxic.

Isolation of *Streptomyces* from soil is relatively easy: A suspension of soil in sterile water is diluted and spread on selective agar medium, and the plates are incubated aerobically at 25°C (Figure 15.38). Media selective for *Streptomyces* contain mineral salts plus polymeric substances such as starch or casein as organic nutrients. Streptomycetes typically produce extracellular hydrolytic enzymes that permit utilization of polysaccharides (starch, cellulose, and hemicellulose), proteins, and fats, and some strains can use hydrocarbons, lignin, tannin, and other polymers. After incubation for 5–7 days in air, the plates are examined for the presence of the characteristic *Streptomyces* colonies (Figure 15.38), and spores from colonies can be restreaked to isolate pure cultures.

(b) The red-colored antibiotic undecylprodigiosin is being excreted by colonies of *S. coelicolor*.

Antibiotics of *Streptomyces*

Perhaps the most striking physiological property of the streptomycetes is the extent to which they produce *antibiotics* (Table 15.8). Evidence for antibiotic production is often seen on the agar plates used in their initial isolation: Adjacent colonies of other bacteria show zones of inhibition (Figure 15.39a).

About 50% of all *Streptomyces* isolated have been found to be antibiotic producers. Over 500 distinct antibiotics are produced by streptomycetes and many more are suspected; most of these have been identified chemically (Figure 15.39b). Some species produce more than one antibiotic, and often the several antibiotics produced by one organism are chemically unrelated. Although an antibiotic-producing organism is resistant to its own antibiotics, it usually remains sensitive to antibiotics

produced by other streptomycetes. Many genes are required to encode the enzymes for antibiotic synthesis, and because of this, the genomes of *Streptomyces* species are typically quite large (8 megabase pairs and larger; ↗ Table 6.1). More than 60 streptomycete antibiotics have been used in human and veterinary medicine, and some of the most commonly used are listed in Table 15.8.

Ironically, despite the extensive research done on antibiotic-producing streptomycetes by the antibiotic industry and the fact that *Streptomyces* antibiotics are a multibillion-dollar-a-year industry, the ecology of *Streptomyces* remains poorly understood. The interactions of these organisms with other bacteria and the ecological rationale for antibiotic production remains an important topic about which we know very little. One hypothesis for

why *Streptomyces* species produce antibiotics is that antibiotic production, which is linked to sporulation (a process itself triggered by nutrient depletion), might be a mechanism to inhibit the growth of other organisms competing with *Streptomyces* cells for limiting nutrients. This would allow the *Streptomyces* to complete the sporulation process and form a dormant structure that would increase their chances of survival.

III • Bacteroidetes

The phylum *Bacteroidetes* contains more than 700 characterized species spread across four orders: *Bacteroidales*, *Cytophagales*, *Flavobacteriales*, and *Sphingobacteriales* (Figure 15.40). The *Bacteroidetes* are gram-negative nonsporulating rods; species are typically saccharolytic and can be aerobic or fermentative, including obligate aerobes, facultative aerobes, and obligate anaerobes. Gliding motility (↗ Section 2.18) is widespread in the phylum, though many species are nonmotile and a few are motile by flagella. The genus *Bacteroides* has been particularly well studied as these organisms are a major component of the microbial community in the human gut.

15.13 *Bacteroidales*

Key Genus: *Bacteroides*

The order *Bacteroidales* primarily contains obligately anaerobic fermentative species. The type genus is *Bacteroides*, which contains species that are saccharolytic, fermenting sugars or proteins

Bacteroidetes

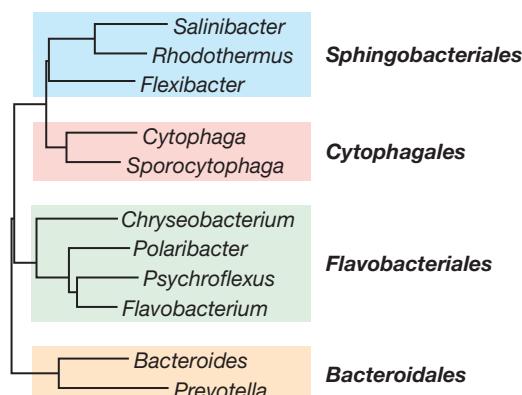

Figure 15.40 Major orders of *Bacteroidetes*. The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Bacteroidetes*. Order names are shown in bold.

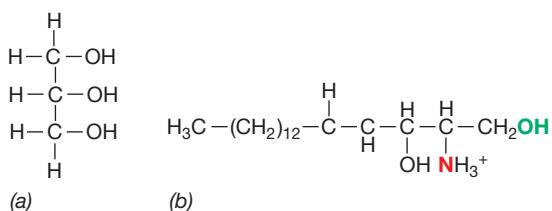

Figure 15.41 Sphingolipids. Comparison of (a) glycerol with (b) sphingosine. In sphingolipids, characteristic of *Bacteroides* species, sphingosine is the esterifying alcohol; a fatty acid is bonded by peptide linkage through the N atom (shown in red), and the terminal —OH group (shown in green) can be any of a number of compounds including phosphatidylcholine (sphingomyelin) or various sugars (cerebrosides and gangliosides).

(depending on the species) to acetate and succinate as major fermentation products. *Bacteroides* are normally commensals, found in the intestinal tract of humans and other animals. In fact, *Bacteroides* species are the numerically dominant bacteria in the human large intestine, where measurements have shown that 10^{10} – 10^{11} prokaryotic cells are present per gram of feces (🔗 Section 22.6). However, species of *Bacteroides* can occasionally be pathogens and are the most important anaerobic bacteria associated with human infections such as *bacteremia* (bacteria in the blood).

Bacteroides thetaiotaomicron is one of the most prominent species of *Bacteroides* found in the lumen of the large intestine. *B. thetaiotaomicron* specializes in the degradation of complex polysaccharides. A majority of its genome is devoted to making enzymes that degrade polysaccharides. The diversity and number of genes for carbohydrate metabolism found in its genome far exceeds those found in any other bacterial species. *B. thetaiotaomicron* produces many enzymes that are not encoded by the human genome and thus it vastly increases the diversity of plant polymers that can be degraded in the human digestive tract.

Species of *Bacteroides* are unusual in that they are one of the few groups of bacteria to synthesize a special type of lipid called **sphingolipid** (Figure 15.41), a collection of lipids characterized by the long-chain amino alcohol sphingosine in place of glycerol in the lipid backbone. Sphingolipids such as sphingomyelin, cerebrosides, and gangliosides are common in mammalian tissues, especially in the brain and other nervous tissues, but rare in most bacteria. The production of sphingolipids can be found in a number of other genera in the phylum *Bacteroidetes* including *Flectobacillus*, *Prevotella*, *Porphyromonas*, and *Sphingobacterium*.

15.14 *Cytophagales*, *Flavobacteriales*, and *Sphingobacteriales*

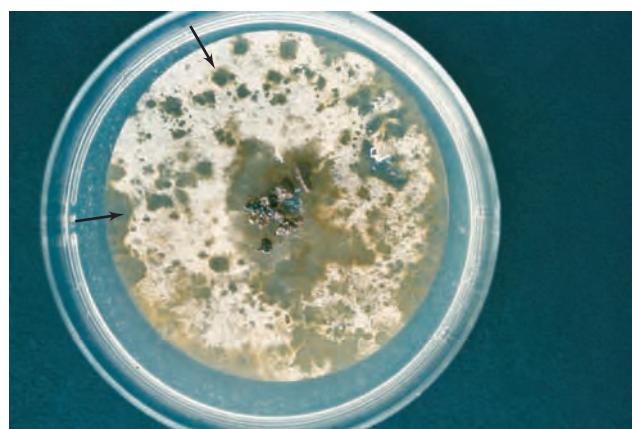

Key Genera: *Cytophaga*, *Flavobacterium*, *Flexibacter*

Cytophagales

The order *Cytophagales* (Figure 15.40) contains almost exclusively obligate aerobes, though some species have limited fermentative capabilities. Cells are typically long, slender, gram-negative rods, often containing pointed ends, and move by gliding (Figure 15.42).

(a)

(b)

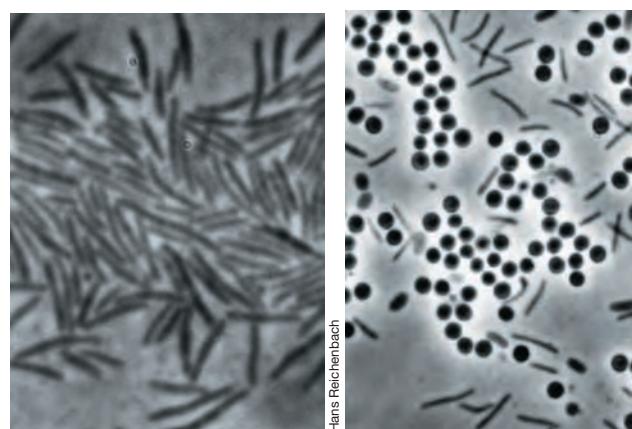

Figure 15.42 *Cytophaga* and *Sporocytophaga*. (a) Streak of an agarolytic marine *Cytophaga* hydrolyzing agar in a Petri dish. (b) Colonies of *Sporocytophaga* growing on cellulose. Note the clearing zones (arrows) where the cellulose has been degraded. (c) Phase-contrast micrograph of cells of *Cytophaga hutchinsonii* grown on cellulose filter paper (cells are about 1.5 µm in diameter). (d) Phase-contrast micrograph of the rod-shaped cells and spherical microcysts of *Sporocytophaga myxococcoides* (cells are about 0.5 µm and microcysts about 1.5 µm in diameter). Although *Sporocytophaga* microcysts are only slightly more heat-tolerant than vegetative cells, they are extremely resistant to desiccation and thus help the organism survive dry periods in soil.

Cytophagas specialize in the degradation of complex polysaccharides. They are widespread in oxic soils and freshwaters, where they probably account for much of the bacterial cellulose digestion.

Cellulose decomposers can easily be isolated by placing small crumbs of soil on pieces of cellulose filter paper laid on the surface of mineral salts agar. The bacteria attach to and digest the cellulose fibers, forming spreading colonies (Figure 15.42c).

Cellulose degradation by cytophagids can proceed by two different mechanisms. The typical mechanism is the free cellulase mechanism in which cells secrete extracellular enzymes called *exoenzymes* that degrade insoluble cellulose outside of the cell. A complex mixture of enzymes is secreted including *processive endocellulases*, which cleave *internal* β -1,4 glucosidic bonds, and *processive exocellulases*, which cleave *terminal* β -1,4 glucosidic bonds, releasing cellobiose. These *exoenzymes* degrade insoluble cellulose into soluble polysaccharides and disaccharides that can be readily assimilated by cells. *Cytophaga hutchinsonii* does not produce processive cellulases, and its degradation of cellulose likely requires physical contact of cellulose fibers with cellulase enzymes located on the outer surface of its cell wall.

The genus *Cytophaga* contains species that can degrade not only cellulose (Figure 15.42c) but also agar (Figure 15.42a) and chitin. In pure culture *Cytophaga* can be grown on agar containing embedded cellulose fibers (Figure 15.42b). The related genus *Sporocytophaga* is similar to *Cytophaga* in morphology and physiology, but the cells form resting spherical structures called *microcysts* (Figure 15.42d), similar to those produced by some fruiting myxobacteria (☞ Section 14.19).

Several species of *Cytophaga* are fish pathogens and can cause serious problems in the cultivated fish industry. Two of the most important diseases are *columnaris disease*, caused by *Cytophaga columnaris*, and *cold-water disease*, caused by *Cytophaga psychrophila*. Both diseases preferentially affect stressed fish, such as those living in waters receiving pollutant discharges or living in high-density confinement situations such as fish hatcheries and aquaculture facilities. Infected fish show tissue destruction, frequently around the gills, probably from proteolytic activities of the *Cytophaga* pathogen.

Flavobacteriales and Sphingobacteriales

Flavobacteriales and *Sphingobacteriales* (Figure 15.40) typically contain aerobic and facultatively aerobic chemoorganotrophs. Like most *Bacteroidetes*, these organisms are gram-negative rods, and are saccharolytic with many species motile by gliding. Species

are found widely in soils and in aquatic habitats, where they typically degrade complex polysaccharides.

Flavobacteriales can be particularly abundant in marine waters including aquatic systems in polar environments. *Flavobacterium* species are primarily found in aquatic habitats, both freshwater and marine, as well as in foods and food-processing plants. Most species are obligate aerobes, though some species are able to reduce nitrate in an anaerobic respiration. Flavobacteria frequently produce yellow pigments and are generally saccharophilic; most can also degrade starch and proteins. Flavobacteria are rarely pathogenic; however, one species, *Flavobacterium meningosepticum*, has been implicated in cases of infant meningitis, and several fish pathogens are also known.

Some *Flavobacteriales* are psychrophilic or psychrotolerant (☞ Section 5.12). These include, in particular, the genera *Polaribacter* and *Psychroflexus*, organisms commonly isolated from cold environments, especially permanently cold environments such as polar waters and sea ice. Many related genera are also capable of good growth below 20°C and can thus be agents of food spoilage. None are pathogenic.

Sphingobacteriales are phenotypically similar to many *Flavobacteriales*. In terms of physiology, species of *Sphingobacteriales* are generally able to degrade a greater breadth of complex polysaccharides than are *Flavobacteriales*, and in this regard they resemble species of *Cytophagales*. The genus *Flexibacter* is typical of many genera of *Sphingobacteriales*. Species of *Flexibacter* differ from those of *Cytophaga* in that they usually require complex media for good growth and are unable to degrade cellulose. Cells of some *Flexibacter* species also undergo changes in cell morphology from long, gliding, threadlike filaments lacking cross-walls to short, nonmotile rods. Many flexibacteria are pigmented due to carotenoids located in their cytoplasmic membrane, or from related pigments called *flexirubins*, located in the cell's outer membrane. *Flexibacter* species are common in soil and freshwaters where they degrade polysaccharides, and none have been identified as pathogens.

IV • Chlamydiae, Planctomycetes, and Verrucomicrobia

The phyla *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia* share an ancestor and are more closely related to each other than to other bacterial phyla (Figure 15.43). These three groups contain organisms that can be found in a variety of habitats including soils, aquatic systems, and in association with eukaryotic hosts. We first consider the chlamydias, a group of small gram-negative bacteria that cause some serious human and animal diseases.

15.15 Chlamydiae

Key Genera: *Chlamydia*, *Chlamydophila*, *Parachlamydia*

The phylum *Chlamydiae* contains a single order, the *Chlamydiales*. The entire phylum consists of obligate intracellular parasites of eukaryotes. Though the species that are human pathogens have been characterized in most detail, the phylum contains diverse species that interact with a wide variety of eukaryotic hosts.

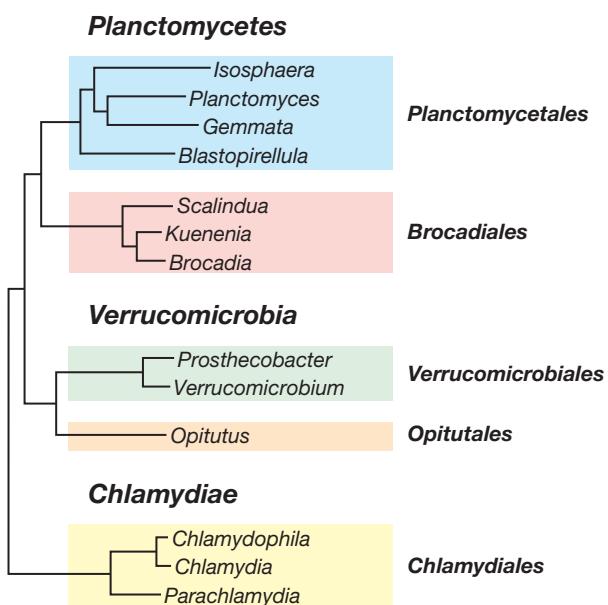

Figure 15.43 Major orders of *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*. The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*. Order names are shown in bold.

Species are typically very small cocci, approximately 0.5 μm in diameter, and display a distinctive developmental cycle. Like many obligate parasites and symbionts, the genomes of *Chlamydiae* are typically reduced, ranging in size from 550–1000 kilobase pairs (➡ Section 6.4).

Life Cycle of *Chlamydiae*

All species of *Chlamydiae* demonstrate a unique chlamydial life cycle (Figure 15.44). Two types of cells are seen in the life cycle: (1) a small, dense cell, called an *elementary body*, which is relatively resistant to drying and is the means of dispersal, and (2) a larger, less dense cell, called a *reticulate body*, which divides by binary fission and is the vegetative form.

Elementary bodies are nonmultiplying cells specialized for infectious transmission. By contrast, reticulate bodies are noninfectious forms that function only to multiply inside host cells to form a large inoculum for transmission. Unlike the rickettsias, the chlamydias are not transmitted by arthropods but are primarily airborne invaders of the respiratory system—hence the significance of resistance to drying of the elementary bodies. A dividing reticulate body can be seen in Figure 15.45. After a number of cell divisions, these vegetative cells are converted into elementary bodies that are released when the host cell disintegrates (Figure 15.44b) and can then infect other nearby host cells. Generation times of 2–3 h have been measured for reticulate bodies, considerably faster than times found for the rickettsias (Section 15.1).

Notable Genera of *Chlamydiae*

Chlamydiae are particularly well adapted to invading and colonizing eukaryotic cells, and different species can infect a diverse array of eukaryotic hosts. The species *Parachlamydia acanthamoebae* infects free-living amoebae, particularly amoebae in the genus *Acanthamoeba*. *Parachlamydia* demonstrates the typical chlamydial life cycle during infection of amoebae (Figure 15.44). Most species of *Chlamydiae* can multiply or survive within free-living

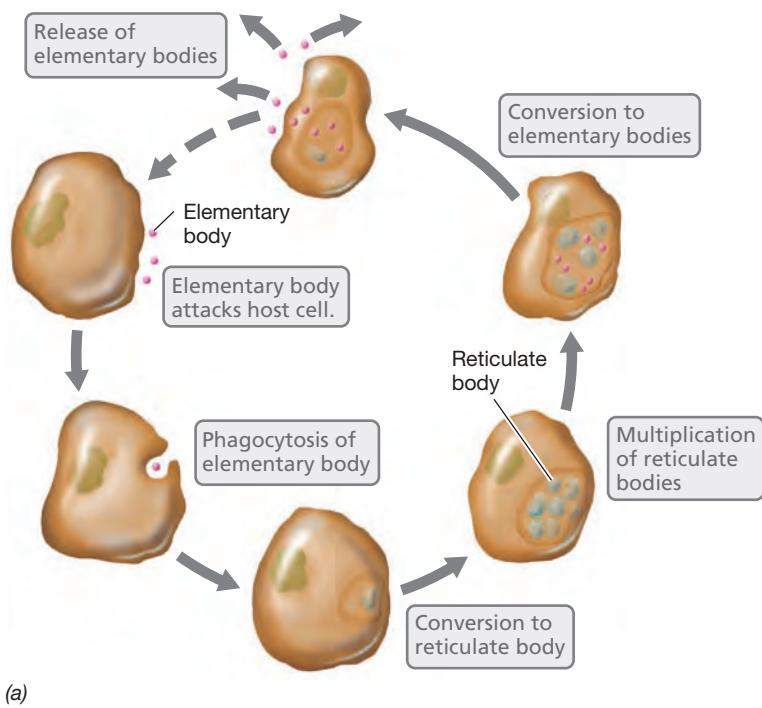

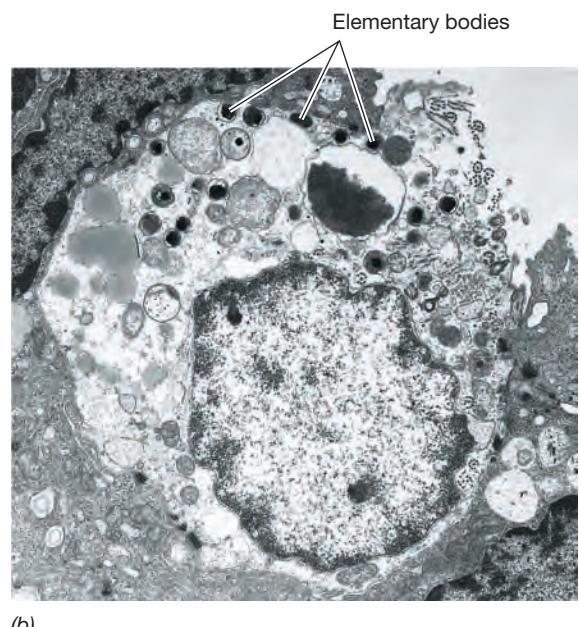

Figure 15.44 The infection cycle of a chlamydia. (a) Schematic diagram of the cycle: The entire cycle takes about 48 h. (b) Human chlamydial infection. Elementary bodies ($\sim 0.3 \mu\text{m}$ in diameter) are the infectious form and reticulate bodies ($\sim 1 \mu\text{m}$ in diameter) are the multiplying form. An infected fallopian tube cell is bursting, releasing mature elementary bodies.

amoebae, and these hosts may be important for the survival and dispersal of *Chlamydiae* in nature. A diversity of 16S rRNA gene sequences from *Chlamydiae* can be detected in natural environments, suggesting that these organisms are widespread and that many of their natural hosts have yet to be identified. While free-living amoebae are the natural hosts for *P. acanthamoebiae*, this species can also infect humans, although only weakly compared with *Chlamydiae* whose natural hosts are human.

The best-studied human pathogens are found in the genera *Chlamydia* and *Chlamydophila*. Several species are recognized within these genera: *Chlamydophila psittaci*, the causative agent of the disease psittacosis; *Chlamydia trachomatis*, the causative agent of trachoma and a variety of other human diseases; and *Chlamydophila pneumoniae*, the cause of some respiratory syndromes. Psittacosis is an epidemic disease of birds that is occasionally transmitted to humans and causes pneumonia-like symptoms. Trachoma, a debilitating disease of the eye characterized by vascularization and scarring of the cornea, is the leading cause of blindness in humans. Other strains of *C. trachomatis* infect the genitourinary tract, and chlamydial infections are currently one of the leading sexually transmitted diseases (Section 29.13).

Molecular and Metabolic Properties

The chlamydias are among the most biochemically limited of all known *Bacteria*. Indeed, their genomes, approximately 1 Mbp in size, appear to be even more biosynthetically limited than those of the rickettsias, the other group of obligate intracellular parasites known among the *Bacteria* (Section 15.1). Interestingly, the *C. trachomatis* genome lacks a gene encoding the protein FtsZ, a key protein in septum formation during cell division (Section 5.2) and thought to be indispensable for growth of all prokaryotes. The cell wall of *C. trachomatis* also appears to lack peptidoglycan, although genes for peptidoglycan biosynthesis are present in its genome. Interestingly, some genes in *C. trachomatis* are distinctly eukaryotic, indicating horizontal transfer from host to bacterium; these genes may encode functions that facilitate the pathogenic lifestyle of *C. trachomatis* (Section 29.13). In sum, the chlamydias appear to have evolved with an efficient and effective survival strategy including parasitizing the resources of the host and producing resistant cell forms for transmission.

15.16 Planctomycetes

Key Genera: *Planctomyces*, *Blastopirellula*, *Gemmata*, *Brocadia*

The phylum *Planctomycetes* contains several morphologically unique bacteria found primarily in two orders, *Planctomycetales* and *Brocadiales* (Figure 15.43).

Planctomycetes are gram-negative bacteria and many divide by budding. They often have stalks or appendages and their cells are arranged in rosettes. *Planctomycetes* are unusual among bacteria because their cell walls lack peptidoglycan and are of an S-layer type (Section 2.12). As expected of organisms lacking peptidoglycan, these bacteria are resistant to antibiotics such as penicillin and cephalosporin that disrupt peptidoglycan synthesis. Another remarkable feature of *Planctomycetes* is that they often contain intracellular compartments that resemble the organelles of eukaryotes.

Compartmentalization in *Planctomycetes*

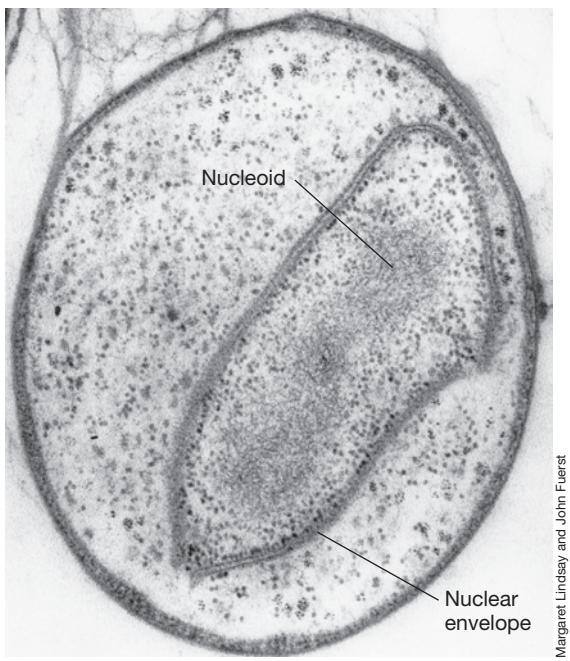

We learned in Section 1.2 of the major structural differences between prokaryotic and eukaryotic cells. In particular, eukaryotes have a membrane-enclosed nucleus whereas in prokaryotes, DNA supercoils and compacts to form the nucleoid present in the cytoplasm. However, *Planctomycetes* are unique among all known prokaryotes in that they show extensive cell compartmentalization, including in some cases a membrane-enclosed nuclear structure.

All *Planctomycetes* produce a structure enclosed by a nonunit membrane and called a *pirellulosome*; this structure contains the nucleoid, ribosomes, and other necessary cytoplasmic components. But in some *Planctomycetes*, for example, in the bacterium *Gemmata* (Figure 15.46), the nucleoid itself is surrounded by a “nuclear envelope” consisting of a double membrane layer as occurs in the nuclear membrane of eukaryotes. DNA in *Gemmata* remains in a covalently closed, circular, and supercoiled form, typical of prokaryotes (Section 4.3), but it is highly condensed and remains partitioned from the remaining cytoplasm by a true unit membrane (Figure 15.46).

Another interesting compartment is the *anammoxosome*, found in species of the *Brocadiales* including *Brocadia anammoxidans*. This bacterium catalyzes the anaerobic oxidation of ammonia (NH_3) within the anammoxosome structure. The anammoxosome membrane is composed of unique lipids that form a rather tight seal, protecting cytoplasmic components from toxic intermediates produced during the anaerobic oxidation of ammonia (Section 13.10).

Planctomyces

Planctomyces is the best-characterized genus in the *Planctomycetes*. In Section 14.21 we considered the stalked proteobacterium *Caulobacter*. *Planctomyces* is also a stalked bacterium (Figure 15.47).

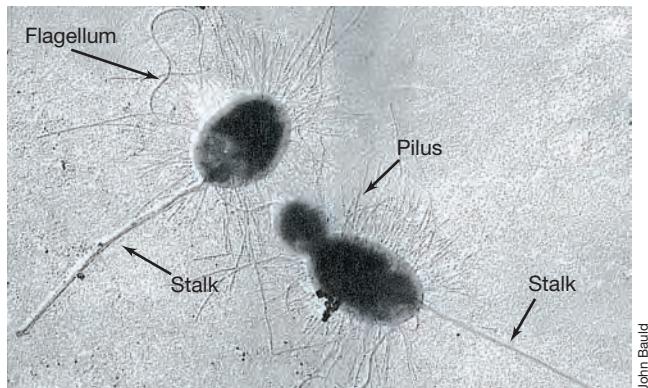

Margaret Lindsay and John Fuerst

Figure 15.46 *Gemmata*: a nucleated bacterium. Thin-section electron micrograph of a cell of *Gemmata obscuriglobus* showing the nucleoid surrounded by a nuclear envelope. The cell is about 1.5 μm in diameter.

However, unlike *Caulobacter*, the stalk of *Planctomyces* consists of protein and does not contain a cell wall or cytoplasm (compare Figure 15.47 with Figure 14.57). The *Planctomyces* stalk presumably functions in attachment, but it is a much narrower and finer structure than the prosthecal stalk of *Caulobacter*.

Like *Caulobacter* (► Figures 7.26 and 14.57), *Planctomyces* is a budding bacterium with a life cycle. Its motile swarmer cells attach to a surface, grow a stalk from the attachment point, and generate a new cell from the opposite pole by budding. This daughter cell produces a flagellum, breaks away from the attached mother cell, and begins the cycle anew. Physiologically, *Planctomyces* species are facultatively aerobic chemoorganotrophs, growing either by fermentation or respiration of sugars.

Note also the flagella (curly appendages) on each cell and the bud that is developing from the nonstalked pole of one cell.

The habitat of *Planctomyces* is primarily aquatic, both freshwater and marine, and the genus *Isosphaera* is a filamentous, gliding hot spring bacterium. The isolation of *Planctomyces* and relatives, like that of *Caulobacter*, requires dilute media. In addition, because all known members of this group lack peptidoglycan, enrichments can be made even more selective by the addition of penicillin.

15.17 Verrucomicrobia

Key Genera: *Verrucomicrobium*, *Prosthecobacter*

The phylum *Verrucomicrobia* contains at least four orders with characterized species, but most are found within the order *Verrucomicrobiales* (Figure 15.43). Species of *Verrucomicrobia* are aerobic or facultatively aerobic bacteria capable of fermenting sugars. An exception is the genus *Methylacidiphilum*, which contains aerobic methanotrophs (► Section 14.17). In addition, some *Verrucomicrobia* form symbiotic associations with protists. *Verrucomicrobia* are widespread in nature, inhabiting freshwater and marine environments as well as forest and agricultural soils. The *Verrucomicrobia* can have membrane-bound intracellular structures similar to those found in the *Planctomycetes*. The *Verrucomicrobia* typically form cytoplasmic appendages called *prosthecae* (► Section 14.21). *Verrucomicrobia* share with other prosthecate bacteria the presence of peptidoglycan in their cell walls and in this way are clearly distinct from *Planctomycetes*.

The genera *Verrucomicrobium* and *Prosthecobacter* produce two to several prosthecae per cell (Figure 15.48). Unlike cells of *Caulobacter* (► Figures 7.26 and 14.57), which contain a single prostheca and produce flagellated and nonprosthecate swarmer cells, *Verrucomicrobium* and *Prosthecobacter* divide symmetrically, and both mother and daughter cells contain prosthecae at the time of cell division. The genus name *Verrucomicrobium* derives from Greek roots meaning “warty,” which is an appropriate description

of cells of *Verrucomicrobium spinosum* with their multiple projecting prosthecae (Figure 15.48).

Species of the genus *Prosthecobacter* contain two genes that show significant homology to the genes that encode tubulin in eukaryotic cells. Tubulin is the key protein that makes up the cytoskeleton of eukaryotic cells (☞ Section 2.22). Although the important cell division protein FtsZ (☞ Section 5.2) is also a tubulin homolog, the *Prosthecobacter* proteins are structurally more

similar to eukaryotic tubulin than is FtsZ. The role of the tubulin proteins in *Prosthecobacter* is unknown since a eukaryotic-like cytoskeleton has not been observed in these organisms.

V • Hyperthermophilic Bacteria

Three phyla of hyperthermophilic bacteria cluster deep in the phylogenetic tree of *Bacteria*, near the root (Figure 15.1). Each group consists of one or two major genera, and a key physiological feature of most species is hyperthermophily—optimal growth at temperatures above 80°C (☞ Section 5.13). We begin with *Thermotoga* and *Thermodesulfobacterium*, each representative of its own lineage.

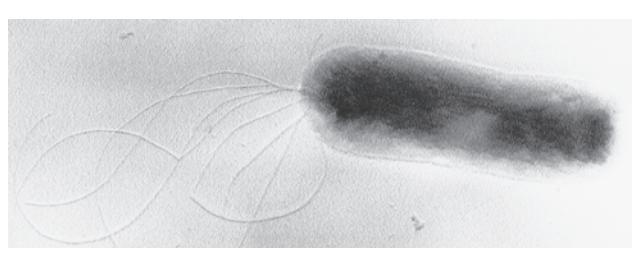

15.18 Thermotogae and Thermodesulfobacteria

Key Genera: *Thermotoga*, *Thermodesulfobacterium*

Thermotoga species are rod-shaped hyperthermophiles that form a sheathlike envelope (called a *toga*; thus the genus name) (Figure 15.49a), stain gram-negatively, and are nonsporulating. *Thermotoga* species are fermentative anaerobes, catabolizing sugars or starch and producing lactate, acetate, CO₂, and H₂ as fermentation products. The organisms can also grow by anaerobic respiration using H₂ as an electron donor and ferric iron as an electron acceptor. Species of *Thermotoga* have been isolated from terrestrial hot springs as well as marine hydrothermal vents.

(b) *Aquifex pyrophilus*—temperature optimum, 85°C. Cells of *Thermotoga* measure 0.6 × 3.5 µm; cells of *Aquifex* measure 0.5 × 2.5 µm.

Despite being bacterial, the genome of *Thermotoga* contains many genes that show strong homology to genes from hyperthermophilic *Archaea*. In fact, over 20% of the genes of *Thermotoga* probably originated from *Archaea* by horizontal gene transfers (☞ Sections 6.12 and 12.5). Although a few archaea-like genes have been identified in the genomes of other *Bacteria* and vice versa, only in *Thermotoga* has such large-scale horizontal transfer of genes between domains been detected thus far.

Thermodesulfobacterium (Figure 15.50) is a thermophilic sulfate-reducing bacterium, positioned on the phylogenetic tree in a separate phylum between *Thermotoga* and *Aquifex* (Figure 15.1). *Thermodesulfobacterium* is a strict anaerobe that uses compounds such as lactate, pyruvate, and ethanol (but not acetate) as electron donors, as do sulfate-reducing bacteria such as *Desulfovibrio* (☞ Section 14.9), reducing SO₄²⁻ to H₂S.

An unusual biochemical feature of *Thermodesulfobacterium* is the production of *ether-linked lipids*. Recall that such lipids are a hallmark of the *Archaea* and that a polyisoprenoid C₂₀ hydrocarbon (phytanyl) replaces fatty acids as the side chains in archaeal lipids (☞ Section 2.7). However, the ether-linked lipids in *Thermodesulfobacterium* are unusual because the glycerol side chains are not phytanyl groups, as they are in *Archaea*, but instead are composed of a unique C₁₇ hydrocarbon along with some fatty acids (Figure 15.50b). Thus we see in *Thermodesulfobacterium* both a deep phylogenetic lineage (Figure 15.1) and a lipid profile that combines features of both the *Archaea* and the *Bacteria*. However, a few other *Bacteria* have also been found to contain ether-linked lipids, and thus these lipids may be more common among *Bacteria* than previously thought.

15.19 Aquifaceae

Key Genera: *Aquifex*, *Thermocrinis*

The genus *Aquifex* (Figure 15.49b) is an obligately chemolithotrophic and autotrophic hyperthermophile and is the most thermophilic of all known *Bacteria*. Various *Aquifex* species utilize H₂, sulfur (S⁰), or thiosulfate (S₂O₃²⁻) as electron donors and O₂ or nitrate (NO₃⁻) as electron acceptors, and grow at temperatures up to 95°C. *Aquifex* can tolerate only very low O₂ concentrations (microaerophilic), and is unable to oxidize all tested organic compounds. *Hydrogenobacter*, a relative of *Aquifex*, shows most of the same properties as *Aquifex*, but is an obligate aerobe.

Aquifex and Autotrophy

Autotrophy in *Aquifex* occurs by way of the reverse citric acid cycle, a series of reactions previously detected only in green sulfur bacteria (Sections 13.3 and 14.6) within the domain *Bacteria*. The complete genome sequence of *Aquifex aeolicus* has been determined, and its entirely chemolithotrophic and autotrophic lifestyle is encoded by a very small genome of only 1.55 megabase pairs (one-third the size of the *Escherichia coli* genome). The discovery that so many hyperthermophilic species of *Archaea* and *Bacteria*, like *Aquifex*, are H₂ chemolithotrophs, coupled with the finding that they branch as very early lineages on their respective phylogenetic trees (Figure 15.1), suggests that H₂ was a key electron donor for energy metabolism in primitive organisms that appeared on early Earth (Sections 12.1 and 16.14).

Thermocrinis

Thermocrinis (Figure 15.51) is a relative of *Aquifex* and *Hydrogenobacter*. This bacterium grows optimally at 80°C as a chemolithotroph oxidizing H₂, S₂O₃²⁻, or S⁰ as electron donors, with O₂ as electron acceptor. *Thermocrinis ruber*, the only known species, grows in the outflow of certain hot springs in Yellowstone National Park (Figure 15.51a) where it forms pink “streamers” consisting of a filamentous form of the cells attached to siliceous sinter (Figure 15.51b). In static culture, cells of *T. ruber* grow as individual rod-shaped cells (Figure 15.51c). However, when cultured in a flowing system in which growth medium is trickled over a solid glass surface to which cells can attach, *Thermocrinis* assumes the streamer morphology it forms in its constantly flowing habitat in nature.

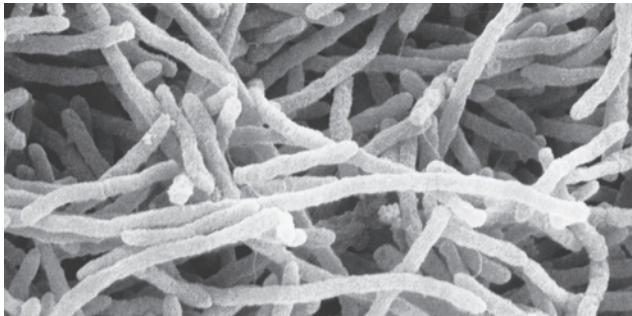

T. ruber is of historical significance in microbiology because it was one of the organisms discovered in the 1960s by Thomas Brock, a pioneer in the field of thermal microbiology. The discovery by Brock that the pink streamers (Figure 15.51b) contained protein and nucleic acids clearly indicated that they were living organisms and not just mineral debris. Moreover, the presence of streamers in 80–90°C hot spring outflow waters but not those of lower temperatures supported Brock’s hypothesis that these organisms actually required heat for growth and were therefore likely to be present in even boiling or superheated

waters. Both of these conclusions were subsequently supported by the discovery by Brock and other microbiologists of dozens of genera of hyperthermophilic prokaryotes inhabiting hot springs, hydrothermal vents, and other thermal environments. More coverage of hyperthermophiles can be found in Sections 5.11, 5.13, and in Chapter 16.

MINIQUIZ

- Of what evolutionary significance is the fact that organisms in the *Aquifex* lineage are both hyperthermophilic and H₂ chemolithotrophs?

VI • Other Bacteria

Thus far in this chapter we have focused on phyla that have many described species (Figure 15.1). Beyond these mainstream bacterial phyla are many others that have but one or at most a handful of characterized species (Figure 15.1b). In addition, many more phyla are known only from community sampling of 16S rRNA genes from nature (☞ Section 18.5). We cannot cover them all. So in this final unit of the chapter we consider one phylum that has been well studied and then summarize some other phyla that are emerging into the mainstream of microbial diversity.

15.20 *Deinococcus–Thermus*

Key Genera: *Deinococcus*, *Thermus*

The *deinococci* group contains only a few characterized genera in two orders, the *Deinococcales* and the *Thermales*. Members of this phylum are typically aerobic chemoorganotrophs that metabolize sugars, amino and organic acids, or various complex mixtures. Though *deinococci* stain gram-positively, they have a gram-negative cell wall structure (Figure 15.52) made up of several layers, including an outer membrane, which is characteristic of gram-negative bacteria (☞ Section 2.11). However, unlike the outer membrane of bacteria such as *Escherichia coli*, the outer membrane of *deinococci* lack lipid A. *Deinococci* also contain an unusual form of peptidoglycan in which ornithine replaces diaminopimelic acid in the N-acetylmuramic acid cross-links (☞ Section 2.10).

Species of *Thermales* are typically thermophiles or hyperthermophiles and the type genus is *Thermus*. *Thermus aquaticus*, discovered in a Yellowstone National Park hot spring in the mid-1960s by Thomas Brock, has been a model organism for

studying life at high temperatures. *T. aquaticus* has subsequently been isolated from many geothermal systems, and is the source of *Taq* DNA polymerase. Because it is so heat-stable, *Taq* polymerase allowed the polymerase chain reaction (PCR) technique for amplifying DNA to be fully automated (☞ Section 11.3), an advance that has revolutionized all of biology.

Radiation Resistance of *Deinococcus radiodurans*

Species of *Deinococcales* have the unusual property of being extremely radiation resistant, and *Deinococcus radiodurans* is the best-studied species in this regard. Most *deinococci* are red or pink due to carotenoids, and many are highly resistant to both radiation and desiccation. Resistance to ultraviolet (UV) radiation can be used to advantage in isolating *deinococci*. These remarkable organisms can be selectively isolated from soil, ground meat, dust, and filtered air following exposure of the sample to intense UV (or even gamma) radiation and plating on a rich medium containing tryptone and yeast extract. For example, *D. radiodurans* cells survive exposure to 15,000 grays (Gy) of ionizing radiation (1 Gy = 100 rad). This is sufficient to shatter the organism's chromosome into hundreds of fragments (by contrast, a human can be killed by exposure to less than 10 Gy).

In addition to impressive radiation resistance, *D. radiodurans* is resistant to the mutagenic effects of many mutagenic agents. The only chemical mutagens that seem to work on *D. radiodurans* are agents such as nitrosoguanidine, which induces deletions in DNA. Deletions are apparently not repaired as efficiently as point mutations in this organism, and mutants of *D. radiodurans* can be isolated in this way.

Note the outer membrane layer. (b) High-magnification micrograph of wall layer. (c) Transmission electron micrograph of cells of *D. radiodurans* colored to show the toroidal morphology of the nucleoid (green).

DNA Repair in *Deinococcus radiodurans*

Studies of *D. radiodurans* have shown that it is highly efficient in repairing damaged DNA. Several different DNA repair enzymes exist in *D. radiodurans*. In addition to the DNA repair enzyme RecA (► Section 10.4), several RecA-independent DNA systems exist in *D. radiodurans* that can repair breaks in single- or double-stranded DNA, and excise and repair misincorporated bases. In fact, repair processes are so effective that the chromosome can even be reassembled from a fragmented state.

It is also thought that the unique arrangement of DNA in *D. radiodurans* cells plays a role in radiation resistance. Cells of *D. radiodurans* always exist as pairs or tetrads (Figure 15.52a). Instead of scattering DNA within the cell as in a typical nucleoid, DNA in *D. radiodurans* is ordered into a toroidal (coiled, or stack of rings) structure (Figure 15.52c). Repair is then facilitated by the fusion of nucleoids from adjacent compartments, because their toroidal structure provides a platform for homologous recombination. From this extensive recombination, a single repaired chromosome emerges, and the cell containing this chromosome can then grow and divide.

15.21 Other Notable Phyla of Bacteria

The basic properties of seven other phyla of *Bacteria* are discussed briefly below. Although most of these have few cultured representatives (Figure 15.1b), many may well be of considerable ecological importance. If so, future research on their culture and ecological activities will supply the necessary proof. Until then, we paint a picture of these phyla with a broad brush to summarize their major characteristics in a general way.

Acidobacteria

Acidobacteria are widespread in the environment as revealed by analyses of 16S rRNA genes retrieved from environmental samples (Figure 15.1b). *Acidobacteria* are abundant in soils, particularly acid soils ($\text{pH} < 6.0$) where they often comprise a majority of some soil communities. *Acidobacteria* also inhabit freshwater, hot spring microbial mats, wastewater treatment reactors, and sewage sludge. There is evidence for as many as 25 major subgroups within the *Acidobacteria*, indicating substantial phylogenetic and metabolic diversity of the species in this phylum. Their abundance, widespread distribution, and likely metabolic diversity indicate they play important ecological roles, especially in soil. Unfortunately, while *Acidobacteria* are widespread in the environment, they have proven difficult to cultivate; as a result, few species have been isolated (Figure 15.1b) and only a handful of genera have been described.

The few species of *Acidobacteria* that have been characterized are metabolically diverse, including both chemoorganotrophs and photoheterotrophs as well as obligate aerobes and obligately fermentative anaerobes. Three species of *Acidobacteria* have

been well characterized, *Acidobacterium capsulatum*, *Geothrix fermentans*, and *Holophaga foetida*; all are gram-negative chemoorganotrophs. *A. capsulatum* is an acidophilic, encapsulated, obligately aerobic bacterium isolated from acid mine drainage; it utilizes various sugars and organic acids (acetate, propionate, lactate, fumarate) to CO_2 coupled to the reduction of ferric iron as electron acceptor (dissimilative iron reduction, ► Section 14.14), and can also ferment citrate to acetate plus succinate as products. *H. foetida* is a strictly anaerobic homoacetogen (► Sections 13.19 and 14.18) that grows by degrading methylated aromatic compounds to acetate. Some *Acidobacteria* degrade polymers such as cellulose and chitin, and at least one genus, *Chloracidobacterium*, is phototrophic (► Section 14.8).

Nitrospirae, *Deferribacteres*, and *Chrysiogenetes*

The phylum *Nitrospirae* is named for the genus *Nitrospira*, a chemolithotroph that oxidizes nitrite to nitrate and grows autotrophically (► Section 14.13), as do species of the proteobacterium *Nitrobacter* (► Section 13.10). *Nitrospira* inhabits many of the same environments as *Nitrobacter*. However, environmental surveys have shown that *Nitrospira* is much more abundant than *Nitrobacter* in nature, and thus most of the nitrite oxidized in nitrogen-rich environments such as wastewater treatment plants and ammonia-rich soils is probably due to *Nitrospira*. Other key *Nitrospirae* include *Leptospirillum*, an aerobic, acidophilic, iron-oxidizing chemolithotroph (► Section 14.15) common in acid mine drainage associated with the mining of coal and iron (► Section 21.1).

The phyla *Deferribacteres* and *Chrysiogenetes* (Figure 15.1) contain anaerobic chemoorganotrophs that display considerable metabolic diversity with respect to the electron acceptors used in anaerobic respirations (Chapter 13). Most, though not all, species are able to grow through anaerobic respiration of nitrate to nitrite or ammonium. The *Deferribacteres* group is named for the genus *Deferribacter*, a thermophilic dissimilative ferric iron-reducer (► Sections 13.21 and 14.14) that can also reduce nitrate and metal oxides. *Geovibrio* is a related genus that can also grow using elemental sulfur (► Section 14.10) as an electron acceptor. The bacterium *Chrysiogenes arsenatis* and its relatives are notable for the ability to couple the oxidation of acetate and a few other organic compounds to the reduction of arsenate as a terminal electron acceptor, reducing it to arsenite. In addition to arsenate, many species of *Chrysiogenetes* can reduce selenate, nitrite, nitrate, thiosulfate, and elemental sulfur in anaerobic respirations (► Section 13.21).

Synergistetes, *Fusobacteria*, *Fibrobacteres*

The phyla *Synergistetes*, *Fusobacteria*, and *Fibrobacteres* contain relatively few characterized species (Figure 15.1b), but those that have been cultured employ fermentative metabolisms. Species in these groups are often associated with the gastrointestinal tracts of animals and some have been associated with human disease.

Synergistetes are gram-negative nonsporulating rods found in association with animals and in anoxic environments in terrestrial and marine systems. Described species are typically obligate anaerobes that degrade proteins and are capable of fermenting

amino acids. In animals they are most often found in the gastrointestinal tract; for example, *Synergistes jonesii* inhabits the rumen. In humans, species of *Synergistetes* have been associated with certain soft tissue wounds and abscesses, dental plaque, and periodontal conditions.

Fusobacteria are gram-negative nonsporulating rods found in sediments and the gastrointestinal systems and oral cavities of animals. *Fusobacteria* are obligate anaerobes that ferment carbohydrates, peptides, and amino acids. Species of the genus *Fusobacterium* are common components of the human microbiome where they colonize mucous membranes. Different species can be found in the oral cavity, the gastrointestinal tract, and the vagina. *Fusobacterium nucleatum* is often found in gingival crevices in the human oral cavity. Some fusobacteria may be human pathogens and *F. nucleatum* is often present in patients suffering from periodontal disease.

While 16S ribosomal RNA genes from *Fibrobacteres* can be recovered from a wide range of habitats, the only characterized species have come from either the rumen or gastrointestinal

tracts of animals. The genus *Fibrobacter* contains gram-negative fermentative strict anaerobes. However, unlike most *Fusobacteria* and *Synergistetes*, species of *Fibrobacter* are unable to ferment proteins or amino acids and specialize instead in the fermentation of carbohydrates, including cellulose. In the rumen, cellulose is the major source of energy, and in such environments it supports not only cellulolytic bacteria such as *Fibrobacter* but many non-cellulolytic anaerobes that use glucose released during cellulose degradation.

MINIQUIZ

- What is a major habitat for many species of *Acidobacteria*?
- How do *Nitrospira* and *Defribacter* differ in terms of lifestyle and metabolism?
- What metabolic characteristics are shared by most *Synergistetes*, *Fusobacteria*, and *Fibrobacteres*, and what disease in humans has been correlated with the presence of *Synergistetes* and *Fusobacteria*?

BIG IDEAS

15.1 • The *Alphaproteobacteria* are the second largest class of *Proteobacteria* and metabolically diverse. Key genera are: *Rhizobium*, *Rickettsia*, *Rhodobacter*, and *Caulobacter*.

15.2 • The *Betaproteobacteria* are the third largest class of *Proteobacteria* and metabolically diverse. Key genera are *Burkholderia*, *Rhodococcus*, *Neisseria*, and *Nitrosomonas*.

15.3 • The *Gammaproteobacteria* are the largest and most diverse class of *Proteobacteria* and contain many human pathogens. The *Enterobacteriales*, or enteric bacteria, are the most heavily studied of all bacteria. Key genera are *Escherichia* and *Salmonella*.

15.4 • The *Pseudomonadales* and *Vibrionales* are among the most common *Gammaproteobacteria*. Key genera are *Pseudomonas* and *Vibrio*.

15.5 • The *Deltaproteobacteria* and *Epsilonproteobacteria* are smaller and less metabolically diverse classes of *Proteobacteria*. Key genera of *Deltaproteobacteria* are *Myxococcus*, *Desulfovibrio*, and *Geobacter*. Key genera of *Epsilonproteobacteria* are *Campylobacter* and *Helicobacter*.

15.6 • Lactic acid bacteria such as *Lactobacillus* and *Streptococcus* produce lactate as the primary end product of fermentation, and they have many roles in food production and preservation. The *Firmicutes* are one of the two main phyla of gram-positive bacteria.

15.7 • Many genera of *Firmicutes* in the orders *Bacillales* and *Clostridiales*, including *Staphylococcus*, *Listeria*, and *Sarcina*, are unable to form endospores.

15.8 • Production of endospores is a hallmark of the key genera *Bacillus* and *Clostridium* and is only found in the phylum *Firmicutes*.

15.9 • The phylum *Tenericutes* contains the mycoplasmas, organisms that lack cell walls and have very small genomes. Many species are pathogenic for humans, other animals, and plants. The key genus is *Mycoplasma*.

15.10 • *Actinobacteria* are the second major phylum of gram-positive bacteria. *Corynebacterium* and *Arthrobacter* are common gram-positive soil bacteria. *Propionibacterium* ferments lactate to propionate and is the key agent responsible for the unique flavor and texture of Swiss cheese.

15.11 • Species of *Actinobacteria* in the genus *Mycobacterium* are mainly harmless soil saprophytes, but *Mycobacterium tuberculosis* causes the disease tuberculosis.

15.12 • The streptomycetes are a large group of filamentous, gram-positive bacteria that form spores at the end of aerial filaments and are found in the phylum *Actinobacteria*. Many clinically useful antibiotics such as tetracycline and neomycin have come from *Streptomyces* species.

15.13 • The phylum *Bacteroidetes* includes gram-negative rods that do not form spores, many of which have gliding motility. Most species in the order *Bacteroidales* are obligate anaerobes that ferment carbohydrates in anoxic environments. The genus *Bacteroides* contains species that are common in the gastrointestinal tract of animals.

15.14 • The *Cytophagales* and *Flavobacteriales* are orders in the *Bacteroidetes* that include aerobic bacteria able to degrade complex polysaccharides such as cellulose. These bacteria are important in organic matter decomposition.

15.15 • The phylum *Chlamydiae* includes small obligate intracellular parasites that are adept at invading eukaryotic cells. Many species cause various diseases in humans and other animals.

15.16 • The *Planctomycetes* are a group of stalked, budding bacteria that form intracellular compartments of various types, in some cases indistinguishable from the nucleus of eukaryotic cells.

15.17 • Species of *Verrucomicrobia* are distinguished by their multiple prosthecate cells and their unique phylogeny.

15.18 • *Thermotogae* and *Thermodesulfobacteria* form two deeply branching phyla within the *Bacteria*. These hyperthermophilic bacteria have proven that extensive horizontal gene transfer has occurred from *Archaea* to *Bacteria* (*Thermotoga*) and that ether-linked lipids are not limited to the *Archaea* (*Thermodesulfobacterium*).

15.19 • The *Aquifex* phylum contains a group of hyperthermophilic, H₂-oxidizing bacteria that form the earliest branch on the tree of the domain *Bacteria*.

15.20 • *Deinococcus* and *Thermus* are the major genera in a distinct phylum of *Bacteria*. *Thermus* is the source of the key enzyme in automated PCR, whereas *Deinococcus* is the most radiation-resistant bacterium known, exceeding even endospores in this regard.

15.21 • *Acidobacteria* are widespread in many environments, especially soils, and show various physiologies. The genus *Nitrospira* includes nitrite-oxidizing bacteria, while species of *Defribacteres* and *Chrysogenes* specialize in various forms of anaerobic respiration. Species of *Synergistetes*, *Fusobacteria*, and *Fibrobacteres* are fermentative anaerobes that inhabit the gastrointestinal tract and other anoxic niches in animals.

Archaea and Global Warming

Anthropogenic CO₂ emissions have significantly affected global climate. However, *Archaea* and *Bacteria* have also profoundly affected our planet, including its climate. One example comes from the Arctic, where soil is frozen as permafrost. Permafrost can be 100 meters deep and it encompasses 25% of the terrestrial surface of the Earth. Within permafrost is stored an enormous mass of organic carbon, most of which has been locked away in ice for more than 20,000 years. But this ice is starting to thaw, and the result could have global consequences.

The Intergovernmental Panel on Climate Change predicts that Arctic temperatures will increase 7°C by the year 2100. When permafrost melts, it is converted into wetlands, and these are major habitats for *Archaea* that produce methane (methanogens). Methane is a greenhouse gas with a warming potential 25 times more powerful than CO₂. Hence, if Arctic warming continues at its present pace, much permafrost carbon could be converted into methane, significantly accelerating global climate change.

At Stordalen Mire in northern Sweden, microbiologists are investigating methanogens in thawed permafrost.¹ Chambers are used to trap and measure methane produced in the wetlands that have replaced thawed permafrost (photo). The source of most of the methane was found to be a novel methanogen, *Methanoflorens stordalenmirensis*, which grows rapidly in thawed permafrost. *M. stordalenmirensis* represents a novel order of methanogens previously called “Rice Cluster II.” These methanogens are present in wetlands worldwide but *M. stordalenmirensis* is the first characterized species of this new taxonomic family, the *Methanoflorentaceae*.

In addition to human impacts on climate, future control of global climate change may well depend in a major way on what is discovered about the ecology of methanogenesis by *M. stordalenmirensis*.

We now consider organisms in the domain *Archaea*. A phylogenetic tree of *Archaea* is shown in **Figure 16.1**. The tree, based on comparative sequences of ribosomal proteins, reveals several phyla, including the *Euryarchaeota*, *Crenarchaeota*, *Thaumarchaeota*, *Korarchaeota*, and *Nanoarchaeota*. The exact ancestry of these groups remains a contentious issue, and phylogenetic trees constructed from 16S ribosomal RNA gene sequences often conflict with those made using other genomic loci (for example, compare Figures 12.13 and 16.1).

The evolutionary history of the *Archaea* is ancient and complex, involving horizontal gene transfers within and between phyla. Common traits shared by all *Archaea* include their ether-linked lipids, their lack of peptidoglycan in cell walls (Chapter 2), and their structurally complex RNA polymerases, which resemble those of *Eukarya* (Figure 4.21). But beyond this, *Archaea* show enormous phenotypic diversity.

Archaea include species that carry out chemoorganotrophic or chemolithotrophic metabolisms, and both aerobic and anaerobic species are common (summarized later in Table 16.6). Chemoorganotrophy is widespread among *Archaea*, and fermentations and anaerobic respirations are common. Chemolithotrophy is also well established in the *Archaea*, with H₂ being a common electron

donor (Section 16.14), and with ammonia oxidation found among species of *Thaumarchaeota*. Anaerobic respiration, especially forms employing elemental sulfur (S⁰) as an electron acceptor, is prevalent among the *Archaea*, especially *Crenarchaeota*. By contrast, aerobic respiration occurs widely in *Thaumarchaeota* and is common among a few groups of *Euryarchaeota* but is characteristic of only a few species of *Crenarchaeota*.

Many metabolic traits of archaeal species are also found in *Bacteria* but others are unique to *Archaea*. **Methanogens**, for example, are *Euryarchaeota* that conserve energy from the production of methane (Section 13.20). **Methanogenesis** is a globally important process that is uniquely archaeal (Sections 13.20, 20.1, and 20.2). *Archaea* are also well known for containing many species of **extremophiles**, including species that are **hyperthermophiles** (organisms with growth temperature optima above 80°C), **halophiles**, and **acidophiles** (Chapter 5). However, a great many species in the *Euryarchaeota* and most *Thaumarchaeota* are not extremophiles and are found in soils, sediments, oceans, lakes, in association with animals, and even in the human gut!

With this brief background and the phylogeny of *Archaea* (Figure 16.1) firmly in mind, we now consider the organismal diversity of this fascinating domain of life.

I • *Euryarchaeota*

Euryarchaeota comprise a large and physiologically diverse group of *Archaea*. This phylum includes methanogens as well as many genera of extremely halophilic (salt-loving) *Archaea*. As a study in physiological contrasts, these two groups are remarkable:

Methanogens are the strictest of anaerobes while extreme halophiles are primarily obligate aerobes. Other groups of euryarchaeotes include the hyperthermophiles *Thermococcus* and *Pyrococcus*, the hyperthermophilic methanogen *Methanopyrus*,

and the cell wall-less *Thermoplasma*, an organism phenotypically similar to the mycoplasmas (Section 15.9). We begin our review of *Euryarchaeota* by reviewing the halophilic *Archaea*.

16.1 Extremely Halophilic Archaea

Key Genera: *Halobacterium*, *Haloferax*, *Natronobacterium*

Extremely halophilic *Archaea*, often called the “haloarchaea,” are a diverse group that inhabits environments high in salt. These include naturally salty environments, such as solar salt evaporation ponds and salt lakes, and artificial saline habitats such as the surfaces of heavily salted foods, for example, certain fish and meats. Such salty habitats are called *hypersaline* (Figure 16.2). The term **extreme halophile** is used to indicate that these organisms are not only halophilic, but that their requirement for salt is very high, in some cases at levels near saturation (Figure 5.26).

An organism is considered an extreme halophile if it requires 1.5 M (about 9%) or more sodium chloride (NaCl) for growth. Most species of extreme halophiles require 2–4 M NaCl (12–23%) for

optimal growth. Virtually all extreme halophiles can grow at 5.5 M NaCl (32%, the limit of saturation for NaCl), although some species grow very slowly at this salinity. Some phylogenetic relatives of extremely halophilic *Archaea*, for example species of *Haloferax* and *Natronobacterium*, are able to grow at much lower salinities, such as at or near that of seawater (about 2.5% NaCl); nevertheless, these organisms are phylogenetic relatives of other extreme halophiles.

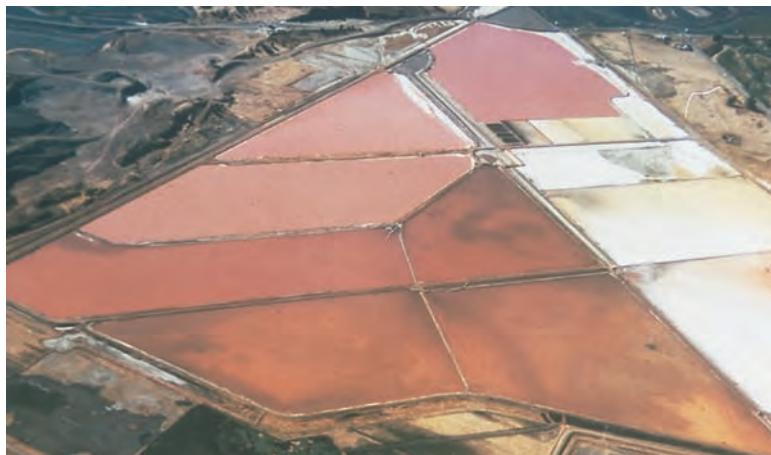

Hypersaline Environments: Chemistry and Productivity

Hypersaline habitats are common throughout the world, but extremely hypersaline habitats are rare. Most such environments are in hot, dry areas of the world. Salt lakes can vary considerably in ionic composition. The predominant ions in a hypersaline lake depend on the surrounding topography, geology, and general climatic conditions.

Great Salt Lake in Utah (USA) (Figure 16.2a), for example, is essentially concentrated seawater. In this hypersaline lake the relative proportions of the various ions [e.g., sodium (Na^+), chloride (Cl^-), and sulfate (SO_4^{2-})] are those of seawater, although the

cells of cyanobacteria and green algae. (b) Aerial view near San Francisco Bay, California, of a series of seawater evaporating ponds where solar salt is prepared. The red-purple color is predominantly due to bacterioruberins and bacteriorhodopsin in cells of haloarchaea. (c) Lake Hamara, Wadi El Natroun,

Egypt. A bloom of pigmented haloalkaliphiles is growing in this pH 10 soda lake. Note the deposits of trona ($\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$) around the edge of the lake. (d) Scanning electron micrograph of halophilic bacteria including square *Archaea* present in a saltern in Spain.

overall concentration of ions is much higher. In addition, the pH of this hypersaline lake is slightly alkaline.

Soda lakes, in contrast, are highly alkaline, hypersaline environments. The water chemistry of soda lakes resembles that of hypersaline lakes such as Great Salt Lake, but because high levels of carbonate minerals are also present in the surrounding strata, the pH of soda lakes is quite high. Waters of pH 10–12 are not uncommon in these environments (Figure 16.2c). In addition, calcium (Ca^{2+}) and Mg^{2+} are virtually absent from soda lakes because they precipitate out at high pH and carbonate concentrations.

The diverse chemistries of hypersaline habitats have selected for a large diversity of halophilic microorganisms. Some organisms are unique to one environment while others are widespread. Moreover, despite their extreme conditions, salt lakes can be highly productive ecosystems (the word *productive* here means high levels of autotrophic CO_2 fixation). *Archaea* are not the only microorganisms present. The eukaryotic alga *Dunaliella* (► Figure 17.33a) is the major, if not the sole, oxygenic phototroph in most salt lakes. In highly alkaline soda lakes where *Dunaliella* is absent, anoxygenic phototrophic purple bacteria of the genera *Ectothiorhodospira* and *Halorhodospira* (► Section 14.5) predominate. Organic matter originating from primary production by oxygenic or anoxygenic phototrophs sets the stage for growth of haloarchaea, which are chemoorganotrophic organisms. In addition, a few extremely halophilic chemoorganotrophic *Bacteria*, such as *Halanaerobium*, *Halobacteroides*, and *Salinibacter*, thrive in such environments.

Marine salterns are also habitats for extreme halophiles. Marine salterns are enclosed basins filled with seawater that are left to evaporate, yielding solar sea salt (Figure 16.2b, d). As salterns approach the minimum salinity limits for haloarchaea, the waters turn a reddish purple color due to the massive growth—called a *bloom*—of cells (the red coloration apparent in Figure 16.2b and c is due to carotenoids and other pigments to be discussed later). Morphologically unusual *Archaea* are often present in salterns, including species with a square or cup-shaped morphology (Figure 16.2d). Extreme halophiles are also present in highly salted foods, such as certain types of sausages, marine fish, and salted pork.

Taxonomy and Physiology of Extremely Halophilic Archaea

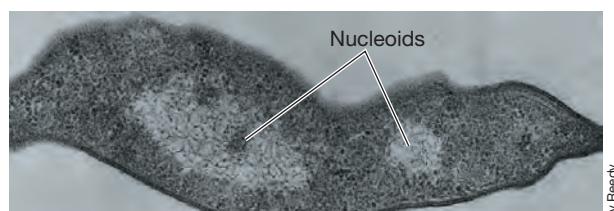

Table 16.1 lists several of the currently recognized genera of extremely halophilic *Archaea*. Besides the term haloarchaea, these *Archaea* are sometimes called “halobacteria,” because the genus *Halobacterium* (Figure 16.3) was the first in this group to be described (prior to the discovery of *Archaea*) and is still the best-studied representative of the group. *Natronobacterium*, *Natronomonas*, and their relatives differ from other extreme halophiles in being extremely alkaliphilic as well as halophilic. As befits their soda lake habitat (Table 16.1 and Figure 16.2c), natronobacteria grow optimally at very low Mg^{2+} concentrations and high pH (9–11).

Haloarchaea stain gram-negatively, reproduce by binary fission, and do not form resting stages or spores. Cells of the various cultured genera are rod-shaped, cocci, or cup-shaped, but even cells that form squares are known (Figure 16.2d). Cells of *Haloquadratum* are square in shape and are only about $0.1 \mu\text{m}$ thick. *Haloquadratum* also forms gas vesicles that allow it to float in its salty hypersaline habitat, probably as a means to be in contact with air since most extreme halophiles are obligate aerobes.

Many other extremely halophilic *Archaea* also produce gas vesicles. Most species of extreme halophiles lack flagella, but a few strains are weakly motile by flagella that rotate to propel the cell forward (► Section 2.17). The genomes of *Halobacterium* and *Halococcus* are unusual in that large plasmids containing up to 30% of the total cellular DNA are present and the GC base ratio of these plasmids (near 60% GC) differs significantly from that of chromosomal DNA (66–68% GC). Plasmids from extreme halophiles are among the largest naturally occurring plasmids known.

(a) Longitudinal section of a dividing cell showing the nucleoids. (b) High-magnification electron micrograph showing the glycoprotein subunit structure of the cell wall.

Most species of extremely halophilic *Archaea* are obligate aerobes. Most haloarchaea use amino acids or organic acids as electron donors and require a number of growth factors such as vitamins for optimal growth. A few haloarchaea oxidize carbohydrates aerobically, but this capacity is rare; sugar fermentation does not occur. Electron transport chains containing cytochromes of the *a*, *b*, and *c* types are present in *Halobacterium*, and energy is conserved during aerobic growth via a proton motive force arising from electron transport. Some haloarchaea have been shown to grow anaerobically, as growth by anaerobic respiration (☞ Section 13.16) linked to the reduction of nitrate or fumarate has been demonstrated in certain species.

Water Balance in Extreme Halophiles

Extremely halophilic *Archaea* require large amounts of NaCl for growth. Detailed salinity studies of *Halobacterium* have shown that the requirement for Na⁺ cannot be satisfied by any other ion, even the chemically related ion potassium (K⁺). However, cells of *Halobacterium* need both Na⁺ and K⁺ for growth, because each plays an important role in maintaining osmotic balance.

As we learned in Section 5.15, microbial cells must withstand the osmotic forces that accompany life. To do so in a high-solute environment such as the salt-rich habitats of *Halobacterium*, organisms must either accumulate or synthesize solutes intracellularly. These solutes are called **compatible solutes**. These compounds counteract the tendency of the cell to become dehydrated under conditions of high osmotic strength by placing the cell in positive water balance with its surroundings. Cells of *Halobacterium*, however, do not synthesize or accumulate organic compounds but instead pump large amounts of K⁺ from the environment into the cytoplasm. This ensures that the concentration of K⁺ *inside* the cell is even greater than the concentration of Na⁺ *outside* the cell (Table 16.2). This ionic condition maintains positive water balance.

The *Halobacterium* cell wall (Figure 16.3b) is composed of glycoprotein and is stabilized by Na⁺. Sodium ions bind to the outer surface of the *Halobacterium* wall and are absolutely essential for maintaining cellular integrity. When insufficient Na⁺ is present, the cell wall breaks apart and the cell lyses. This is a consequence of the exceptionally high content of the *acidic* (negatively charged) amino acids aspartate and glutamate in the glycoprotein of the *Halobacterium* cell wall. The negative charge on the carboxyl group of these amino acids is bound to Na⁺; when Na⁺ is diluted away, the negatively charged parts of the proteins tend to repel each other, leading to cell lysis.

Halophilic Cytoplasmic Components

Like cell wall proteins, cytoplasmic proteins of *Halobacterium* are highly acidic, but it is K⁺, not Na⁺, that is required for activity. This makes sense because K⁺ is the predominant cation in the cytoplasm of cells of *Halobacterium* (Table 16.2). Besides having a high acidic amino acid composition, halobacterial cytoplasmic proteins typically contain lower levels of hydrophobic amino acids and lysine, a positively charged (basic) amino acid, than proteins of nonhalophiles. This is also to be expected because in a highly ionic cytoplasm, polar proteins would tend to remain in solution whereas nonpolar proteins would tend to cluster and perhaps lose activity. The ribosomes of *Halobacterium* also require high KCl levels for stability, whereas ribosomes of nonhalophiles have no KCl requirement.

Table 16.2 Concentration of ions in cells of *Halobacterium salinarum*^a

Ion	Concentration in medium (M)	Concentration in cells (M)
Na ⁺	4.0	1.4
K ⁺	0.032	4.6
Mg ²⁺	0.13	0.12
Cl ⁻	4.0	3.6

^aData from *Biochim. Biophys. Acta* 65: 506–508 (1962).

Extremely halophilic *Archaea* are thus well adapted, both internally and externally, to life in a highly ionic environment. Cellular components exposed to the external environment require high Na⁺ for stability, whereas internal components require high K⁺. With the exception of a few extremely halophilic members of the *Bacteria* that also use KCl as a compatible solute, in no other group of prokaryotes do we find this unique requirement for such high amounts of specific cations.

Bacteriorhodopsin and Light-Mediated ATP Synthesis in *Halobacteria*

Certain species of haloarchaea can catalyze a light-driven synthesis of ATP. This occurs without chlorophyll pigments, so it is not photosynthesis. However, other light-sensitive pigments are present, including red and orange carotenoids—primarily C₅₀ pigments called *bacterioruberins*—and inducible pigments involved in energy conservation; we discuss these pigments here.

Under conditions of low aeration, *Halobacterium salinarum* and some other haloarchaea synthesize a protein called **bacteriorhodopsin** and insert it into their cytoplasmic membranes. Bacteriorhodopsin is so named because of its structural and functional similarity to rhodopsin, the visual pigment of the eye. Conjugated to bacteriorhodopsin is a molecule of retinal, a carotenoid-like molecule that can absorb light energy and pump a proton across the cytoplasmic membrane. The retinal gives bacteriorhodopsin a purple hue. Thus cells of *Halobacterium* that are switched from growth under high-aeration conditions to oxygen-limiting growth conditions (a trigger of bacteriorhodopsin synthesis) gradually change color from orange-red to purple-red as they synthesize bacteriorhodopsin and insert it into their cytoplasmic membranes.

Bacteriorhodopsin absorbs green light around 570 nm. Following absorption, the retinal of bacteriorhodopsin, which normally exists in a *trans* configuration (Ret_T), becomes excited and converts to the *cis* (Ret_C) form (Figure 16.4). This transformation is coupled to the translocation of a proton across the cytoplasmic membrane. The retinal molecule then decays to the *trans* isomer along with the uptake of a proton from the cytoplasm, and this completes the cycle. The proton pump is then ready to repeat the cycle (Figure 16.4). As protons accumulate on the outer surface of the membrane, a proton motive force is generated that is coupled to ATP synthesis through the activity of a proton-translocating ATPase (☞ Section 3.11; Figure 16.4).

Bacteriorhodopsin-mediated ATP production in *H. salinarum* supports slow growth of this organism under anoxic conditions. The light-stimulated proton pump of *H. salinarum* also functions to pump Na⁺ out of the cell by activity of a Na⁺–H⁺ antiport system and to drive the uptake of nutrients, including the K⁺ needed for osmotic balance. Amino acid uptake by *H. salinarum* is

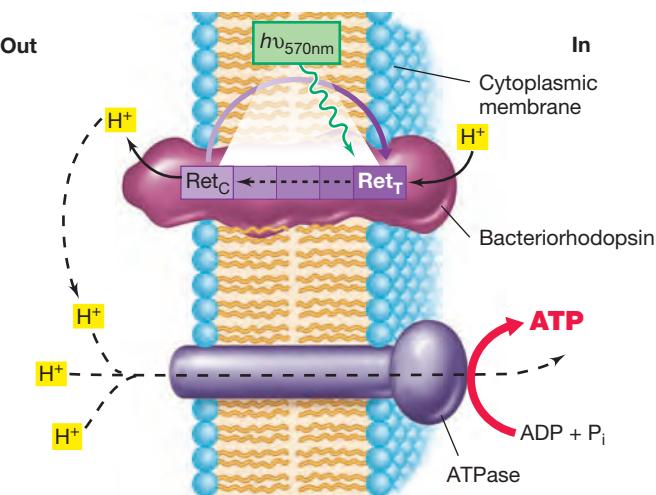

Figure 16.4 Model for the mechanism of bacteriorhodopsin. Light of 570 nm ($h\nu_{570\text{nm}}$) converts the protonated retinal of bacteriorhodopsin from the *trans* form (Ret_T) to the *cis* form (Ret_C), along with translocation of a proton to the outer surface of the cytoplasmic membrane, thus establishing a proton motive force. ATPase activity is driven by the proton motive force.

indirectly driven by light as well, because amino acids are cotransported into the cell with Na^+ by an amino acid– Na^+ symporter (☞ Section 2.9); removal of Na^+ from the cell occurs by way of the light-driven $\text{Na}^+–\text{H}^+$ antiporter.

Other Rhodopsins

Besides bacteriorhodopsin, at least three other rhodopsins are present in the cytoplasmic membrane of cells of *H. salinarum*. **Halorhodopsin** is a light-driven chloride (Cl^-) pump that brings Cl^- into the cell as the anion for K^+ . The retinal of halorhodopsin binds Cl^- and transports it into the cell. Two other light sensors, called *sensory rhodopsins*, are present in *H. salinarum*. These light sensors control phototaxis (movement toward light, ☞ Section 2.19) by the organism. Through the interaction of a cascade of proteins similar to those in chemotaxis (☞ Sections 2.19 and 7.8), sensory rhodopsins affect flagellar rotation, moving cells of *H. salinarum* toward light where bacteriorhodopsin can function to make ATP (Figure 16.4).

We will learn when we consider marine microbiology (☞ Sections 19.9 and 19.11) that several *Proteobacteria* (domain *Bacteria*) that inhabit the upper layers of the ocean contain bacteriorhodopsin-like proteins called *proteorhodopsins*. As far

as is known, proteorhodopsin functions like bacteriorhodopsin except that different spectral forms exist, each form being tuned to the absorption of its own specific wavelengths of light. Proteorhodopsin as a mechanism for energy conservation in marine bacteria makes good ecological sense because levels of dissolved organic matter in the open oceans are typically very low, and thus a strictly chemoorganotrophic lifestyle would be difficult.

MINIQUIZ

- If cells of *Halobacterium* require high levels of Na^+ for growth, why is this not true for the organism's cytoplasmic enzymes?
- What benefit does bacteriorhodopsin confer on a cell of *Halobacterium salinarum*?

16.2 Methanogenic Archaea

Key Genera: *Methanobacterium*, *Methanocaldococcus*, *Methanosarcina*

Many *Euryarchaeota* are methanogens, microorganisms that produce methane (CH_4) as an integral part of their energy metabolism (methane production is called *methanogenesis*). In Section 13.20 we considered the biochemistry of methanogenesis. Later, we will learn how methanogenesis is the terminal step in the biodegradation of organic matter in many anoxic habitats in nature (☞ Section 20.2). Table 16.3 lists the major sources of biogenic methane in nature.

Diversity and Physiology of Methanogens

Methanogens show a variety of morphologies (Figure 16.5 and Table 16.4). Their taxonomy is based on both phenotypic and phylogenetic analyses, with several taxonomic orders being recognized (in taxonomy, an order contains groups of related families, each of which contains one or more genera; ☞ Section 12.10).

Methanogens show a diversity of cell wall chemistries. These include the pseudomurein walls of *Methanobacterium* species and relatives (Figure 16.6a), walls composed of methanochondroitin (so named because of its structural resemblance to chondroitin, the connective tissue polymer of vertebrate animals) in *Methanosarcina* and relatives (Figure 16.6b), the protein or glycoprotein walls of *Methanocaldococcus* (Figure 16.7a) and *Methanoplanus* species, respectively, and the S-layer walls of *Methanospirillum* (Figure 16.5c; ☞ Section 2.12).

Physiologically, methanogens are obligate anaerobes, and strict anoxic techniques are necessary to culture them. Most

^aTaxonomic orders are listed in bold. An order is a taxonomic rank that consists of several families; families consist of several genera.

methanogens are mesophilic and nonhalophilic, although species that grow optimally at very high (Figure 16.7) or very low temperatures, at very high salt concentrations, or at extremes of pH, have also been described. Several substrates can be converted to CH_4 by methanogens. Interestingly, these substrates do not include such common compounds as glucose and organic or fatty acids (other than acetate and pyruvate). Compounds such as glucose can be converted to CH_4 , but only in reactions in which methanogens and other anaerobes cooperate. With the right mixture of

organisms, virtually any organic compound, even hydrocarbons, can be converted to CH_4 plus CO_2 (Section 20.2).

Three classes of compounds make up the list of methanogenic substrates shown in **Table 16.5**. These are *CO₂-type* substrates, *methylated* substrates, and *acetate*. CO₂-type substrates include CO₂ itself, which is reduced to CH₄ using H₂ as the electron donor. Other substrates of this type include formate (which is CO₂ + H₂ in combined form) and CO, carbon monoxide. Methylated substrates include methanol (CH₃OH) and many others (Table 16.5).

A cell is about 1 μm in diameter. (b) *Methanotorris igneus* (temperature optimum, 88°C), thin section. A cell is about 1 μm in diameter. (d) *Methanoaeta thermophila* (temperature optimum, 60°C), phase-contrast micrograph. A cell is about 1 μm in diameter. The refractive bodies inside the cells are gas vesicles.

Methanol (CH_3OH) can be reduced using an external electron donor such as H_2 , or, alternatively, in the absence of H_2 , some CH_3OH can be oxidized to CO_2 to generate the electrons needed to reduce other molecules of CH_3OH to CH_4 (Figure 13.50a). The final methanogenic process is the cleavage of acetate to CO_2 plus CH_4 . Only a few known methanogens are acetotrophic (Tables 16.4 and 16.5), although acetate is a major source of CH_4 in nature. The biochemistry of methanogenesis from each of these classes of substrates is considered in Section 13.20 along with how CH_4 formation is linked to energy conservation.

***Methanocaldococcus jannaschii* as a Model Methanogen**

The genome of the hyperthermophilic methanogen *Methanocaldococcus jannaschii* (Figure 16.7a) and many other methanogens have been sequenced. The 1.66-Mbp circular genome of *M. jannaschii*, an organism that has been used as a model for the molecular study of methanogenesis and archaeal motility (see “Archaeal Tortoise and Hare”, page 25) contains about 1700 genes, and genes encoding enzymes of methanogenesis and several other key cell functions have been identified. Interestingly, the majority of *M. jannaschii* genes encoding functions such as central metabolic pathways and cell division are similar to those in *Bacteria*. By contrast, most of the *M. jannaschii* genes encoding core molecular processes such as transcription and translation more closely resemble those of eukaryotes. These findings reflect the various traits shared by organisms in the three cellular domains and are consistent with our understanding of how the three domains of cells evolved, as discussed in Chapter 12. However, analyses of the *M. jannaschii* genome also show that fully 40% of its genes have no counterparts in genes from either of the other domains. Some of these are genes that encode the enzymes needed for methanogenesis, of course, but many others likely encode novel cellular functions absent from cells in the other domains or may encode redundant functions carried out by classes of enzymes distinct from those found in *Bacteria* and *Eukarya*.

16.3 Thermoplasmatales

Key Genera: *Thermoplasma*, *Picrophilus*, *Ferroplasma*

A phylogenetically distinct line of Archaea contains thermophilic and extremely acidophilic genera: *Thermoplasma*, *Ferroplasma*, and *Picrophilus* (Figure 16.1). These prokaryotes are among the most acidophilic of all known microorganisms, with *Picrophilus* being capable of growth even below pH 0. Most are thermophilic as well. These genera also form their own taxonomic order within the *Euryarchaeota*, the *Thermoplasmatales*. We begin with a description of the mycoplasma-like organisms *Thermoplasma* and *Ferroplasma*.

Archaea Lacking Cell Walls

Thermoplasma and *Ferroplasma* lack cell walls, and in this respect they resemble the mycoplasmas (Section 15.9). *Thermoplasma* (Figure 16.8) is a chemoorganotroph that grows optimally at 55°C and pH 2 in complex media. Two species of *Thermoplasma* have

(a)

(b)

Figure 16.8 *Thermoplasma* species. (a) *Thermoplasma acidophilum*, an acidophilic and thermophilic mycoplasma-like archaeon; electron micrograph of a thin section. The diameter of cells varies from 0.2 to 5 μm . The cell shown is about 1 μm in diameter. (b) Shadowed preparation of cells of *Thermoplasma volcanium* isolated from hot springs. been described, *Thermoplasma acidophilum* and *Thermoplasma volcanium*. Species of *Thermoplasma* are facultative aerobes, growing either aerobically or anaerobically by sulfur respiration (Section 13.18). Most strains of *T. acidophilum* have been obtained from self-heating coal refuse piles. Coal refuse contains coal fragments, pyrite (FeS_2), and other organic materials extracted from coal. When dumped into piles in surface-mining operations, coal refuse heats as a result of microbial metabolism bringing it to combustion temperature (Figure 16.9). This sets the stage for growth of *Thermoplasma*, which likely metabolizes organic compounds leached from the hot coal refuse. The second species, *T. volcanium*, has been isolated in hot acidic soils throughout the world and is highly motile by multiple flagella (Figure 16.8b).

To survive the osmotic stresses of life without a cell wall and to withstand the dual environmental extremes of low pH and high temperature, *Thermoplasma* has evolved a unique cytoplasmic

The pile, containing coal debris, pyrite, and other microbial substrates, self-heats due to microbial metabolism.

membrane structure. The membrane contains a lipopolysaccharide-like material called *lipoglycan*. This substance consists of a tetraether lipid monolayer membrane with mannose and glucose (Figure 16.10). This molecule constitutes a major fraction of the total lipids of *Thermoplasma*. The membrane also contains glycoproteins but not sterols. These molecules render the *Thermoplasma* membrane stable to hot, acidic conditions.

Like mycoplasmas (Section 15.9), *Thermoplasma* contains a relatively small genome (1.5 Mbp). In addition, *Thermoplasma* DNA is complexed with a highly basic DNA-binding protein that organizes the DNA into globular particles resembling the nucleosomes of eukaryotic cells. This protein is homologous to the histone-like DNA-binding protein HU of *Bacteria*, which plays an important role in organization of the DNA in the cell. In contrast, several other *Euryarchaeota* contain basic proteins homologous to the DNA-binding histone proteins of eukaryotic cells.

Ferroplasma

Ferroplasma is a chemolithotrophic relative of *Thermoplasma*. *Ferroplasma* is a strong acidophile; however, it is not a thermophile, as it grows optimally at 35°C. *Ferroplasma* oxidizes ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) to obtain energy (this reaction generates acid, see Figure 16.18d) and uses CO_2 as its carbon source (autotrophy). *Ferroplasma* grows in mine tailings containing pyrite (FeS_2), which is its energy source. The extreme acidophily of *Ferroplasma* allows it to drive the pH of its habitat down to extremely acidic values. After moderate acidity is generated from Fe^{2+} oxidation by acidophilic organisms such as *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* (Section 20.5), *Ferroplasma* becomes active and subsequently generates the very

low pH values typical of acid mine drainage. Acidic waters at pH 0 can be generated by the activities of *Ferroplasma*.

Picrophilus

A phylogenetic relative of *Thermoplasma* and *Ferroplasma* is *Picrophilus*. Although *Thermoplasma* and *Ferroplasma* are extreme acidophiles, *Picrophilus* is even more so, growing optimally at pH 0.7 and capable of growth at pH values lower than 0. *Picrophilus* also has a cell wall (an S-layer; Section 2.12) and a much lower DNA GC base ratio than does *Thermoplasma* or *Ferroplasma*. Although phylogenetically related, *Thermoplasma*, *Ferroplasma*, and *Picrophilus* have quite distinct genomes. Two species of *Picrophilus* have been isolated from acidic Japanese solfataras, and like *Thermoplasma*, both grow heterotrophically on complex media.

The physiology of *Picrophilus* is of interest as a model for extreme acid tolerance. Studies of its cytoplasmic membrane point to an unusual arrangement of lipids that forms a highly acid-impermeable membrane at very low pH. By contrast, at moderate acidities such as pH 4, the membranes of cells of *Picrophilus* become leaky and disintegrate. Obviously, this organism has evolved to survive only in highly acidic habitats.

16.4 Thermococcales and Methanopyrus

Key Genera: *Thermococcus*, *Pyrococcus*, *Methanopyrus*

A few euryarchaeotes thrive in thermal environments and some are hyperthermophiles. We consider here three hyperthermophilic euryarchaeotes that branch very near the root of the *Euryarchaeota* (Figure 16.1). Two of these, *Thermococcus* and *Pyrococcus*, form a distinct taxonomic order: the *Thermococcales*. The third organism, *Methanopyrus*, is a methanogen that closely resembles other methanogens (Section 16.2 and Table 16.4) in its basic physiology but is unusual in its hyperthermophily, lipids, and phylogenetic position (Figure 16.1).

Thermococcus and Pyrococcus

Thermococcus is a spherical hyperthermophilic euryarchaeote indigenous to anoxic thermal waters in various locations throughout the world. The spherical cells contain a tuft of polar flagella and are thus highly motile (Figure 16.11). *Thermococcus* is an obligately anaerobic chemoorganotroph that metabolizes proteins and other complex organic mixtures (including some sugars) with elemental sulfur (S^0) as electron acceptor at temperatures from 55 to 95°C.

Pyrococcus is morphologically similar to *Thermococcus* (Figure 16.11b). *Pyrococcus* differs from *Thermococcus* primarily by its higher temperature requirements; *Pyrococcus* grows between 70 and 106°C with an optimum of 100°C. *Thermococcus* and *Pyrococcus* are also metabolically quite similar. Proteins, starch, or maltose are oxidized as electron donors, and S^0 is the terminal electron acceptor and is reduced to hydrogen sulfide (H_2S). Both *Thermococcus* and *Pyrococcus* form H_2S when S^0 is present, but form H_2 when S^0 is absent (see Table 16.8).

(b) Dividing cell of *Pyrococcus furiosus*. Electron micrograph of thin section. Cells of both organisms are about 0.8 μm in diameter.

Methanopyrus

Methanopyrus is a rod-shaped hyperthermophilic methanogen (Figure 16.12). *Methanopyrus* was isolated from hot sediments near submarine hydrothermal vents and from the walls of “black smoker” hydrothermal vent chimneys (Section 16.11; ↗ Section 19.13). *Methanopyrus* shares phenotypic properties with both the hyperthermophiles and the methanogens. *Methanopyrus* produces CH_4 only from $\text{H}_2 + \text{CO}_2$ and grows rapidly for an autotrophic organism (generation time <1 h at 100°C). In special pressurized vessels, growth of one strain of *Methanopyrus* has been recorded at 122°C, the highest temperature yet shown to support microbial growth.

Methanopyrus is also unusual because it contains membrane lipids found in no other known organism. Recall that in the lipids of *Archaea*, the glycerol side chains contain **phytanyl** rather than fatty acids bonded in ether linkage to the glycerol (↗ Section 2.7). In *Methanopyrus*, this ether-linked lipid is an *unsaturated* form of the otherwise saturated dibiphytanyl tetraethers found in all other hyperthermophilic *Archaea*. These unusual lipids may help to stabilize the cytoplasmic membrane of *Methanopyrus* at its unusually high growth temperatures.

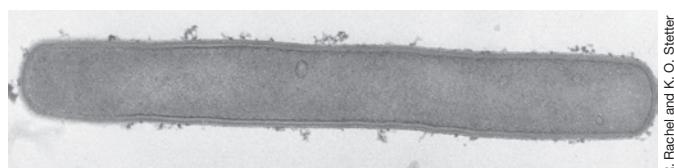

Figure 16.12 *Methanopyrus*. *Methanopyrus* grows optimally at 100°C and can make CH_4 only from $\text{CO}_2 + \text{H}_2$. 16.5 Archaeoglobales

Key Genera: *Archaeoglobus*, *Ferroglobus*

We will see later that a number of hyperthermophilic *Crenarchaeota* catalyze anaerobic respirations in which elemental sulfur (S^0) is used as an electron acceptor, being reduced to H_2S (see Table 16.6). One hyperthermophilic euryarchaeote, *Archaeoglobus*, can reduce sulfate (SO_4^{2-}) and forms a phylogenetically distinct lineage within the *Euryarchaeota* (Figure 16.1).

Archaeoglobus

Archaeoglobus was isolated from hot marine sediments near hydrothermal vents. In its metabolism, *Archaeoglobus* couples the oxidation of H_2 , lactate, pyruvate, glucose, or complex organic compounds to the reduction of SO_4^{2-} to H_2S . Cells of *Archaeoglobus* are irregular cocci (Figure 16.13a) and grow optimally at 83°C.

Archaeoglobus and methanogens share some characteristics. We learned in Section 13.20 about the unique biochemistry of methanogenesis. Briefly, this process requires a series of novel coenzymes,

(a)

(b)

Figure 16.13 *Archaeoglobales*. (a) Transmission electron micrograph of the sulfate-reducing hyperthermophile *Archaeoglobus fulgidus*. The cell measures 0.7 μm in diameter. (b) Freeze-etched electron micrograph of *Ferroglobus placidus*, a ferrous iron-oxidizing, nitrate-reducing hyperthermophile. The cell measures about 0.8 μm in diameter.

and with rare exceptions, these coenzymes have only been found in methanogens. Surprisingly, however, *Archaeoglobus* also contains many of these coenzymes and cultures of this organism actually produce small amounts of CH₄. Thus, *Archaeoglobus*, which also shows a rather close phylogenetic relationship to methanogens (Figure 16.1), may be a metabolically intermediate type of organism, bridging the energy-conserving processes of methanogenesis and other forms of respiration among Archaea. Not surprisingly then, the genome of *Archaeoglobus*, which contains about 2400 genes, shares a number of genes in common with methanogens (Section 16.2).

Ferroglobus

Ferroglobus (Figure 16.13b) is related to *Archaeoglobus* but is not a sulfate reducer. Instead, *Ferroglobus* is an iron-oxidizing chemolithotroph, conserving energy from the oxidation of Fe²⁺ to Fe³⁺ coupled to the reduction of nitrate (NO₃⁻) to nitrite (NO₂⁻) (see Table 16.6). *Ferroglobus* grows autotrophically and can also use H₂ or H₂S as electron donors in its energy metabolism. *Ferroglobus* was isolated from a shallow marine hydrothermal vent and grows optimally at 85°C.

Ferroglobus is interesting for several reasons, but especially for its ability to oxidize Fe²⁺ to Fe³⁺ under anoxic conditions. This process might help explain the origin of the abundant Fe³⁺ in ancient rocks such as the banded iron formations (☞ Section 12.2), rocks dated to before the predicted appearance of cyanobacteria on Earth. With organisms like *Ferroglobus*, it would have been possible for Fe²⁺ oxidation to proceed without the need for molecular oxygen (O₂) as an electron acceptor. The metabolism of *Ferroglobus* thus has implications for dating the origin of cyanobacteria and the subsequent oxygenation of Earth. Certain anoxygenic phototrophic bacteria can also oxidize Fe²⁺ under anoxic conditions (☞ Sections 13.3 and 13.9), and so several anaerobic routes to ancient Fe³⁺ are possible. This makes it difficult to estimate when cyanobacteria first appeared on Earth and to what degree nonphototrophic organisms helped trigger the Great Oxidation Event (☞ Figure 12.1).

II • Thaumarchaeota, Nanoarchaeota, and Korarchaeota

Our understanding of Archaea has been revolutionized by development of molecular phylogeny (☞ Sections 12.4 and 12.5) and methods for studying microorganisms without the need for cultivation in laboratory cultures (☞ Sections 18.5–18.7). The Thaumarchaeota, Nanoarchaeota, and Korarchaeota were all discovered and characterized initially with the aid of techniques for analysis of 16S ribosomal RNA genes. From these initial efforts, species representing each of these phyla were subsequently isolated or at least grown in enrichment cultures. We begin our consideration of these unusual phyla with the Thaumarchaeota.

16.6 Thaumarchaeota and Nitrification in Archaea

Key Genera: *Nitrosopumilus*, *Nitrososphaera*

Early surveys of 16S ribosomal RNA genes from open ocean microbial communities resulted in the shocking conclusion that Archaea were abundant and widespread in the oceans. At the time, the archaeal domain was considered to contain only extremophiles and obligate anaerobes, and their presence in oxygen-rich temperate and even polar oceanic environments was something of a mystery. Even more remarkable, these novel Archaea were widespread and common in soils all over the world. Phylogenetic analysis of their 16S ribosomal RNA gene sequences initially suggested that this novel group of Archaea was a deeply divergent lineage of the Crenarchaeota, a group of hyperthermophilic Archaea (see Section 16.9). It was only after genome sequence analysis of the marine nitrifier *Nitrosopumilus maritimus* that it became clear that the Thaumarchaeota are a distinct phylum of Archaea. Analyses of genome sequences confirm that Thaumarchaeota constitute a unique phylum of Archaea and that they diverged from the primary line of archaeal descent prior to the divergence of Crenarchaeota and Euryarchaeota (Figure 16.1).

Physiological Characteristics of Thaumarchaeota

The physiology of Thaumarchaeota remained a mystery until the isolation of *Nitrosopumilus maritimus* (Figure 16.14). *N. maritimus* grows chemolithotrophically by aerobically oxidizing ammonia (NH₃) to nitrite (NO₂⁻), the first step in nitrification (☞ Sections 13.10, 14.13, and 20.3). This organism uses CO₂ as its sole carbon source (autotrophy), as do nitrifying Bacteria (☞ Section 14.13). However, unlike ammonia-oxidizing Bacteria such as *Nitrosomonas*, *N. maritimus* is adapted to life under extreme nutrient limitation, as would befit an organism indigenous to open ocean waters. *N. maritimus* can grow at NH₃ concentrations that are a hundred times lower than those required by bacterial nitrifiers, and are actually growth inhibited at the higher NH₃ concentrations required to support growth of nitrifying species of Bacteria.

Several species of Thaumarchaeota have been isolated and characterized, revealing a number of properties common to this group. Species have been isolated from habitats including the oceans, marine sediment, an estuary, soil, and hot springs. All

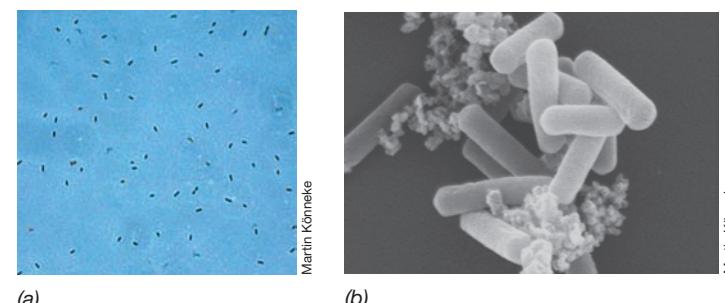

Figure 16.14 *Nitrosopumilus maritimus*, a nitrifying species of Archaea.

existing isolates are chemolithotrophic ammonia-oxidizers, and most species, like *N. maritimus*, are able to grow at very low concentrations of NH₃. The membranes of all *Thaumarchaeota* also have a unique lipid called *crenarchaeol* (➡ Figure 2.17c), a compound limited to species of this phylum. In addition, autotrophy in *Thaumarchaeota* is supported by the 3-hydroxypropionate/4-hydroxybutyrate cycle, which further distinguishes archaeal nitrifiers from nitrifying *Bacteria* that employ the Calvin cycle for CO₂ fixation (➡ Section 13.5). The 3-hydroxypropionate/4-hydroxybutyrate cycle also allows for the assimilation of organic carbon, and some archaeal nitrifiers have been shown to assimilate pyruvate during mixotrophic growth. Growth temperatures of *Thaumarchaeota* vary widely, as some species thrive in polar seas while others inhabit hot spring environments up to about 75°C.

Nitrososphaera viennensis, which represents a lineage of *Thaumarchaeota* found widely in soils, can grow at a wide range of NH₃ concentrations. Like marine species of *Thaumarchaeota*, *N. viennensis* can grow at low concentrations of NH₃, but *N. viennensis* can also tolerate high levels (up to 10 mM) of ammonium at neutral pH. Hence, *N. viennensis*, and other archaeal nitrifiers, may be active in soils that have fairly high levels of ammonia and in these environments they may compete directly with bacterial nitrifiers. In addition, several species of *Thaumarchaeota*, including *N. viennensis*, possess urease activity. *N. viennensis* can grow with urea as the sole source of energy, hydrolyzing it to ammonia, which is subsequently used as an electron donor.

Environmental Distribution of *Thaumarchaeota*

We now know that *Thaumarchaeota*, ubiquitous in soils and found throughout the marine water column from the equator to the polar seas, are one of the most abundant and widespread phyla on our planet. In surveys of soil or marine samples, thaumarchaea are often found to be the dominant group of *Archaea*. By using fluorescent phylogenetic probes (FISH, ➡ Section 18.4), thaumarchaea have been detected in oxic marine waters worldwide; they thrive even in waters and sea ice near Antarctica (Figure 16.15). Marine species are planktonic (suspended freely or attached to suspended particles in the water column, Figure 16.15b) and

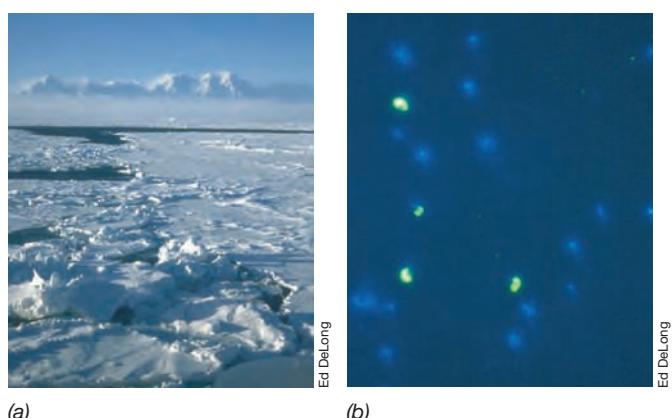

Figure 16.15 Cold-dwelling *Thaumarchaeota*. (a) Photo of the Antarctic Peninsula taken from shipboard. The frigid waters that lie under the surface ice shown here are habitats for cold-dwelling *Thaumarchaeota*. present in significant numbers ($\sim 10^4/\text{ml}$) in waters that are both nutrient-poor and very cold (0–4°C in seawater and below 0°C in sea ice). Marine thaumarchaea are found throughout the oceans and may constitute 20% of picoplankton (very small prokaryotes) worldwide. They are particularly abundant in the deep ocean where they can also account for up to 40% of picoplankton (➡ Section 19.12). The NH₃ concentration in marine waters is often at the threshold for archaeal nitrification, suggesting that *Thaumarchaeota* may play a major role in controlling the levels of NH₃ in the oceans (see “Genomics and New Archaea,” page 183).

Thaumarchaea are also common in soils, comprising as much as 1–2% of the total ribosomal RNA in soil communities and, in some soils, outnumbering nitrifying *Bacteria* by 1000-fold. They are found in soils across a wide range of pH from 3.5 to 8.7. While widely present in soils, thaumarchaea may be particularly important in acid soils (pH < 5.5), which make up more than 30% of all soils. Nitrifiers oxidize NH₃, but at low pH, NH₄⁺ predominates and is thus unavailable for nitrification. While nitrification occurs in acid soils, and often at high rates, bacterial nitrifiers have not been observed to grow below pH 6.3. In contrast, the thaumarchaeotal species *Nitrosotalea devanaterra*, isolated from acidic agricultural soil, grows optimally at pH 4–5. The ability of thaumarchaea to grow at low NH₃ concentrations explains how they can be successful in acidic soils where free NH₃ is present in very low concentration.

16.7 Nanoarchaeota and the “Hospitable Fireball”

Key Genus: *Nanoarchaeum*

The *Nanoarchaeota* are represented by a single species, the highly unusual *Nanoarchaeum equitans*. *N. equitans* is one of the smallest cellular organisms known and has the smallest genome among species of *Archaea* (0.49 Mb). The coccoid cells of *N. equitans* are very small, about 0.4 µm in diameter, and have only about 1% of the volume of an *Escherichia coli* cell. They cannot grow in pure culture and replicate only when attached to the surface of their host organism, *Ignicoccus hospitalis* (Section 16.11), a hyperthermophilic species of *Crenarchaeota* whose name means “the hospitable fireball.” *N. equitans* grows to 10 or more cells per *Ignicoccus* cell and lives an apparently parasitic lifestyle (Figure 16.16), making it the only known archaeal symbiont.

Nanoarchaeum and Its Host

N. equitans and its host *Ignicoccus* were first isolated from a submarine hydrothermal vent (➡ Section 19.13) off the coast of Iceland. However, environmental sampling of 16S ribosomal RNA genes (➡ Section 18.5) indicates that organisms phylogenetically similar to *N. equitans* exist in other submarine hydrothermal vents and in terrestrial hot springs, so *Archaea* of this kind are probably distributed worldwide in suitable hot habitats. Like its host *Ignicoccus*, *N. equitans* grows at temperatures from 70 to 98°C and optimally at 90°C.

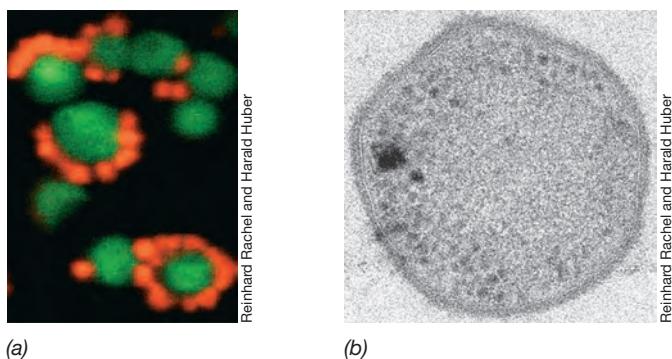

Figure 16.16 *Nanoarchaeum equitans*. (a) Fluorescence micrograph of cells of *N. equitans* (red) attached to cells of *Ignicoccus* (green). Cells were stained by FISH (Section 18.4) using specific nucleic acid probes targeted to each organism. (b) Transmission electron micrograph of a thin section of a cell of *N. equitans*. Note the distinct cell wall. Cells of *N. equitans* are about 0.4 μm in diameter. Note the unique phylogeny of *Nanoarchaeum* in Figure 16.1.

The metabolism of *Nanoarchaeum* is not fully understood, but it likely depends on its host for many metabolic functions. *Ignicoccus* is an autotroph that uses H_2 as an electron donor and S^0 as an electron acceptor and so probably supplies *N. equitans* with organic carbon. *N. equitans* is incapable of metabolizing H_2 and S^0 for energy, and whether it generates ATP from substances obtained from *Ignicoccus* or obtains its ATP directly from its host is unknown. The appearance of *N. equitans* cells is typical of *Archaea*, with a cell wall consisting of an S-layer (Section 2.12) that overlays what appears to be a periplasmic space (Figure 16.16b).

Although the sequence of its 16S ribosomal RNA gene clearly places *N. equitans* in the domain *Archaea*, the sequence differs at many sites from 16S ribosomal RNA gene sequences from other *Archaea*, even in regions of the molecule that are highly conserved among *Archaea*. These differences initially led to the conclusion that *N. equitans* was an early-branching lineage of *Archaea* (Figure 12.13). However, more detailed phylogenetic analyses of genes encoding ribosomal proteins suggest that the divergence of *N. equitans* occurred at about the time that the *Euryarchaeota* were formed (Figure 16.1). Some analyses even suggest that *N. equitans* may be a species of *Euryarchaeota*. However, genomic analyses show the organism to lack several genes that encode information processing and cell division in *Euryarchaeota*. Conclusive phylogenetic placement of the *Nanoarchaeota* will ultimately require the discovery of more species from this group.

The *N. equitans* Genome

The sequence of the *N. equitans* genome provides insight into this organism's obligately parasitic lifestyle. Its single, circular genome is only 490,885 nucleotides long, one of the smallest cellular genomes yet sequenced (Table 6.1). Genes for several important metabolic functions are missing from the *N. equitans* genome, including those for the biosynthesis of amino acids, nucleotides, coenzymes, and lipids. Also missing are genes encoding proteins for widely distributed catabolic pathways, such as glycolysis. Presumably, all of these functions are carried out for *N. equitans* by its *Ignicoccus* host, with transfer of needed substances from *Ignicoccus* to the attached *N. equitans* cells. *N. equitans* also lacks some

of the genes necessary to encode ATPase, and this indicates that it may not synthesize a functional ATPase. If true, this would be a first for cellular organisms. If no ATPase is present and substrate-level phosphorylation does not occur (due to the lack of glycolytic enzymes), then *N. equitans* would be dependent on *Ignicoccus* for energy as well as carbon.

With so many genes missing, which genes remain in the *N. equitans* genome? *N. equitans* contains genes encoding the key enzymes for DNA replication, transcription, and translation as well as genes for DNA repair enzymes. In addition to its small size, the genome of *N. equitans* is also among the most gene dense of any organism known; over 95% of the *N. equitans* chromosome encodes proteins. It appears that *N. equitans* is living near the limits of life in terms of cell volume and genetic capacity.

16.8 Korarchaeota and the “Secret Filament”

Key Genus: *Korarchaeum*

Ribosomal RNA sequences of *Korarchaeota* have been observed in a range of geothermal habitats, both submarine and terrestrial. However, *Korarchaeum cryptofilum*, whose name means “the cryptic filament of youth,” is the only characterized species in the phylum *Korarchaeota*.

First observed as a 16S ribosomal RNA gene phylotype recovered from the hot spring named Obsidian Pool in Yellowstone National Park, USA, *K. crypto filum* has yet to be grown in pure culture, as for *N. equitans* (Section 16.7). However, its genome sequence has been determined from metagenomic analyses (see Sections 6.10 and 18.7) of an enrichment culture. *K. crypto filum* is an obligately anaerobic chemoorganotroph and a hyperthermophile, growing at 85°C. Cells are long, thin (<0.2- μm diameter) filaments of variable length (Figure 16.17a–c), with most filaments being around 15 μm long but some reaching as much as 100 μm . Filaments of *K. crypto filum* have a tough paracrystalline S-layer (Figure 16.17d), which maintains cell integrity in its extremely hot habitat.

Though *K. crypto filum* cannot be grown in isolation, its genome sequence provides clues about its lifestyle. *K. crypto filum* lacks the ability to perform anaerobic respiration (with the possible exception of proton reduction, Section 13.21) and lives a fermentative lifestyle. Similar to other archaeal hyperthermophiles, *K. crypto filum* grows by fermentation of peptides or amino acids (see Table 16.6). *K. crypto filum* lacks many core genes in biosynthesis including the ability to synthesize purines, coenzyme A, and several essential cofactors. Presumably *K. crypto filum* obtains these essential components from its environment. The inability of *K. crypto filum* to synthesize molecules essential for its own growth may be explained by the evolution of mutual dependence as described by the Black Queen hypothesis (Explore the Microbial World, Chapter 12). This dependence on other

(b) Phase-contrast image of filaments of *K. crypto filum*. (c) Scanning electron micrograph of a *K. crypto filum* filament. (d) Transmission electron micrograph of the surface of a *K. crypto filum* filament showing the paracrystalline S-layer (➡ Section 2.12). members of the hot spring microbial community may explain why *K. crypto filum* has proven difficult to obtain in pure culture.

As with the *Nanoarchaeota*, there is some uncertainty about the phylogenetic position of the *Korarchaeota*. The genome of *K. crypto filum* includes some gene families that share affinity with *Euryarchaeota* and others that share affinity with *Crenarchaeota*. For example, phylogenetic analysis of ribosomal proteins, RNA polymerase subunits, and ribosomal RNA genes indicate affinity between *Crenarchaeota* and *Korarchaeota*. In contrast, genes for cell division, tRNA maturation, and DNA replication and

repair indicate affinity between *Euryarchaeota* and *Korarchaeota*. The unique genetic composition of *K. crypto filum* supports its placement near the base of the archaeal radiation (Figure 16.1), and future work on this interesting archaeon should clarify its actual phylogenetic position.

MINIQUIZ

- What is the most likely reason that *Korarchaeum crypto filum* has been difficult to isolate in pure culture?

III • Crenarchaeota

Among *Archaea* in laboratory culture, the *Crenarchaeota* are mostly hyperthermophiles and include species growing optimally above the boiling point of water. Many hyperthermophiles are chemolithotrophic autotrophs, and because no phototrophs can survive such temperatures, these organisms are the sole primary producers in these habitats.

16.9 Habitats and Energy Metabolism of Crenarchaeota

Most hyperthermophilic *Archaea* have been isolated from geothermally heated soils or waters containing S^0 and H_2S , and most species metabolize sulfur in one way or another. In terrestrial environments, sulfur-rich springs, boiling mud, and soils may have temperatures up to 100°C and are mildly to extremely acidic owing to the production of sulfuric acid (H_2SO_4) from the biological oxidation of H_2S and S^0 (➡ Sections 13.8 and 20.4). Such hot, sulfur-rich environments, called **solfataras**, are found throughout the world (Figure 16.18), including Italy, Iceland, New Zealand, and Yellowstone National Park in Wyoming (USA). Depending on the surrounding geology, solfataras can be mildly acidic to slightly

alkaline (pH 5–8) or extremely acidic, with pH values below 1. Hyperthermophilic crenarchaeotes have been obtained from all of these environments, but most inhabit neutral or weakly acidic thermal habitats.

Hyperthermophilic *Crenarchaeota* also inhabit undersea hot springs called **hydrothermal vents**. We discuss the geology and microbiology of these habitats in Section 19.13. Here we only note that submarine waters can be much hotter than surface waters because the water is under hydrostatic pressure. Indeed, all hyperthermophiles with growth temperature optima above 100°C originate from submarine sources. These sources include shallow (2–10 m depth) vents such as those off the coast of Vulcano, Italy, as well as deep (2000–4000 m depth) vents near ocean-spreading centers (see Figure 16.24). Deep hydrothermal vents are the hottest habitats so far known to yield prokaryotes.

With a few exceptions, hyperthermophilic *Crenarchaeota* are obligate anaerobes. Their energy-yielding metabolism is either chemoorganotrophic or chemolithotrophic (or both, for example, in *Sulfolobus*) and is dependent on diverse electron donors and acceptors. Fermentation is rare and most bioenergetic strategies involve anaerobic respirations (Table 16.6). Energy is conserved

 (a) A typical solfatara; steam rich in H₂S rises to the surface. (b) Sulfur-rich hot spring, a habitat containing dense populations of *Sulfolobus*. The acidity in solfataras and sulfur springs comes from the oxidation of H₂S and S⁰ to H₂SO₄ (sulfuric acid) by *Sulfolobus* and related prokaryotes. (c) A typical neutral pH boiling spring, Imperial Geyser. Many different species of hyperthermophilic *Archaea* may reside in such a habitat. during these respiratory processes by the same general mechanism widespread in *Bacteria*: electron transfer within the cytoplasmic membrane leading to the formation of a proton motive force from which ATP is made by way of proton-translocating ATPases (☞ Section 3.11). Classical substrate-level phosphorylation, a hallmark of fermentative *Bacteria* (☞ Section 3.7), is unknown in *Archaea*.

Many hyperthermophilic crenarchaeotes can grow chemolithotrophically under anoxic conditions, with H₂ as the electron donor and S⁰ or NO₃⁻ as the electron acceptor; a few can also oxidize H₂ aerobically (Table 16.6). H₂ respiration with ferric iron (Fe³⁺) as electron acceptor also occurs in several hyperthermophiles. Other chemolithotrophic lifestyles include the oxidation of S⁰ and Fe²⁺ aerobically or Fe²⁺ anaerobically with NO₃⁻ as the acceptor (Table 16.6). Only one sulfate-reducing hyperthermophile is known (the euryarchaeote *Archaeoglobus*, Section 16.5). The only bioenergetic option apparently impossible is photosynthesis, a means of energy conservation that is apparently limited to temperatures below 74°C (see Figure 16.28).

16.10 Crenarchaeota from Terrestrial Volcanic Habitats

Key Genera: *Sulfolobus*, *Acidianus*, *Thermoproteus*, *Pyrobaculum*

Terrestrial volcanic habitats can have temperatures as high as 100°C and are thus suitable for hyperthermophilic *Archaea*. Two phylogenetically related organisms isolated from these environments are *Sulfolobus* and *Acidianus*. These genera form the heart of an order called the *Sulfolobales* (Table 16.7). In addition, *Sulfolobus* has been a model organism for molecular biology studies of *Archaea*.

Sulfolobales

Sulfolobus grows in sulfur-rich acidic thermal areas (Figure 16.18) at temperatures up to 90°C and at pH values of 1–5. *Sulfolobus* is an aerobic chemolithotroph that oxidizes H₂S or S⁰ to H₂SO₄ and fixes CO₂ as a carbon source. *Sulfolobus* can also grow chemoorganotrophically. Cells of *Sulfolobus* are more or less spherical but contain distinct lobes (Figure 16.19a). Cells adhere tightly to sulfur crystals, where they can be seen with a microscope after staining with fluorescent dyes (Figure 13.21b). Besides the aerobic respiration of sulfur or organic compounds, *Sulfolobus* can also oxidize Fe²⁺ to Fe³⁺, and this ability has been harnessed for the high-temperature leaching of iron and copper ores (Sections 20.5 and 21.1).

A facultative aerobe resembling *Sulfolobus* also lives in acidic solfatitic springs. This organism, *Acidianus* (Figure 16.19b), differs from *Sulfolobus* most clearly by its ability to grow using S⁰ both anaerobically as well as aerobically. Under aerobic conditions the organism uses S⁰ as an electron donor, oxidizing S⁰ to H₂SO₄, with O₂ as an electron acceptor. Anaerobically, *Acidianus* uses S⁰ as an electron acceptor with H₂ as an electron donor, forming H₂S as the reduced product. Thus, the metabolic fate of S⁰ in cultures of *Acidianus* depends on the presence or absence of O₂. Like *Sulfolobus*, *Acidianus* is roughly spherical in shape but is not as lobed (Figure 16.19b). It grows at temperatures from 65°C up to a maximum of 95°C, with an optimum of about 90°C. As a group, then, the *Sulfolobales* contain the most thermophilic of all highly acidophilic Archaea.

Thermoproteales

Key genera within the *Thermoproteales* are *Thermoproteus*, *Thermofilum*, and *Pyrobaculum*. The genera *Thermoproteus* and *Thermofilum* consist of rod-shaped cells that inhabit neutral or slightly acidic hot springs. Cells of *Thermoproteus* are rigid rods about 0.5 μm in diameter and highly variable in length, ranging from short cells of 1–2 μm (Figure 16.20a) up to filaments 70–80 μm long. Filaments of *Thermofilum* are thinner, some as little as 0.17–0.35 μm wide, with filament lengths ranging up to 100 μm (Figure 16.20b).

Both *Thermoproteus* and *Thermofilum* are strict anaerobes that carry out an S⁰-based anaerobic respiration (Table 16.6). Most *Thermoproteus* isolates can grow chemolithotrophically on H₂ or chemoorganotrophically on complex carbon substrates such as yeast extract, small peptides, starch, glucose, ethanol, malate, fumarate, or formate (Table 16.6). *Pyrobaculum* (Figure 16.20c) is a rod-shaped hypertherophile but is physiologically distinct from other *Thermoproteales* in that some species of *Pyrobaculum* can respire aerobically. However, *Pyrobaculum* can also grow by anaerobic respiration with NO₃⁻, Fe³⁺, or S⁰ as electron acceptors and H₂ as an electron donor (that is, they can grow chemolithotrophically and autotrophically). Other species of *Pyrobaculum* can grow anaerobically on organic electron donors, reducing S⁰ to H₂S. The growth temperature optimum of *Pyrobaculum* is 100°C, and species of this organism have been isolated from terrestrial hot springs and from hydrothermal vents.

16.11 Crenarchaeota from Submarine Volcanic Habitats

Key Genera: *Pyrodictium*, *Pyrolobus*, *Ignicoccus*, *Staphylothermus*

We now consider the microbiology of submarine volcanic habitats, homes to the most thermophilic of all known *Archaea*. These habitats include both shallow-water thermal springs and deep-sea hydrothermal vents. We discuss the geology of these fascinating microbial habitats in Section 19.13 and the interesting animal communities that develop there in Section 22.12. The organisms to be described here constitute an order of *Archaea* called the *Desulfuroccales* (Table 16.7).

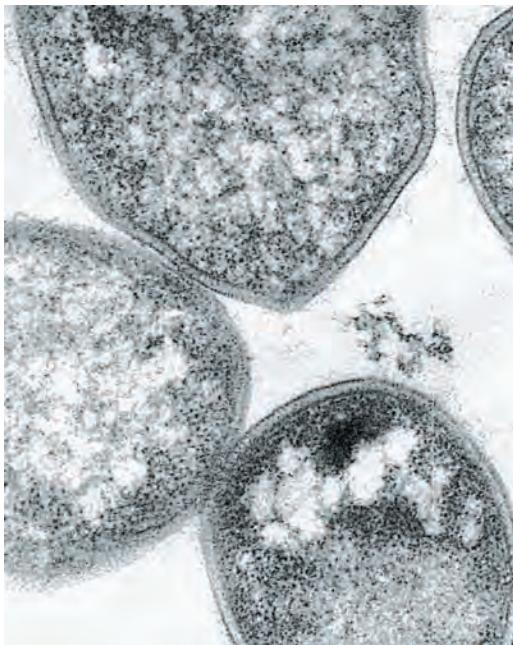

Pyrodictium* and *Pyrolobus

Pyrodictium and *Pyrolobus* are examples of microorganisms whose growth temperature optimum lies above 100°C; the optimum for *Pyrodictium* is 105°C and for *Pyrolobus* is 106°C. Cells of *Pyrodictium* are irregularly disc-shaped and grow in culture in a mycelium-like layer attached to crystals of S⁰. The cell mass consists of a network of fibers to which individual cells are attached (Figure 16.21a). The fibers are hollow and consist of protein arranged in a fashion similar to that of bacterial flagella (► Section 2.17). However, the filaments do not function in motility but instead as organs of attachment. The cell walls of *Pyrodictium* are composed of glycoprotein. Physiologically, *Pyrodictium* is a strict anaerobe that grows chemolithotrophically on H₂ as an electron donor and S⁰ as an electron acceptor or chemorganotrophically on complex mixtures of organic compounds (Table 16.6).

Pyrolobus fumarii (Figure 16.21c) is one of the most thermophilic of the hyperthermophiles. Its growth temperature

Although the temperature optimum of *P. aerophilum* is 100°C, optima for other Thermoproteales are all below 90°C (Table 16.7).

maximum is 113°C (Table 16.7). *P. fumarii* lives in the walls of “black smoker” hydrothermal vent chimneys (➡ Section 19.13 and Figures 19.35, 19.37, and 19.38) where its autotrophic abilities contribute organic carbon to this otherwise inorganic environment. *P. fumarii* cells are coccoid-shaped (Figure 16.21c), and the cell wall is composed of protein. The organism is an obligate H₂ chemolithotroph, growing by the oxidation of H₂ coupled to the reduction of NO₃⁻ to ammonium (NH₄⁺), thiosulfate (S₂O₃²⁻) to H₂S, or very low concentrations of O₂ to H₂O. Besides its extremely thermophilic nature, *P. fumarii* can withstand temperatures substantially above its growth temperature maximum. For example, cultures of *P. fumarii* survive autoclaving (121°C) for 1 h, a condition that even bacterial endospores (➡ Section 2.16) cannot withstand.

Another organism in this group shares with *Pyrolobus* a growth temperature optimum of 106°C. However, “Strain 121,” as this organism has been called, actually shows weak growth at 121°C, and cells remain viable for 2 h at 130°C. Only *Methanopyrus*, a hyperthermophilic methanogen, can grow at a higher temperature (122°C, Section 16.4). Strain 121 consists of coccoid, flagellated cells (Figure 16.21d); the organism is also a strict anaerobe and grows chemolithotrophically and autotrophically with Fe³⁺ as electron acceptor and formate or H₂ as electron donors. It is thus clear that the *Pyrodictium/Pyrolobus* group collectively contains the most hyperthermophilic examples of all known prokaryotes.

Desulfurococcus and Ignicoccus

Other notable members of the Desulfurococcales include *Desulfurococcus*, the genus for which the order is named (Figure 16.22), and *Ignicoccus*. *Desulfurococcus* is a strictly anaerobic S⁰-reducing

(c) Thin section of a cell of *Pyrolobus fumarii*, one of the most thermophilic of all known bacteria (growth temperature optimum, 106°C); a cell is about $1.4\text{ }\mu\text{m}$ in diameter. (d) Negative stain of a cell of "Strain 121," capable of growth at 121°C ; a cell is about $1\text{ }\mu\text{m}$ wide. Although the *Desulfurococcales* contain the greatest number of hyperthermophiles capable of growth above 100°C , the most thermophilic of all known Archaea is actually a euryarchaeote, *Methanopyrus* (Section 16.4).

organism like *Pyrodictium*, but differs from this organism in its phylogeny and the fact that it is much less thermophilic, growing optimally at about 85°C .

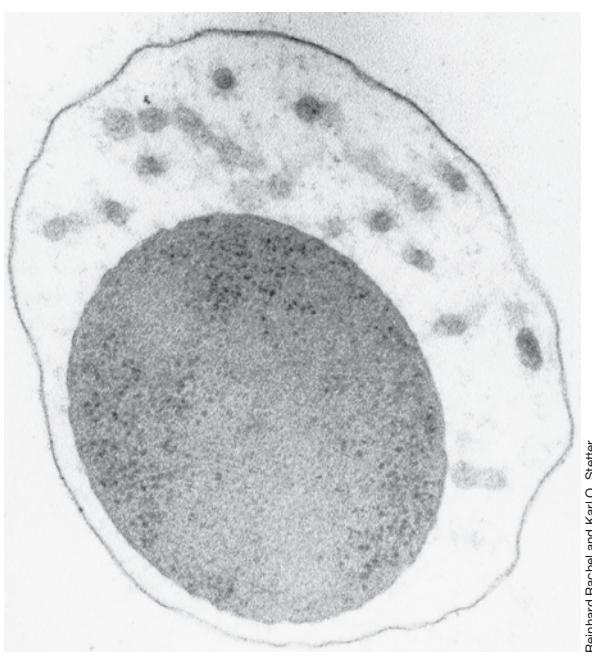

Ignicoccus grows optimally at 90°C , and its energy metabolism is based on H_2 as an electron donor and S^0 as an electron acceptor, as is that of so many hyperthermophilic Archaea (Table 16.6). Some *Ignicoccus* species are hosts to the small parasitic archaeon, *Nanoarchaeum equitans* (Section 16.7). *Ignicoccus* (Figure 16.22b) has a novel cell structure that lacks an S-layer and possesses a unique *outer cellular membrane*. This outer cellular membrane is distinct in several ways from the outer membrane of gram-negative *Bacteria* (Section 2.11). Most notably, the outer cellular membrane of *Ignicoccus* contains ATPase and is the site of energy conservation. *Ignicoccus* also contains an inner cellular membrane that contains the

cytoplasm and the enzymes responsible for biosynthesis and information processing. In this way neither the outer nor inner cellular membrane satisfies the typical definition of a cytoplasmic membrane (Section 2.7).

Between the inner and outer cellular membranes of *Ignicoccus* is a large *intermediate compartment* that is analogous to the periplasm of gram-negative *Bacteria* but is much larger in volume, representing some two to three times the volume of the cytoplasm (Figure 16.22b). The periplasm of *Ignicoccus* also contains membrane-bound vesicles (Figure 16.22b) that may function in exporting substances outside the cell. In this way, the cell structure of *Ignicoccus* resembles that of *Eukarya*. Hence, *Ignicoccus* has been proposed to be a modern descendant of the ancestral cell type that gave rise to the origin of eukaryotic cells (Figure 12.9).

Staphylothermus

A morphologically unusual member of the order *Desulfurococcales* is the genus *Staphylothermus* (Figure 16.23). Cells of *Staphylothermus* are spherical, about 1 µm in diameter, and form aggregates of up to 100 cells, much like its morphological counterpart among the *Bacteria*, *Staphylococcus* (► Figures 15.20 and 29.29a). Unlike many hyperthermophiles, *Staphylothermus* is not a chemolithotroph, but instead a chemoorganotroph, growing optimally at 92°C. Energy is obtained from the fermentation of peptides, producing the fatty acids acetate and isovalerate as fermentation products (Table 16.6).

Isolates of *Staphylothermus* have been obtained from both shallow marine hydrothermal vents and very hot black smokers (see Figure 16.24; ► Section 19.13). This organism is apparently widely distributed in submarine thermal areas, where it is likely to play a significant role in consuming proteins released from dead organisms.

MINIQUIZ

- What can we conclude about the *Pyrodictium/Pyrolobus* group in terms of life at high temperature?
- What unusual structural features are present in *Ignicoccus* and *Staphylothermus*?

IV • Evolution and Life at High Temperatures

Most of the hyperthermophiles discovered so far are species of *Archaea* and some grow near to what may be the upper temperature limit for life. Here we consider the major factors that likely define the upper temperature limit for life and the biological adaptations of hyperthermophiles that permit them to exist at the exceptionally high temperatures of 100°C and higher. We end with a discussion of the importance of hydrogen (H₂) metabolism to the biology of hyperthermophiles.

16.12 An Upper Temperature Limit for Microbial Life

Habitats that contain liquid water—a prerequisite for cellular life—and that have temperatures higher than 100°C are only found where geothermally heated water flows out of vents or rifts in the ocean floor (► Figures 12.3 and 19.34–19.38). The hydrostatic pressure that overlies the water keeps it from boiling, allowing it to reach

temperatures of up to about 400°C in vents at several thousand meters' depth. In contrast, terrestrial hot springs can boil and therefore only attain temperatures near 100°C. It is not surprising, then, that hydrothermal vents have been rich sources of hyperthermophilic *Archaea* with growth temperature optima above 100°C (Table 16.7).

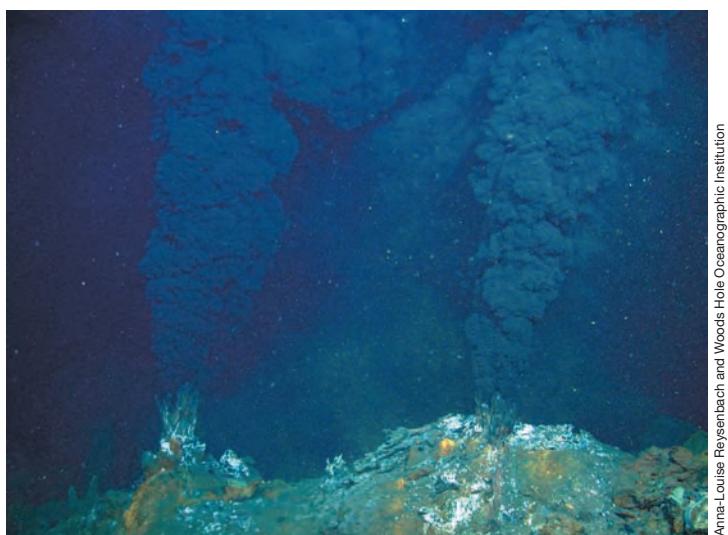

Black smokers emit hydrothermal vent fluid at 250–350°C or higher. Metallic mounds or more upright structures called *chimneys* form from the metal sulfides that precipitate out of the hot fluid as it mixes with the surrounding, much cooler seawater (Figure 16.24). As far as is known, the superheated vent water itself is sterile. However, hyperthermophiles thrive in mounds or smoker chimney walls where temperatures are compatible with their survival and growth (☞ Section 19.13 and Figure 19.37). By studying structures such as these, we can address the question, “What is the upper temperature for microbial (and presumably all forms of) life?”

What Is the Upper Temperature Limit for Life?

How high a temperature can hyperthermophiles withstand? Over the past several decades, the known upper temperature limit for life has been pushed higher and higher with the isolation and characterization of new species of thermophiles and hyperthermophiles (Figure 16.25). For some time the record holder was *Pyrolobus fumarii* (Figure 16.21c), with its upper temperature limit for growth of 113°C. The current record holder, *Methanopyrus* (Section 16.4 and Figure 16.12), however, has pushed the limit somewhat higher, with the ability to grow at 122°C and to survive substantial periods at even higher temperatures. Given the trend over the past several years (Figure 16.25), one can predict that *Archaea* even more hyperthermophilic than *Methanopyrus* may inhabit hydrothermal environments but have yet to be isolated. Indeed, many experts predict that the upper temperature limit for prokaryotic life is likely to exceed 140°C, perhaps even 150°C, and that the maximum temperature allowing survival but not growth is even hotter yet.

Biochemical Problems at Supercritical Temperatures

Whatever the upper temperature limit is for life, it is likely to be defined by one or more biochemical challenges that evolution has

been unable to solve. There is obviously an upper limit, but we do not yet know what it is. Water samples taken directly from superheated (>250°C) hydrothermal vent discharges are devoid of measurable biochemical markers (DNA, RNA, and protein) that would signal life as we know it, while vents emitting water at temperatures below about 150°C yield evidence of macromolecules. These results are consistent with laboratory experiments on the stability of key biomolecules. For example, ATP is degraded almost instantly at 150°C. Thus, above 150°C, any life forms would have to deal with the heat lability of a molecule that is, as far as is known, universally distributed in cells. As a caveat, however, the stability of small molecules such as ATP may be significantly greater under cytoplasmic conditions of high levels of dissolved solutes than in pure solutions tested in the laboratory. Nevertheless, if life forms exist at temperatures above 150°C, they must be unique in many ways, either using a suite of novel small molecules absent from cells as we know them, or deploying special protection systems that maintain small molecules in a stable state such that biochemistry can proceed.

16.13 Molecular Adaptations to Life at High Temperature

Because all cellular structures and activities are affected by heat, hyperthermophiles are likely to exhibit multiple adaptations to the exceptionally high temperatures of their habitats. Here we briefly

examine some adaptations employed by hyperthermophiles to protect their proteins and nucleic acids at high temperatures.

Protein Folding and Thermostability

Because most proteins denature at high temperatures, much research has been done to identify the properties of thermostable proteins. Protein thermostability derives from the folding of the molecule itself, not because of the presence of any special amino acids. Perhaps surprisingly, however, the amino acid composition of thermostable proteins is not particularly unusual except perhaps in their slight bias for increased levels of amino acids that promote alpha-helical secondary structures. In fact, many enzymes from hyperthermophiles contain the same major structural features in both primary and higher-order structure (☞ Section 4.14) as their heat-labile counterparts from organisms that grow best at much lower temperatures.

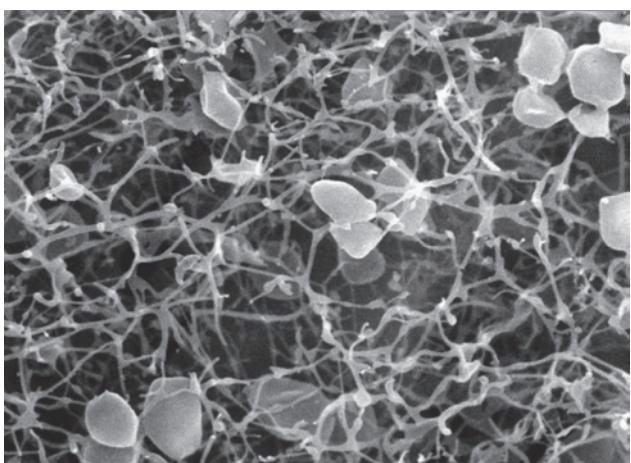

Thermostable proteins typically do display some structural features that likely improve their thermostability. These include having highly hydrophobic cores, which decrease the tendency of the protein to unfold in an ionic environment, and more ionic interactions on the protein surfaces, which also help hold the protein together and work against unfolding. Ultimately, it is the *folding* of the protein that most affects its heat stability, and noncovalent ionic bonds called *salt bridges* on a protein's surface likely play a major role in maintaining the biologically active structure. But, as previously stated, many of these changes are possible with only minimal changes in primary structure (amino acid sequence), as seen when thermostable and heat-labile forms of the same protein are compared.

Chaperonins: Assisting Proteins to Remain in Their Native State

Earlier we discussed a class of proteins called *chaperonins* (heat shock proteins; ☞ Section 4.14) that function to refold partially denatured proteins. Hyperthermophilic *Archaea* have special classes of chaperonins that function only at the highest growth temperatures. In cells of *Pyrodictium abyssi* (Figure 16.26), for example, a major chaperonin is the protein complex called the **thermosome**. This complex keeps other proteins properly folded and functional at high temperature, helping cells survive even at temperatures above their maximal growth temperature. Cells of *P. abyssi* grown near its maximum temperature (110°C) contain high levels of the thermosome. Possibly because of this, the cells can remain viable following a heat shock, such as a 1-h treatment in an autoclave (121°C). In cells experiencing such a treatment and then returned to the optimum temperature, the thermosome, which is itself quite heat-resistant, is thought to refold sufficient copies of key denatured proteins that *P. abyssi* can once again begin to grow and divide. Thus, due to chaperonin activity, the upper temperature limit at which many hyperthermophiles can *survive* is higher than the upper temperature at which they can *grow*. The “safety net” of chaperonin activity probably ensures that cells in nature that briefly experience temperatures above their growth temperature maximum are not killed by the exposure.

DNA Stability: Solutes, Reverse Gyrase, and DNA-Binding Proteins

What keeps DNA from melting at high temperatures? Various mechanisms are known to contribute. One such mechanism

increases cellular solute levels, in particular potassium (K^+) or compatible organic compounds. For example, the cytoplasm of the hyperthermophilic methanogen *Methanopyrus* (Section 16.4) contains molar levels of potassium cyclic 2,3-diphosphoglycerate. This solute prevents chemical damage to DNA, such as depurination or depyrimidization (loss of a nucleotide base through hydrolysis of the glycosidic bond) from high temperatures, events that can lead to mutation (☞ Section 10.2). This compound and other compatible solutes, such as potassium di-*myo*-inositol phosphate, which protects against osmotic stress, and the polyamines putrescine and spermidine, which stabilize both ribosomes and nucleic acids at high temperature, help maintain key cellular macromolecules in hyperthermophiles in their active forms.

A unique protein found *only* in hyperthermophiles is responsible for DNA stability in these organisms. All hyperthermophiles produce a special DNA topoisomerase called **reverse DNA gyrase**. This enzyme introduces positive supercoils into the DNA of hyperthermophiles (in contrast to the negative supercoils introduced by DNA gyrase present in all other prokaryotes; ☞ Section 4.4). Positive supercoiling stabilizes DNA to heat and thereby prevents the DNA helix from spontaneously unwinding. The noticeable absence of reverse DNA gyrase in prokaryotes whose growth temperature optima lie below 80°C strongly suggests a specific role for this enzyme in DNA stability at high temperatures.

Species of *Euryarchaeota* also contain highly basic (positively charged) DNA-binding proteins that are remarkably similar in amino acid sequence and folding properties to the core histones of the *Eukarya* (☞ Figure 2.61). Archaeal histones from the hyperthermophilic methanogen *Methanothermus fervidus* (Figure 16.7c) have been particularly well studied. These proteins wind and compact DNA into nucleosome-like structures (Figure 16.27) and maintain the DNA in a double-stranded form at very high temperatures. Archaeal histones are found in most *Euryarchaeota*, including extremely halophilic *Archaea*, such as *Haloarcula*. However, because the extreme halophiles are not thermophiles, archaeal histones may have other functions besides DNA stability, in particular in assisting in gene expression by opening the helix to allow for transcriptional proteins to bind.

Compare this micrograph with an artist's depiction of the histones and nucleosomes of Eukarya shown in Figure 2.61b.

Lipid and Ribosomal RNA Stability

How have the lipids and the protein-synthesizing machinery of hyperthermophiles adjusted to high temperatures? Virtually all hyperthermophilic *Archaea* synthesize lipids of the dibiphytanyl tetraether type (➡ Section 2.7). These lipids are naturally heat-resistant because the phytanyl units forming each half of the membrane structure are covalently bonded to one another; this yields a *lipid monolayer* membrane instead of the normal lipid bilayer (➡ Figure 2.17). This structure resists the tendency of heat to pull apart a lipid bilayer constructed of fatty acid or phytanyl side chains that are not covalently bonded.

A final point on molecular adaptations to life at high temperatures is that of the base composition of ribosomal RNAs. Ribosomal RNAs are key structural and functional components of the ribosome, the cell's protein-synthesizing apparatus (➡ Section 4.13). Hyperthermophilic species of both *Bacteria* and *Archaea* show as much as a 15% greater proportion of GC base pairs in their small ribosomal subunit RNAs compared with organisms that grow at

lower temperatures. GC base pairs form three hydrogen bonds compared to the two of AU base pairs (➡ Figure 4.2), and thus the higher GC content of the ribosomal RNAs should confer greater thermal stability on the ribosomes of these organisms and this should assist protein synthesis at high temperatures. By contrast to ribosomal RNAs, the GC content of genomic DNA of hyperthermophiles is often rather low, which suggests that the thermal stability of ribosomal RNA might be an especially significant factor for life under hyperthermophilic conditions.

16.14 Hyperthermophilic Archaea, H₂, and Microbial Evolution

When cellular life first arose on Earth nearly 4 billion years ago, it is virtually certain that temperatures were far hotter than they are today. Thus, for hundreds of millions of years, Earth may have been suitable only for hyperthermophiles. Given the discussion above on the temperature limits to life, it has been hypothesized that biological molecules, biochemical processes, and the first cells arose on Earth around hydrothermal springs and vents on the seafloor as they cooled to temperatures compatible with biological molecules (➡ Section 12.1 and Figures 12.3 and 12.4). The phylogeny of modern hyperthermophiles (Figure 16.1), as well as the similarities in their habitats and metabolism to those of early cells on Earth, suggests that hyperthermophiles may be the closest remaining descendants of ancient cells and are a living window into the biology of ancient microbial life.

Hyperthermophilic Habitats and H₂ as an Energy Source

The oxidation of H₂ linked to the reduction of Fe³⁺, S⁰, NO₃⁻, or, rarely, O₂ is a widespread form of energy metabolism in hyperthermophiles (Table 16.6 and Figure 16.28). This, coupled with the likelihood that these hyperthermophiles best characterize early Earth

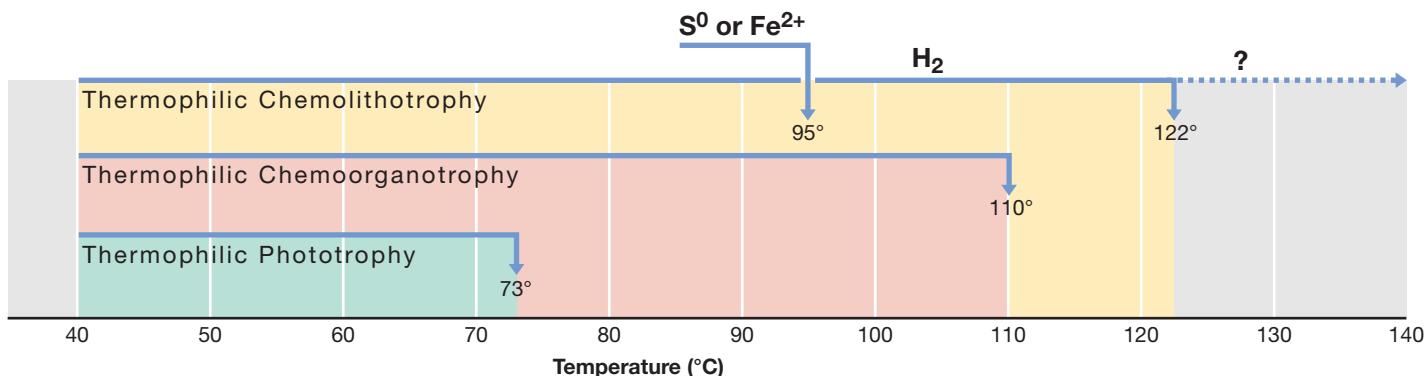

Figure 16.28 Upper temperature limits for energy metabolism. The record holder for phototrophy is *Synechococcus lividus* (*Bacteria*, cyanobacteria); for chemoorganotrophy, *Pyrodictium occultum* (*Archaea*); for chemolithotropy with S⁰ as electron donor, *Acidianus infernus* (*Archaea*); for chemolithotropy with Fe²⁺ as electron donor, *Ferroglobus placidus* (*Archaea*); and for chemolithotropy with H₂ as electron donor, *Methanopyrus kandleri* (*Archaea*, 122°C).

phenotypes, points to the important role H₂ has played in the evolution of microbial life. Hydrogen metabolism may have evolved in primitive organisms because of the ready availability of H₂ and suitable inorganic electron acceptors in their primordial environments, but also because a H₂-based energy economy requires relatively few proteins (☞ Figure 12.5). As chemolithotrophs, these organisms may have obtained all of their carbon from CO₂ or might have assimilated available organic compounds directly for biosynthetic needs. Either way it is likely that the oxidation of H₂ was the energetic driving force for maintaining life processes.

If one compares microbial energy conservation mechanisms as a function of temperature from data of cultured prokaryotes, only chemolithotrophic organisms are known at the hottest temperatures (Figure 16.28). Chemoorganotrophy occurs up to at least 110°C, as this is the upper temperature limit for growth of *Pyrodictium occultum*, an organism that can conserve energy and grow by fermentation and by chemolithotrophic growth on H₂ with S⁰ as electron

acceptor (Table 16.6). Photosynthesis is the least heat-tolerant of all bioenergetic processes, with no hyperthermophilic representatives known and an apparent upper temperature limit of 73°C. This is consistent with the conclusion that anoxygenic photosynthesis first appeared on Earth some hundreds of millions of years after the first life forms are thought to have appeared (☞ Figure 12.1).

Comparisons of bioenergetic options as a function of temperature (Figure 16.28) point to the H₂-oxidizing hyperthermophilic *Archaea* and *Bacteria* as the most likely extant examples of Earth's earliest cellular life forms. More so than any other prokaryotes, these organisms retain the metabolic and physiological traits one would predict to be necessary for existence on a hot early Earth.

BIG IDEAS

16.1 • Extremely halophilic *Archaea* require large amounts of NaCl for growth and accumulate large levels of KCl in their cytoplasm as a compatible solute. These salts affect cell wall stability and enzyme activity. The light-mediated proton pump bacteriorhodopsin helps extreme halophiles make ATP.

16.2 • Methanogenic *Archaea* are strict anaerobes whose metabolism is linked to the production of CH₄. Methane can be produced by CO₂ reduction by H₂, from methyl substrates such as CH₃OH, or from acetate.

16.3 • *Thermoplasma*, *Ferroplasma*, and *Picrophilus* are extremely acidophilic thermophiles that form their own phylogenetic family of *Archaea*. Cells of *Thermoplasma* and *Ferroplasma* lack cell walls, resembling the mycoplasmas in this regard.

16.4 • *Methanopyrus* is a hyperthermophilic methanogen that contains unusual lipids and can grow at 122°C, the highest temperature supporting growth of any life form.

16.5 • *Archaeoglobus* and *Ferroglobus* are related anaerobic *Archaea* that carry out different anaerobic respirations. *Archaeoglobus* is a sulfate reducer and *Ferroglobus* is a nitrate reducer that oxidizes ferrous iron.

16.6 • *Thaumarchaeota* are widespread and abundant in soils and marine environments. All cultivated species of thaumarchaea are autotrophic ammonia-oxidizers and these organisms are important in the global nitrogen cycle.

16.7 • *Nanoarchaeum equitans* is a hyperthermophile that forms its own phylum, the *Nanoarchaeota*, and is a parasite

of the crenarchaeote *Ignicoccus*. *N. equitans* has a tiny, highly compact genome and depends on *Ignicoccus* for most of its cellular needs, including both carbon and energy.

16.8 • *Korarchaeum cryptofilum* forms its own phylum, the *Korarchaeota*, and is a hyperthermophile that lacks important biosynthetic pathways, obtaining key building blocks from its environment. *K. cryptofilum* has some genes that are similar to *Euryarchaeota* and other genes that are similar to *Crenarchaeota*.

16.9 • A wide variety of chemoorganotrophic and chemolithotrophic energy metabolisms have been found in hyperthermophilic *Crenarchaeota*, including fermentation and anaerobic respirations. Strictly autotrophic lifestyles are common but photosynthesis is absent.

16.10 • Hyperthermophilic *Crenarchaeota* thrive in terrestrial hot springs of various chemistries. These include in particular organisms such as *Sulfolobus*, *Acidianus*, *Thermoproteus*, and *Pyrobaculum*.

16.11 • In deep-sea hydrothermal systems, *Crenarchaeota* such as *Pyrolobus*, *Pyrodictium*, *Ignicoccus*, and *Staphylothermus* thrive. With the exception of the methanogen *Methanopyrus* (*Euryarchaeota*), species of these genera grow at the highest temperatures of all *Archaea*, in many cases well above the boiling point of water.

16.12 • Life as we know it is probably limited to temperatures below 150°C. Key small molecules, such as ATP, are quickly destroyed above this temperature although extremely heat-stable macromolecules may not be.

16.13 • Macromolecules in hyperthermophiles are protected from heat denaturation by their heat-stable folding patterns (proteins), solutes and binding proteins (DNA), unique monolayer membrane architecture (lipids), and the high GC content of their ribosomal RNAs.

16.14 • Hydrogen metabolism is likely to have been the driving force behind the energetics of the earliest cells on Earth. Chemolithotrophic metabolisms based on H₂ as an electron donor are found in the most heat-tolerant of all known prokaryotes.

Horizontal Gene Transfer in an Extremophilic Eukaryote

Horizontal gene transfer (HGT) is a hallmark of *Bacteria* and *Archaea*, but what about microbial eukaryotes—does HGT occur in them as well? The answer is clearly yes, because researchers have now discovered a microbial eukaryote that has acquired several important genes from its bacterial and archaeal neighbors.

The red alga *Galdieria sulphuraria* inhabits hot, acidic, sulfur- and metal-rich environments (photo). The alga is remarkably tolerant of heat, acid, salt, and toxic metals, including arsenic, aluminum, cadmium, and mercury. A close inspection of the genome of *G. sulphuraria* (photo inset) found that at least 75 genes had been acquired by HGT from prokaryotes and that many of these conferred key extremophilic properties on this alga.¹ Chief among these were a family of genes encoding soluble ATPases found in hot spring *Archaea* that likely contribute to heat tolerance; such ATPases have not been found in any other eukaryotes.

Other key genes acquired by *G. sulphuraria* allow the alga to survive salt stress and metal toxicity and to synthesize a cytoplasmic membrane with low proton permeability, a necessity for thriving in highly acidic environments. *G. sulphuraria* also has the unusual ability (for an alga) to grow in darkness on over 50 different carbon sources. This diverse capacity has been linked to genes acquired by HGT, including genes encoding transporters for sugars, amino acids, fatty acids, and glycerol.

As more genomes from microbial eukaryotes are unraveled, the mosaic nature of the *G. sulphuraria* genome may turn out to be more common. But for now, this physiologically tough red alga stands out as a remarkable example of a microbial eukaryote whose genome has been bolstered by horizontal gene transfers across phylogenetic domains.

I • Organelles and Phylogeny of Microbial Eukaryotes

In Chapter 2 we discussed the architecture of the microbial eukaryotic cell. There we reviewed the typical components of the eukaryotic cell: the nucleus, mitochondrion, endoplasmic reticulum, and Golgi complex (structures common to virtually all eukaryotes), and the chloroplast, present in phototrophic eukaryotes (► Sections 2.20–2.22). In this chapter we consider the phylogeny and diversity of microbial eukaryotes. We begin by considering the mitochondrion and chloroplast, structures whose evolutionary history is distinct from that of the eukaryotic cell itself (► Sections 2.21 and 12.3).

17.1 Endosymbioses and the Eukaryotic Cell

Biologists agree that the eukaryotic cell is a genetic chimera. The main part of the eukaryotic cell including its cytoplasm (and likely its nucleus) can be traced to the *Eukarya* domain, whereas its energy-producing organelles—the mitochondria and chloroplasts—contain their own DNA and are clearly derived from *Bacteria*.

Initial speculation on the link between organelles and bacteria goes back over a century and was based on the fact that microscopically, mitochondria and chloroplasts “looked like” bacteria. Through the years this idea slowly gathered experimental support to yield the current view that mitochondria and chloroplasts are ancestors of respiratory or phototrophic *Bacteria*, respectively, that established residence inside another cell type as a source of ATP in exchange for a safe and stable existence. This is the **endosymbiotic hypothesis** (► Section 12.3) and is a major tenet of modern biology.

Support for the Endosymbiotic Hypothesis

Several lines of evidence support the endosymbiotic hypothesis:

- 1. Mitochondria and chloroplasts contain DNA.** Although most mitochondrial and chloroplast proteins are encoded by nuclear DNA, a few are encoded by a small genome residing within the organelle itself. These include proteins of the respiratory chain (mitochondrion) and photosynthetic apparatus (chloroplast) as well as ribosomal RNAs and transfer RNAs. Most mitochondrial DNA and all chloroplast DNA is of a covalently closed circular form like that of most *Bacteria* (► Section 1.2). Organellar DNA can be visualized in eukaryotic cells with special staining methods (Figure 17.1).
- 2. The eukaryotic nucleus contains genes derived from *Bacteria*.** Genomic sequences of eukaryotic cells have clearly shown that several nuclear genes encode functions specific to mitochondria and chloroplasts. Moreover, because these gene sequences more closely resemble those of *Bacteria* than those of *Archaea* or *Eukarya*, it is concluded that these genes were translocated to the nucleus from ancestors of mitochondria and chloroplasts during the transition from engulfed cells to dedicated organelles.
- 3. Organellar ribosomes and their phylogeny.** Ribosomes are either 80S in size, typical of the cytoplasm of eukaryotic cells,

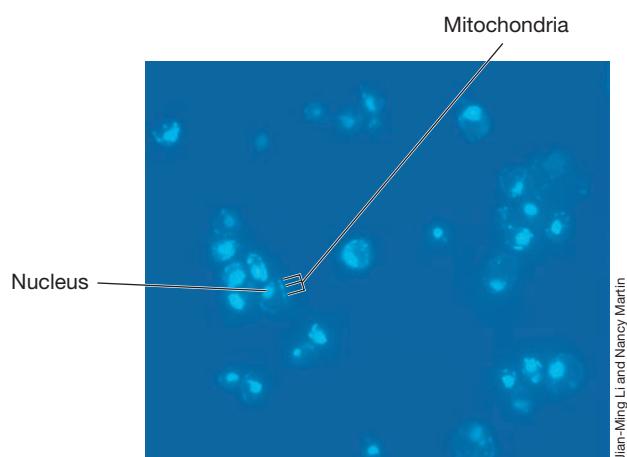

or 70S, typical of *Bacteria* and *Archaea*. Mitochondria and chloroplasts contain 70S ribosomes, and phylogenetic analyses of their ribosomal RNA gene sequences (Chapter 12) along with genomic studies of organellar DNA (► Section 6.5) show unequivocally that these structures were originally *Bacteria*.

- 4. Antibiotic specificity.** Several antibiotics (for example, streptomycin) kill or inhibit *Bacteria* by interrupting 70S ribosome protein synthesis functions. These same antibiotics also inhibit protein synthesis in mitochondria and chloroplasts.
- 5. Hydrogenosomes.** Hydrogenosomes are membrane-enclosed organelles found in certain amitochondriate eukaryotic anaerobes that supply the cell with ATP from fermentative reactions (► Figure 2.64b). Like mitochondria, hydrogenosomes also contain their own DNA and ribosomes, and phylogenetic analyses of hydrogenosome ribosomal RNA have revealed their connection to *Bacteria*.

Secondary Endosymbiosis

The mitochondrion, chloroplast, and hydrogenosome are structures that originated from *primary* endosymbiosis events. That is, these structures are derived from cells of *Bacteria*. Primary endosymbioses gave rise to the chloroplast in the common ancestor of green algae, red algae, and plants (Figure 17.2 and see Figure 17.3). However, following this primary event, several unrelated groups of nonphototrophic microbial eukaryotes also acquired chloroplasts but by *secondary* rather than primary endosymbioses. The secondary events occurred when entire green algal or red algal cells were engulfed and their chloroplasts stably retained, thereby making the engulfing cell phototrophic.

Secondary endosymbioses within the green algae account for the presence of chloroplasts in euglenids and chlorarachniophytes, while alveolates (ciliates, apicomplexans, and dinoflagellates) and stramenopiles obtained their chloroplasts through

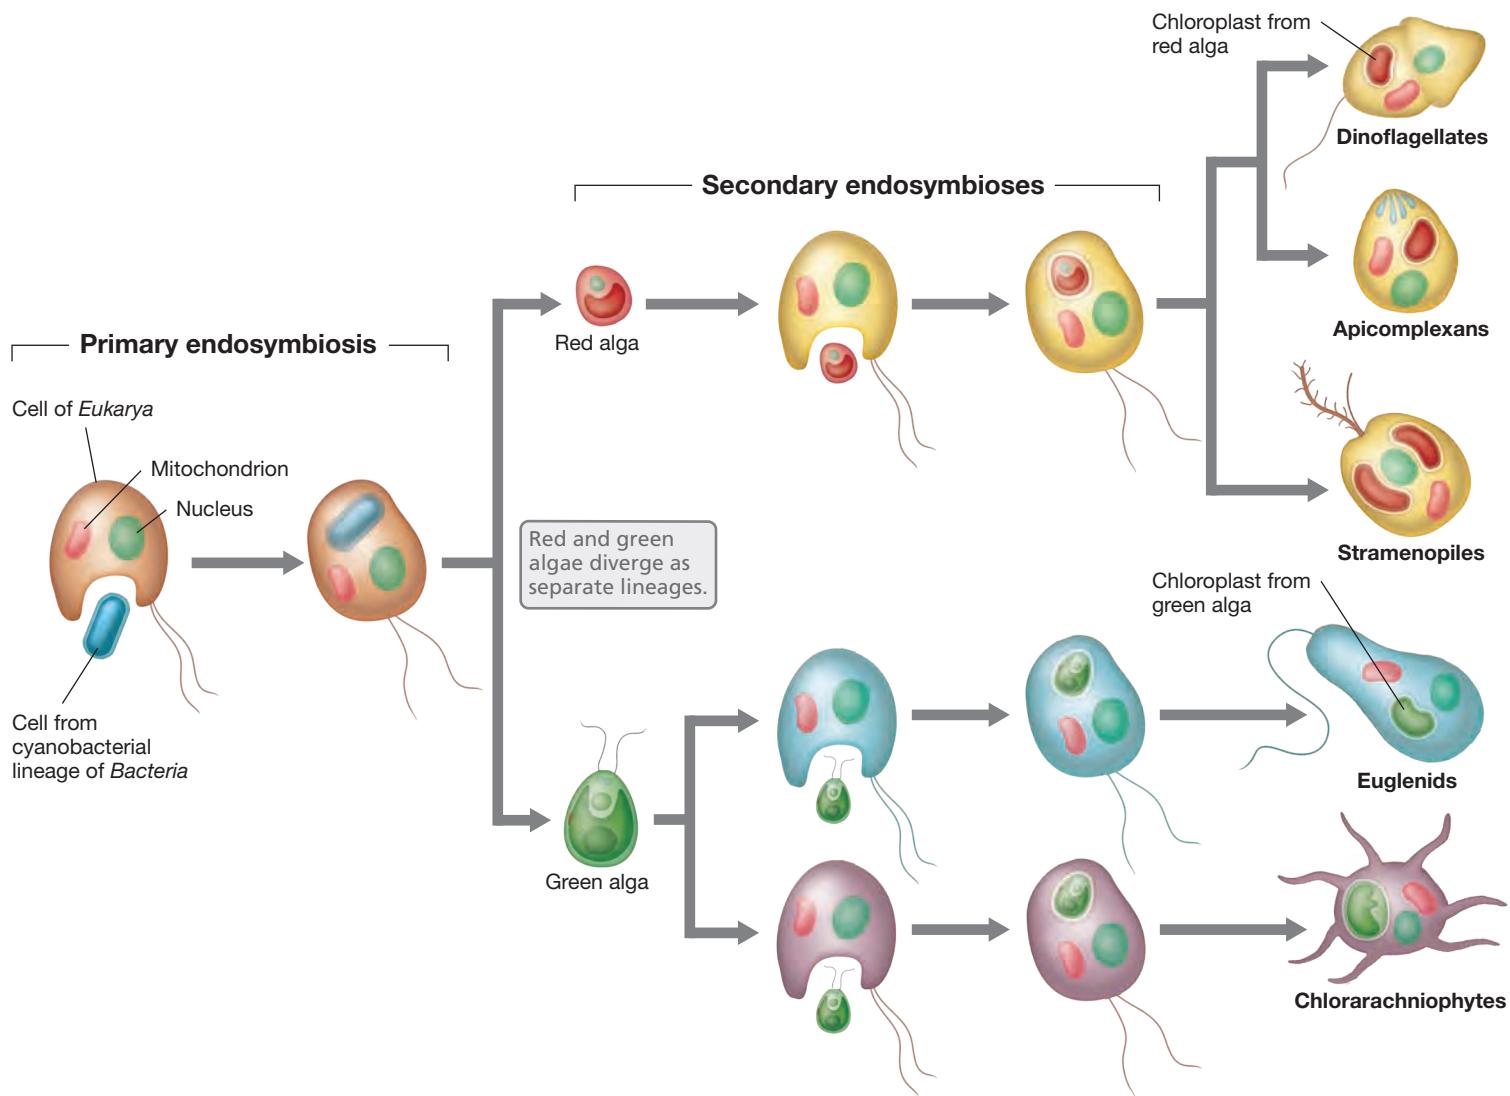

Figure 17.2 Endosymbioses. Following primary endosymbiotic association(s) leading to the mitochondrion, primary endosymbioses with phototrophic *Bacteria* led to the red and green algae. Secondary symbioses of green and red algae spread the property of photosynthesis to many independent lineages of protists.

secondary endosymbioses with red algae (Figure 17.2 and see Figure 17.3). The ancestral red algal chloroplasts were apparently lost from some lineages, such as the ciliates, or became greatly reduced in size in others, such as the apicomplexans, where only traces of chloroplasts remain. In some other organisms, such as the dinoflagellates, the red algal chloroplast was apparently replaced altogether with a chloroplast from different algae, including green algae.

These many examples of endosymbiotic events underscore the importance of endosymbiosis in the evolution and diversification of microbial eukaryotes. It is unlikely that primary endosymbiotic events occurred only once in evolutionary history—after all, trial and error is the essence of evolution—and secondary endosymbioses almost certainly occurred quite commonly (Figure 17.2). Even today there are many examples of nonphototrophic protists that engulf phototrophic protists, and the entrapped phototrophs carry out photosynthesis for extended periods (Section 22.14). Indeed, endosymbioses are apparently a common and ongoing occurrence in the eukaryotic world.

17.2 Phylogenetic Lineages of Eukarya

From the universal phylogenetic tree of life (Figures 1.6b and 12.13) we learned that *Eukarya* are more closely related to *Archaea* than to *Bacteria*. The phylogeny of microbial *Eukarya* was originally inferred from sequences of ribosomal RNA (rRNA) obtained from eukaryotic cell cytoplasmic (18S) ribosomes. However, unlike the 16S rRNA-based trees of prokaryotes, certain aspects of the 18S phylogenetic tree of eukaryotes have proven unreliable, and hence the modern eukaryal tree has been deduced from a combination of comparative sequencing methods.

The Ribosomal RNA View and Other Views of Eukaryotic Evolution

The ribosomal RNA view of eukaryal phylogeny distinguishes microbial eukaryotes such as the diplomonad *Giardia*, the microsporidian *Encephalitozoon*, and the parabasalid *Trichomonas*, as having diverged very early in the evolution of *Eukarya*, well before other organisms such as the algae and fungi (➡ Figure 1.6b). Supporting this view was the observation that these putative early-branching eukaryotes appeared phenotypically “primitive” as well, lacking mitochondria for example, and this was consistent with their having arisen before primary endosymbiotic events occurred. However, we now know that these amitochondriate eukaryotes contain hydrogenosomes, structures analogous to the mitochondrion (Section 17.1), and therefore may not be as phylogenetically “ancient” as they were once thought to be. Because of these inconsistencies, other molecular tools have been deployed to help resolve the true phylogeny of microbial eukaryotes.

Molecular sequencing of several eukaryotic genes including those encoding cytoskeleton tubulin proteins, RNA polymerase, ATPase, and heat shock proteins, has been used to generate the modern phylogenetic tree of *Eukarya*. Phylogenies based on these markers show several differences from that based on ribosomal RNA sequences. First, it appears that a major phylogenetic radiation took place as an early event in eukaryote evolution. This radiation included evolution of the ancestors of all, or virtually all, modern eukaryotic organisms. Second, the composite eukaryal tree shows that amitochondriate eukaryotes, once thought to be

basal (early evolving), are instead *highly derived* organisms, and that animals and fungi are closely related (Figure 17.3).

The tree of *Eukarya* also shows how secondary endosymbioses account for the origin of chloroplasts in some unicellular phototrophic eukaryotes. Following primary endosymbiosis of the cyanobacterial ancestor of chloroplasts by early mitochondrion-containing eukaryotes, these now phototrophic eukaryotes diverged into red and green algae. Then, in secondary endosymbioses, ancestors of the euglenozoans and cercozoans engulfed green algae while ancestors of the alveolates and stramenopiles engulfed red algae (Figures 17.2 and 17.3). These secondary endosymbioses account for the great phylogenetic diversity of phototrophic eukaryotes and are likely to have occurred relatively recently in evolutionary time.

Eukaryotic Evolution: The Big Picture

Although phylogenies based on ribosomal RNA gene sequences (Chapter 12) confirm the three domains of life—*Bacteria*, *Archaea*, and *Eukarya*—our picture of eukaryotic evolution has changed dramatically with the incorporation of other gene and protein sequences. Major new concepts include the fact that certain eukaryotic groups thought to have arisen very early probably arose more recently and that secondary endosymbioses have played a major role in spreading the capacity for photosynthesis within microbial *Eukarya* (Figure 17.3).

The origin of the mitochondrion likely predated this major radiation of eukaryotic cells, as all extant *Eukarya* contain mitochondria

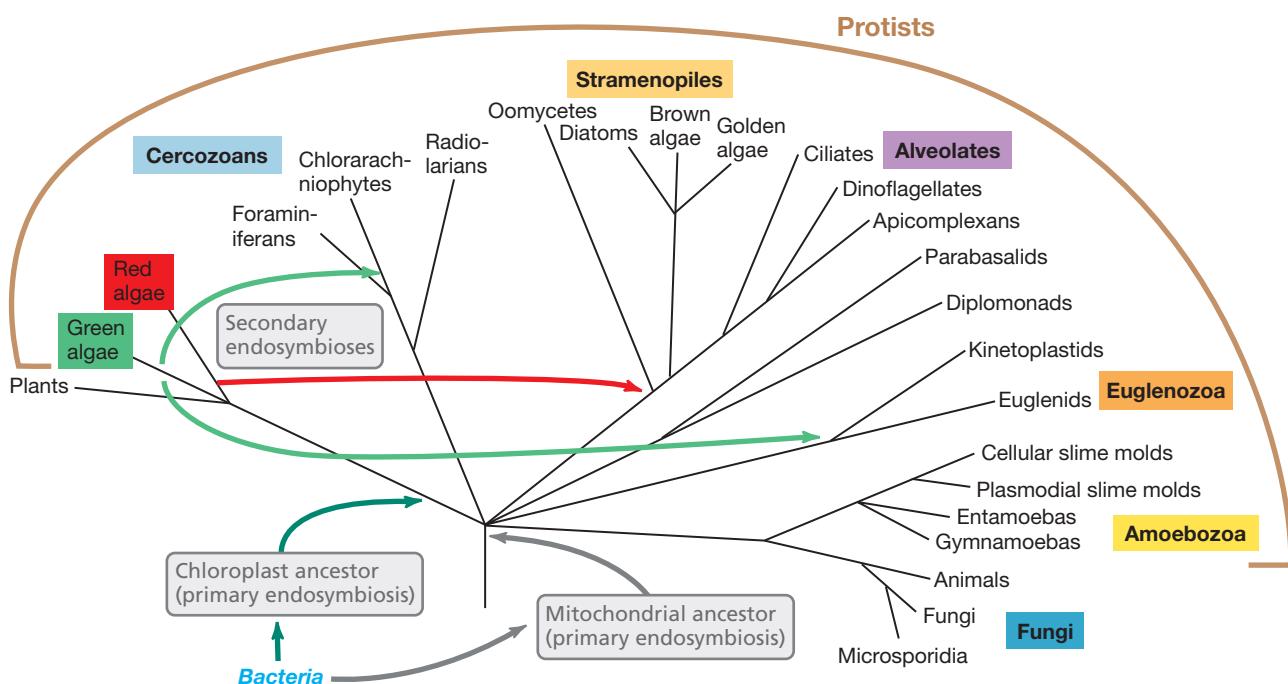

Figure 17.3 Phylogenetic tree of *Eukarya*. This composite tree is based on sequences of several genes and proteins. Dark green and red arrows indicate primary endosymbiotic events for the acquisition of the mitochondrion (red) and the chloroplast (green). Light green arrows indicate secondary endosymbiotic acquisition of chloroplasts from green algae by various protists, and the red arrow indicates secondary endosymbiotic acquisition of chloroplasts from red algae. Note that the greatest diversity in the eukaryotic world resides in the protists.

or hydrogenosomes or some genetic trace of these structures. The mitochondrion or similar structure would have provided the early eukaryotic cell with dramatic new metabolic capabilities and likely triggered the evolutionary radiation of eukaryotic microorganisms. What promoted this primary endosymbiotic event is unknown, but quite possibly it was the accumulation of O₂ in the atmosphere from cyanobacterial photosynthesis (☞ Figure 12.1). Somewhat later in evolutionary time, the ancestor of the chloroplast was acquired in a primary endosymbiotic event, with eukaryotic phototrophic diversity unfolding later through secondary endosymbioses (Figure 17.2).

The phylogenetic tree shown in Figure 17.3 should not be considered the final word on eukaryotic evolution. As new results reveal previously unsuspected aspects of eukaryotic biology, new pictures of eukaryotic phylogeny will emerge periodically. But at

this point it appears that two points are clear. First, a composite tree, rather than an 80S ribosomal RNA tree, is the scaffold upon which the eukaryotic tree of life will rest; and second, acquisition of the mitochondrion by primitive *Eukarya* was central to the evolutionary success of this domain.

II • Protists

With the big picture of eukaryotic cell phylogeny in mind, we proceed to examine the major groups of eukaryotic microorganisms. We begin with protists other than the green and red algae. **Protists** include both phototrophic and nonphototrophic microbial eukaryotes. These organisms are widely distributed in nature, exhibit a wide range of morphologies, and show great phylogenetic diversity. Indeed, protists represent much of the diversity found in the domain *Eukarya* (Figure 17.3).

17.3 Diplomonads and Parabasalids

Key Genera: *Giardia*, *Trichomonas*

Diplomonads and parabasalids are unicellular, flagellated protists that lack mitochondria and chloroplasts. They live in anoxic habitats, such as animal intestines, either symbiotically or as parasites, and conserve energy from fermentation. Some diplomonads cause serious and common diseases in fish, domestic animals, and humans, and one parabasalid causes a major sexually transmitted disease of humans. Both groups share a relatively recent common ancestor before they diverged to form separate phylogenetic lineages (Figure 17.3).

Diplomonads

Diplomonads (Figure 17.4a) characteristically contain two nuclei of equal size, and also contain mitosomes, much reduced mitochondria lacking electron transport proteins and enzymes of the citric acid cycle. The diplomonad *Giardia* has a relatively small genome for a eukaryote, about 12 megabase pairs. The genome is also quite compact, contains few introns, and lacks genes for many metabolic pathways, including the citric acid cycle (☞ Figure 3.22). These characteristics likely account for the organism's parasitic lifestyle. *Giardia intestinalis* (Figure 17.4a), also known as *Giardia lamblia*, causes giardiasis, one of the most common waterborne diarrheal diseases in the United States. We examine the disease giardiasis in Section 32.4.

Parabasalids

Parabasalids contain a *parabasal body* that, among other functions, gives structural support to the cell's Golgi complex. These

microbial eukaryotes lack mitochondria but contain hydrogenosomes for anaerobic metabolism (☞ Section 2.21). Parabasalids live in the intestinal and urogenital tract of vertebrates and invertebrates as parasites or as commensal symbionts (☞ Section 32.4). The parabasalid *Trichomonas vaginalis* is motile by a tuft of flagella (Figure 17.4b) and causes a widespread sexually transmitted disease in humans.

The genomes of parabasalids are unique among eukaryotes in that most of them lack introns, the noncoding sequences characteristic of eukaryotic genes (☞ Sections 4.9 and 6.6). In addition, the genome of *T. vaginalis* is surprisingly huge for a parasitic organism, about 160 megabase pairs, and shows evidence of genes acquired from bacteria by horizontal gene transfer. Much of the genome of *T. vaginalis* contains repetitive DNA sequences and transposable

elements (Section 10.11), which has made genomic analyses difficult. But *Trichomonas* is still thought to contain nearly 60,000 genes, about twice that of the human genome and near the upper limit observed thus far for eukaryotic genomes.

17.4 Euglenozoans

Key Genera: *Trypanosoma*, *Euglena*

Euglenozoans are a diverse assemblage of unicellular, free-living or parasitic flagellated eukaryotes that includes the kinetoplastids and euglenids. These microbial eukaryotes shared a very recent common ancestor before they diverged into separate phylogenetic lineages (Figure 17.3).

Kinetoplastids

Kinetoplastids are a well-studied group of euglenozoans and are named for the presence of the *kinetoplast*, a mass of DNA present in their single, large mitochondrion. Kinetoplastids live primarily in aquatic habitats, where they feed on bacteria. Some species, however, are parasites of animals and cause serious diseases in humans and vertebrate animals. Cells of *Trypanosoma*, a genus infecting humans, are small, about 20 µm long, thin, and crescent-shaped. Trypanosomes have a single flagellum that originates in a basal body and folds back laterally across the cell where it is enclosed by a flap of cytoplasmic membrane (Figure 17.5). Both the flagellum and the membrane participate in propelling the organism, making effective movement possible even in viscous liquids, such as blood, where pathogenic trypanosomes are often found.

Trypanosoma brucei (Figure 17.5) causes *African sleeping sickness*, a chronic and usually fatal human disease. The parasite lives and grows primarily in the bloodstream, but in the later stages of the disease it invades the central nervous system, causing an

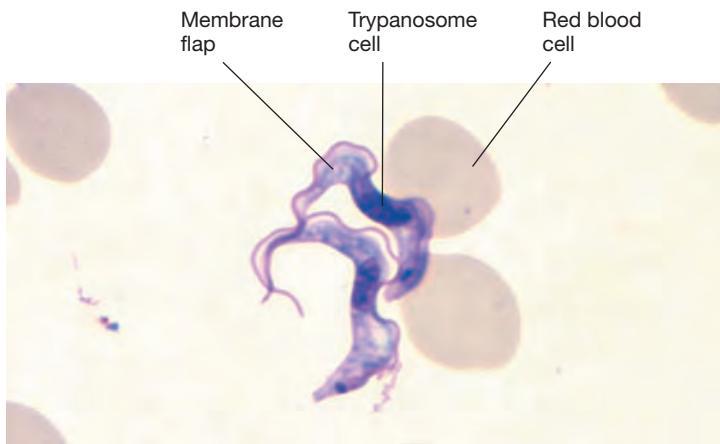

Figure 17.5 Trypanosomes. Photomicrograph of the flagellated euglenozoan *Trypanosoma brucei*, the causative agent of African sleeping sickness. Blood smear preparation. A cell is about 3 µm wide.

inflammation of the brain and spinal cord that is responsible for the characteristic neurological symptoms of the disease. The parasite is transmitted from host to host by the tsetse fly, *Glossina* spp., a bloodsucking fly found only in certain parts of Africa. After moving from the human to the fly in a blood meal, the parasite proliferates in the intestinal tract of the fly and invades the insect's salivary glands and mouthparts, from which it is transferred to a new human host by a fly bite (Section 32.6).

Other kinetoplastids that are human parasites include *Trypanosoma cruzi*, the causative agent of *Chagas' disease*, and *Leishmania* species, the causative agents of cutaneous and systemic *leishmaniasis*. Chagas' disease is spread by the bite of a blood-feeding insect called the "kissing bug." The disease is usually self-limiting, but it can become chronic and lead to a fatal infection. Leishmaniasis is a disease of tropical and subtropical regions transmitted to humans and other mammals by a bite from the sandfly. This potentially fatal disease can be localized to the skin surrounding a fly bite or can infect the spleen and liver and cause systemic infection. Both Chagas' disease and leishmaniasis are covered in more detail in Section 32.6.

Euglenids

Another well-studied group of euglenozoans are the euglenids (Figure 17.6). Unlike the kinetoplastids, these motile microbial eukaryotes are nonpathogenic and both chemotrophic and phototrophic. Most euglenids contain two flagella, dorsal and ventral, and their active motility allows the organisms to access both illuminated and dark habitats in their environment to support their alternate nutritional lifestyles.

Euglenids live exclusively in aquatic habitats, both freshwater and marine, and contain chloroplasts, which support phototrophic growth (Figure 17.6). In darkness, however, cells of *Euglena*, a typical euglenid, can lose their chloroplasts and exist as chemoorganotrophs. Many euglenids can also feed on bacterial

cells via **phagocytosis**, a process of surrounding a particle with a portion of their flexible cytoplasmic membrane to engulf the particle and bring it into the cell where it is digested.

17.5 Alveolates

Key Genera: *Gonyaulax*, *Plasmodium*, *Paramecium*

The alveolates as a group are characterized by their *alveoli*, cytoplasmic sacs located just under the cytoplasmic membrane. Although the function of alveoli is unknown, they may help the cell maintain osmotic balance by controlling water influx and efflux, and in the dinoflagellates, may function as armor plates (see Figure 17.9). Three phylogenetically distinct, although related, kinds of alveolates are known: the *ciliates*, which use cilia for motility; the *dinoflagellates*, which are motile by means of a flagellum; and the *apicomplexans*, which are animal parasites (Figure 17.3).

Ciliates

Ciliates possess *cilia* (Figure 17.7) at some stage of their life cycle. Cilia are structures that function in motility and may cover the cell or form tufts or rows, depending on the species. Probably

photosynthesize through secondary endosymbioses (Figures 17.2 and 17.3). Flagella encircling the cell impart spinning movements that give dinoflagellates their name (*dinos* is Greek for “whirling”). Dinoflagellates have two flagella of different lengths and with different points of insertion into the cell, transverse and longitudinal. The transverse flagellum is attached laterally, whereas the longitudinal flagellum originates from the lateral groove of the cell and extends lengthwise (see Figure 17.10b). Some dinoflagellates are free-living, whereas others live a symbiotic existence with animals that form coral reefs, obtaining a sheltered and protected habitat in exchange for supplying phototrophically fixed carbon as a food source for the reef.

Several species of dinoflagellates are toxic. For example, dense suspensions of *Gonyaulax* cells, called “red tides” (Figure 17.10a) due to the red-colored pigments of this organism, can form in warm and typically polluted coastal waters. Such blooms are often associated with fish kills and poisoning in humans following consumption of mussels that have accumulated *Gonyaulax* through filter feeding. Toxicity results from a neurotoxin that can cause a condition called *paralytic shellfish poisoning* in humans and some marine animals, such as sea otters. Symptoms include numbness of the lips, dizziness, and difficulty breathing; in severe cases, death can result from respiratory failure. *Pfiesteria* is another toxic dinoflagellate. Toxic spores of *Pfiesteria piscicida* (Figure 17.10b) infect fish and eventually kill them due to neurotoxins that affect movement and destroy skin. Lesions form on areas of the fish, allowing opportunistic bacterial pathogens to grow (Figure 17.10c). Symptoms of human toxemia from *Pfiesteria* poisoning include skin rashes and respiratory problems.

Apicomplexans

Apicomplexans are nonphototrophic obligate parasites that cause severe human diseases such as malaria (*Plasmodium* species) (Figure 17.11a), toxoplasmosis (*Toxoplasma*) (Figure 17.11b), and coccidioidomycosis (*Eimeria*). These organisms are characterized by nonmotile adult stages, and nutrients are taken up in soluble form across the cytoplasmic membrane as in bacteria and fungi.

(b) Scanning electron micrograph of a toxic spore of *Pfiesteria piscicida*; the structure is about 12 µm wide. (c) A fish killed by *P. piscicida*; note the lesions of decaying flesh.

Apicomplexans produce structures called *sporozoites* (Figure 17.11b), which function in transmission of the parasite to a new host, and the name apicomplexan derives from the presence at one apex of the sporozoite of a complex of organelles that penetrate host cells. Apicomplexans also contain *apicoplasts*. These are degenerate chloroplasts that lack pigments and phototrophic capacity but contain a few of their own genes. Apicoplasts catalyze fatty acid, isoprenoid, and heme biosyntheses, and export their products to the cytoplasm. It is hypothesized that apicoplasts are derived from red algal cells engulfed by apicomplexans in a secondary endosymbiosis (Figures 17.2 and 17.3). Over time, the chloroplast of the red algal cell degenerated to play a nonphototrophic role in the apicomplexan cell.

Both vertebrates and invertebrates can be hosts for apicomplexans. In some cases, an alternation of hosts takes place, with some stages of the life cycle linked to one host and some to another. Important apicomplexans are the coccidia, typically bird parasites, and species of *Plasmodium* (malaria parasites) (Figure 17.11a). We reserve detailed discussion of malaria—a disease that throughout history has killed more humans than any other disease—for Section 32.5.

17.6 Stramenopiles

Key Genera: *Phytophthora*, *Nitzschia*, *Ochromonas*, *Macrocystis*

The stramenopiles include both chemoorganotrophic and phototrophic microorganisms as well as macroorganisms. Members of this group bear flagella with many short, hairlike extensions (Figure 17.2), and this morphological feature gives the group its name (from Latin *stramen* for “straw” and *pilus* for “hair”). The diatoms, oomycetes, golden algae, and brown algae are the major groups of stramenopiles (Figure 17.3).

Diatoms

Diatoms include over 200 genera of unicellular, phototrophic, microbial eukaryotes, and are major components of the planktonic (suspended) phytoplankton microbial community in marine and fresh waters. Diatoms characteristically produce a cell wall made of silica to which protein and polysaccharide are added. The wall, which protects the cell against predation, exhibits widely different shapes in different species and can be highly ornate (Figure 17.12). The external structure formed by this wall, called a *frustule*, often remains after the cell dies and the organic materials have disappeared. Diatom frustules typically show morphological symmetry, including *pinnate symmetry* (having similar parts arranged on opposite sides of an axis, as in the common diatom *Nitzschia*, Figure 17.12b), and *radial symmetry*, as in the marine diatoms *Thalassiosira* and *Asterolampra* (Figure 17.12c, d). Because the diatom frustules, which are composed mainly of silica, are resistant to decay, these structures can remain intact for long periods of time and often sink and remain in the sediments

for millions of years. Diatom frustules constitute some of the best unicellular eukaryotic fossils known, and from dating of frustule samples, it has been shown that diatoms first appeared on Earth relatively recently, about 200 million years ago.

Oomycetes

The oomycetes, also called *water molds*, were previously grouped with fungi based on their filamentous growth and the presence of **coenocytic** (that is, multinucleate) hyphae, morphological traits characteristic of fungi (Section 17.9). Phylogenetically, however, the oomycetes are distant from fungi and are closely related to other stramenopiles (Figure 17.3). Oomycetes differ from fungi in other fundamental ways, as well. For example, the cell walls of oomycetes are typically made of cellulose instead of the chitin cell walls of fungi, and the water molds have flagellated cells, which are lacking in all but a few fungi. Nonetheless, oomycetes are ecologically similar to fungi in that they grow as a mass of hyphae decomposing dead plant and animal material in aquatic habitats.

Oomycetes have had a major impact on human society, as many species are plant pathogens (phytopathogens). The oomycete *Phytophthora infestans*, which causes late blight disease of potatoes, contributed to massive famines in Ireland in the mid-nineteenth century. The famines led to the death of a million Irish and triggered great waves of Irish immigration to North America. Other major phytopathogens include *Pythium*, a common pathogen of greenhouse seedlings, and *Albugo*, which causes “white rusts” on several agricultural crops.

Golden Algae and Brown Algae

Along with the diatoms, golden and brown algae form major lineages of stramenopiles. Golden algae, also called *chrysophytes*, are primarily unicellular marine and freshwater phototrophs. Some species are chemoorganotrophs and feed by either phagocytosis or by transporting soluble organic compounds across the cytoplasmic membrane. Some golden algae, such as *Dinobryon* (Figure 17.13a), found in freshwater, are colonial. However, most golden algae are unicellular and motile by the activity of two flagella of unequal length.

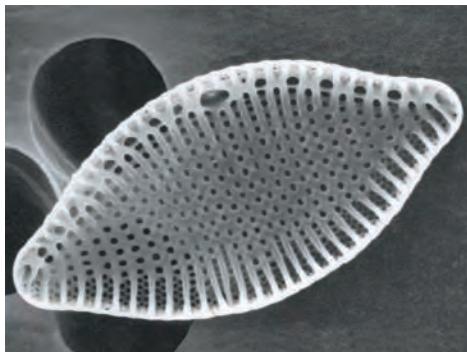

Golden algae are so named because of their golden-brown color (Figure 17.13a, c). This is due to chloroplast pigments dominated by the brown-colored carotenoid fucoxanthin. The major chlorophyll pigment in golden algae is chlorophyll c rather than chlorophyll a, and they lack the phycobiliproteins present in red algal chloroplasts (Section 17.15). Cells of the unicellular golden alga *Ochromonas*, the best-studied genus of this group, have only one or two chloroplasts (Figure 17.13c).

Brown algae are primarily marine and are multicellular and typically macroscopic. No unicellular brown algae are known. The kelps, such as the giant kelp *Macrocystis* (Figure 17.13b), which can grow up to 50 m in length, are perhaps the most widespread of brown algae. *Fucus*, another common seaweed of intertidal regions, can grow up to 2 m. As their name implies, brown algae are brown or green-brown in color depending on how much of the carotenoid pigment fucoxanthin they produce. Most marine “seaweeds” are brown algae and their rapid growth, especially in cold marine waters, can cause nuisance problems when they wash ashore and decay.

17.7 Cercozoans and Radiolarians

Cercozoans and radiolarians have diverged from one another rather recently (Figure 17.3) and are distinguished from other protists by their threadlike cytoplasmic extrusions (pseudopodia) by which they move and feed. Cercozoans were previously classified as *amoeba* because of their pseudopodia, but it is now known that many phylogenetically diverse organisms employ pseudopodia for motility and feeding purposes.

Cercozoans

Cercozoa include the chlorarachniophytes and foraminiferans as major groups. Chlorarachniophytes are freshwater and marine amoeba-like phototrophs that develop a flagellum for dispersal; their acquisition of green algal chloroplasts is a prime example of a secondary endosymbiosis (Figure 17.2) and shows how extensively this process has molded several phylogenetically distinct lineages of microbial eukaryotes (Figure 17.3).

In contrast to chlorarachniophytes, foraminifera are exclusively marine and form shell-like structures called *tests*, which have distinctive characteristics and are often quite ornate (Figure 17.14a). Tests are typically made of organic materials reinforced with calcium carbonate. The test is not firmly attached to the cell, and the amoeba-like cell may extend partway out of the test during feeding. However, because of the weight of the test, the cell

usually sinks to the bottom of the water column, and it is thought that the organisms feed on dissolved organic matter and particulate deposits, primarily bacteria, other protists, and the remains of dead organisms near the sediments. Foraminiferan cells can also host a variety of algae that form endosymbiotic relationships with the protist and supply it with organic carbon, probably in exchange for inorganic nutrients derived from the breakdown of dead organisms. Phototrophs are found primarily in planktonic foraminifera that remain suspended in the water column to provide their endosymbionts with sufficient sunlight.

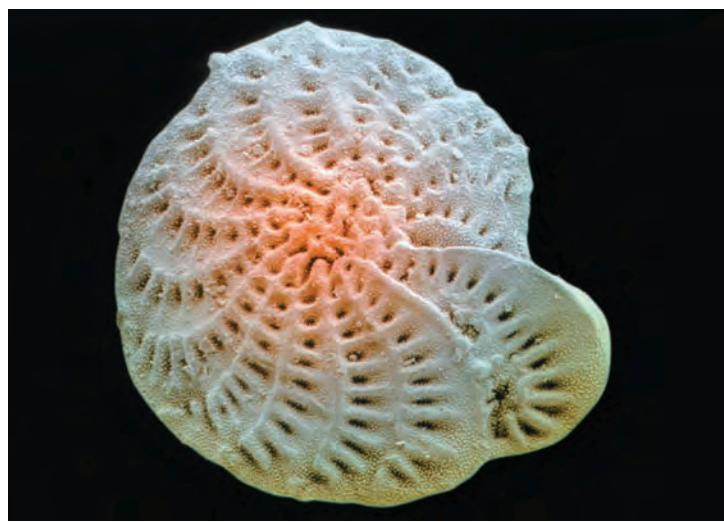

Foraminiferan tests (Figure 17.14a) are relatively resistant to decay and are readily fossilized. These buried and preserved tests are quite useful to geologists. Because particular taxa of foraminifera are typically associated with particular strata in the geological

record, fossilized tests in samples obtained from exploratory wells are used by oil industry paleontologists as a means to date and assess the petroleum potential of a given drill site.

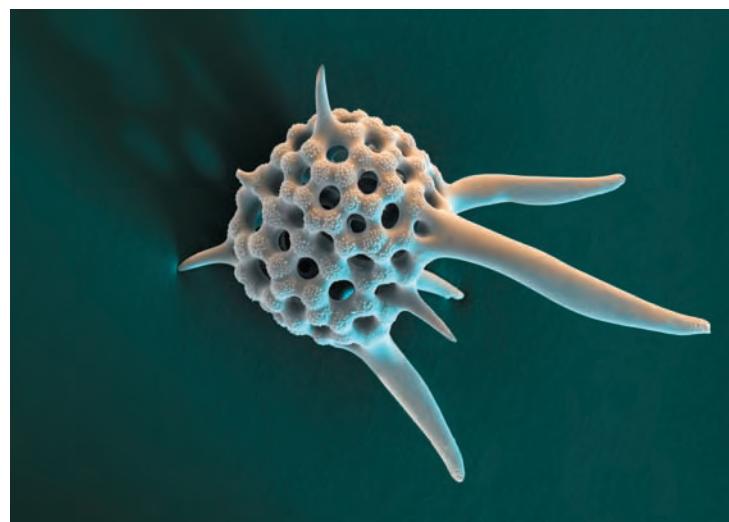

Radiolarians

Radiolarians are mostly planktonic marine eukaryotes, which, like cercozoans, also form threadlike pseudopodia (Figure 17.14b). Radiolarians are strictly heterotrophic and mainly reside in the upper 100 m or so of ocean waters where they consume bacteria and particulate organic matter. Some species associate with algae that take on a symbiotic (but not endosymbiotic) role and supply nutrients to the radiolarian.

The name “radiolarian” comes from the radial symmetry of their tests, transparent or translucent mineral skeletons made of silica in

one fused piece (Figure 17.14b). Along with the accumulation of lipid droplets and large cytoplasmic vacuoles, the needle-like pseudopodia of radiolarians probably help keep the organisms from sinking in their mainly open ocean (planktonic) habitats. However, when cells eventually die, their tests settle to the ocean floor and can build up over time into thick layers of slowly decaying cell material.

17.8 Amoebozoa

Key Genera: *Amoeba*, *Entamoeba*, *Physarum*, *Dictyostelium*

The amoebozoans are a large group of terrestrial and aquatic protists that use lobe-shaped pseudopodia for movement and feeding, in contrast to the threadlike pseudopodia of cercozoans and radiolarians. The major groups of amoebozoans are the *gymnamoebas*, the *entamoebas*, and the *plasmodial* and *cellular slime molds*. Phylogenetically, the amoebozoans diverged from a lineage that eventually led to the fungi and animals (Figure 17.3).

Gymnamoebas and Entamoebas

The gymnamoebas are free-living protists that inhabit aquatic and soil environments. They use pseudopodia to move by a process called *amoeboid movement* (Figure 17.15) and feed by phagocytosis on bacteria, other protists, and particulate organic materials. Amoeboid movement results from streaming of the cytoplasm as it flows forward at the less contracted and viscous cell tip, taking the path of least resistance. Cytoplasmic streaming is facilitated by microfilaments (➡ Section 2.22), which exist in a thin layer just beneath the cytoplasmic membrane. *Amoeba* (Figure 17.15) is a common organism in pond waters, with species varying in size from 15 μm in diameter—clearly microscopic—to over 750 μm —visible with the naked eye.

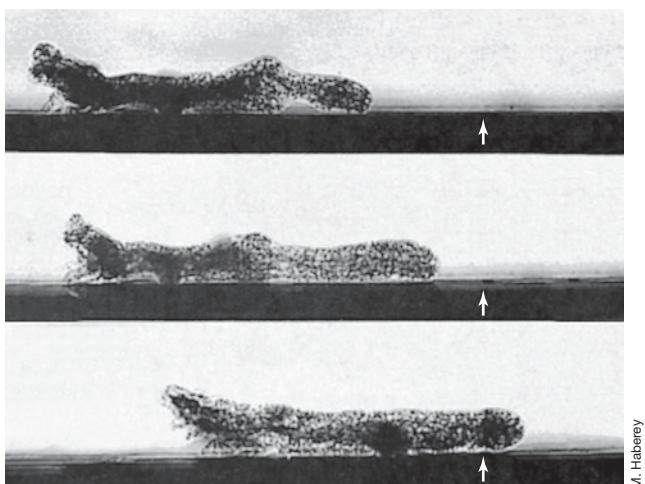

Figure 17.15 Time-lapse view of the amoebozoan *Amoeba proteus*. The time interval from top to bottom is about 6 sec. The arrows point to a fixed spot on the surface. A single cell is about 80 μm wide.

In contrast to gymnamoebas, the entamoebas are parasites of vertebrates and invertebrates. Their usual habitat is the oral cavity or intestinal tract of animals. *Entamoeba histolytica* is pathogenic in humans and can cause amebic dysentery, an ulceration of the intestinal tract that results in a bloody diarrhea. This parasite forms cysts that are transmitted from person to person by fecal contamination of water, food, and eating utensils. In Section 32.3 we discuss the etiology and pathogenesis of amebic dysentery, an important cause of death from intestinal parasites in humans.

Slime Molds

The **slime molds** were previously grouped with fungi since they undergo a similar life cycle and produce fruiting bodies with spores for dispersal. As protists, however, slime molds are motile and can move across a solid surface fairly quickly (see Figures 17.16–17.18). Slime molds are divided into two groups, *plasmodial slime molds* (also called *acellular slime molds*), whose vegetative forms are masses of protoplasm of indefinite size and shape called plasmodia (Figure 17.16), and *cellular slime molds*, whose vegetative forms are single amoebae. Slime molds live primarily on decaying plant matter, such as leaf litter, logs, and soil where they consume other microorganisms, especially bacteria, which they ingest by phagocytosis. Slime molds can maintain themselves in a vegetative state for long periods but eventually form differentiated sporelike structures that can remain dormant and then germinate later to once again generate the active amoeboid state.

Plasmodial slime molds, such as *Physarum*, exist in the vegetative phase as an expanding single mass of protoplasm called the *plasmodium* that contains many diploid nuclei (Figure 17.16). The plasmodium is actively motile by amoeboid movement, and from this phase, a sporangium containing haploid spores can be produced; when conditions are favorable, the spores germinate to yield haploid flagellated swarm cells. The fusion of two swarm cells then regenerates a diploid plasmodium.

In contrast to their plasmodial relatives, cellular slime molds are individual haploid cells and form diploids only under certain conditions. The well-studied cellular slime mold *Dictyostelium discoideum* undergoes an asexual life cycle in which vegetative cells

aggregate, migrate as a cell mass, and eventually produce fruiting bodies in which cells differentiate and form spores (Figures 17.17 and 17.18). When cells of *Dictyostelium* are starved, they aggregate and form a pseudoplasmodium; in this stage cells lose their individuality, but do not fuse. Aggregation is triggered by the production

of cyclic adenosine monophosphate (cAMP). The first cells of *Dictyostelium* that produce this compound attract neighboring cells and eventually aggregate into motile masses of cells called *slugs*. Fruiting body formation begins when the slug becomes stationary and vertically oriented. The emerging structure differentiates into a stalk and a head, with stalk cells forming cellulose, which provides the rigidity of the stalk, and the head cells differentiating into spores. Eventually, spores are released and dispersed, with each spore forming a new amoeba (Figures 17.17 and 17.18).

In addition to this asexual process, *Dictyostelium* can produce sexual spores. These form when two amoebae in an aggregate fuse to form a single giant amoeba. A thick cellulose wall develops around this cell to form a structure called the *macrocyst*, and this can remain dormant for long periods. Eventually, the diploid nucleus undergoes meiosis to form haploid nuclei that become integrated into new amoebae that can once again initiate the asexual cycle.

III • Fungi

Fungi are a large, diverse, and widespread group of organisms, consisting of the *molds*, *mushrooms*, and *yeasts*. Approximately 100,000 species of fungi have been described, and as many as 1.5 million species may exist. Fungi form a phylogenetic cluster distinct from other protists and are the microbial group most closely related to animals (Figure 17.3).

Most fungi are microscopic and terrestrial. They inhabit soil or dead plant matter and play crucial roles in the mineralization of organic carbon. A large number of fungi are plant pathogens, and a few cause diseases of animals, including humans. Certain fungi also establish symbiotic associations with many plants, facilitating the plant's acquisition of minerals from soil, and many fungi benefit humans through fermentation and the synthesis of antibiotics.

17.9 Fungal Physiology, Structure, and Symbioses

In this section we describe some general features of fungi, including their physiology, cell structure, and the symbiotic associations they develop with plants and animals. In the following section we examine fungal reproduction and phylogeny.

Nutrition and Physiology

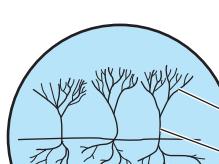

Fungi are chemoorganotrophs—typically displaying simple nutritional requirements—and most are aerobic. Fungi feed by secreting extracellular enzymes that digest polymeric materials, such as polysaccharides or proteins, into monomers that are assimilated as sources of carbon and energy. As decomposers, fungi digest dead animal and plant materials. As parasites of plants or animals, fungi use the same mode of nutrition but take up nutrients from the living cells of the plants and animals they invade rather than from dead organic materials.

A major ecological activity of fungi, especially basidiomycetes, is the decomposition of wood, paper, cloth, and other products derived from these natural sources. Lignin, a complex polymer in which the building blocks are phenolic compounds, is an important constituent of woody plants, and in association with cellulose it confers rigidity on them. Lignin is decomposed in nature almost exclusively through the activities of certain basidiomycetes called *wood-rotting fungi*. Two types of wood rot are known: *brown rot*, in which the cellulose is attacked preferentially and the lignin left unmetabolized, and *white rot*, in which both cellulose and lignin are decomposed. The white rot fungi are of major ecological importance because they play such a key role in decomposing woody materials in forests.

Fungal Morphology, Spores, and Cell Walls

Most fungi are multicellular, forming a network of filaments called *hyphae* (singular, *hypha*) from which asexual spores are produced (Figure 17.19). Hyphae are tubular cell walls that surround the cytoplasmic membrane. Fungal hyphae are often septate, with cross-walls dividing each hypha into separate cells. In some cases, however, the vegetative cell of a fungal hypha contains more than one nucleus, and hundreds of nuclei can form due to repeated nuclear divisions without the formation of cross-walls, a condition called *coenocytic*. Each hyphal filament grows mainly at the tip by extension of the terminal cell (Figure 17.19).

Hyphae typically grow together across and above a surface to form a compact, macroscopically visible tuft called a *mycelium* (Figure 17.20a). From the mycelium, aerial hyphae reach up into the air above the surface, and spores called **conidia** are formed on their tips (Figure 17.20b). Conidia are asexual spores and they are often pigmented black, green, red, yellow, or brown (Figure 17.20). Conidia give the mycelium a dusty appearance (Figure

(b)

The conidiophore is about 300 µm long and the conidia about 3 µm wide.

Some fungi form macroscopic reproductive structures called *fruiting bodies* (**mushrooms** or puff balls, for example), in which millions of spores are produced that can be dispersed by wind, water, or animals (Figure 17.21). In contrast to mycelial fungi, some fungi grow as single cells; these are the **yeasts**.

Most fungal cell walls consist of **chitin**, a polymer of *N*-acetyl glucosamine. Chitin is arranged in the walls in microfibrillar bundles, as is cellulose in plant cell walls, to form a thick, tough wall structure. Other polysaccharides such as mannans and galactosans, or even cellulose itself, replace or supplement chitin in some fungal cell walls. Fungal cell walls are typically 80–90% polysaccharide, with only small amounts of proteins, lipids, polyphosphates, and inorganic ions making up the wall-cementing matrix.

Symbioses and Pathogenesis

Most plants are dependent on certain fungi to facilitate their uptake of minerals from soil. These fungi form symbiotic associations with the plant roots called *mycorrhizae* (the word means, literally, “fungus roots”). Mycorrhizal fungi establish close physical contact with the roots and help the plant obtain phosphate and other minerals and also water from the soil. In return, the fungi obtain nutrients such as sugars from the plant root (Figure 22.24). There are two kinds of mycorrhizal associations. One, *ectomycorrhizae*, typically forms between basidiomycetes (Section 17.14) and the roots of woody plants, while the second,

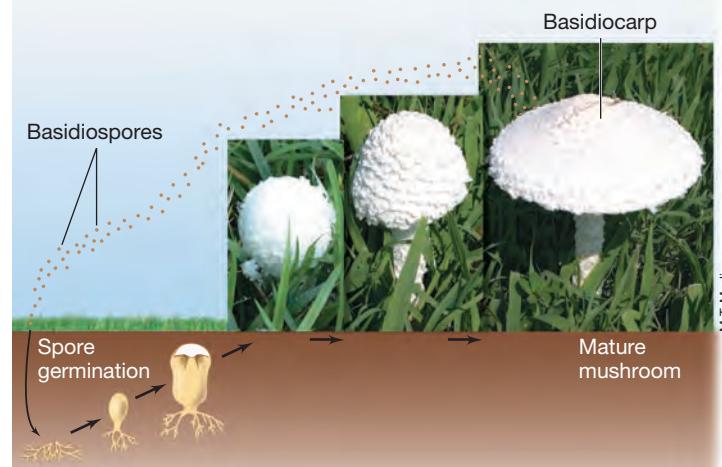

Figure 17.21 Mushroom life cycle. Mushrooms typically develop underground and then emerge on the surface rather suddenly (usually overnight), triggered by an influx of moisture. Photos of stages in formation of a common lawn mushroom (see also Section 17.14).

endomycorrhizae, forms between glomeromycete fungi (Section 17.12) and many nonwoody plants. Some fungi also form associations with cyanobacteria or green algae. These are the *lichens*, the colorful and crusty growths often seen on the surfaces of trees and rocks. We explore the biology of lichens and mycorrhizae in more detail in Sections 22.1 and 22.5, respectively.

Fungi can invade and cause disease in plants and animals. Fungal plant pathogens cause widespread crop and plant damage worldwide, and fruit and grain crops in particular suffer significant yearly losses due to fungal infection. Human fungal diseases, called *mycoses*, range from relatively minor and easily cured conditions, such as athlete’s foot, to serious, life-threatening systemic mycoses, such as histoplasmosis. Section 32.2 describes the major human diseases caused by fungi.

17.10 Fungal Reproduction and Phylogeny

Fungi reproduce by *asexual* means in one of three ways: (1) by the growth and spread of hyphal filaments; (2) by the asexual production of spores (conidia; Figures 17.20 and 17.21); or (3) by simple cell division, as in budding yeasts (Figure 17.22). Most fungi also form sexual spores, typically as part of an elaborate life cycle. Some fungi, such as the well-known mold *Penicillium* (the source of the antibiotic penicillin), were long thought to lack a sexual stage and reproduce only by way of conidia. But it has now been shown that *Penicillium* (and probably all fungi of its taxonomic class, the *Deuteromycetes*) go through a sexual stage in their life cycles.

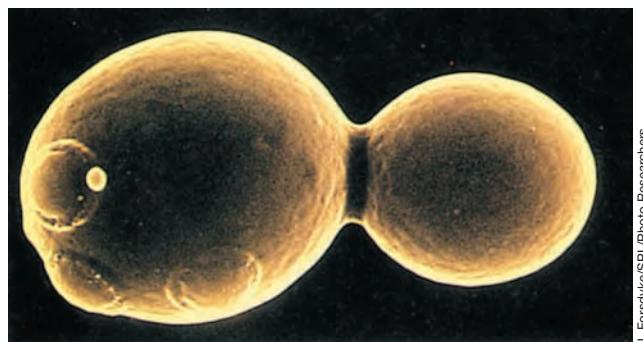

Figure 17.22 The common baker's and brewer's yeast *Saccharomyces cerevisiae* (Ascomycetes). In this colorized scanning electron micrograph, note the budding division and scars from previous buds. A single cell is about 6 µm in diameter.

Sexual Spores of Fungi

Some fungi produce spores as a result of sexual reproduction. The spores develop from the fusion of either unicellular gametes or specialized hyphae called *gametangia*. Alternatively, sexual spores can originate from the fusion of two haploid cells to yield a diploid cell; this then undergoes meiosis and mitosis to yield individual haploid spores. Depending on the group, different types of sexual spores are produced. Spores formed within an enclosed sac (ascus) are called *ascospores*. Many yeasts produce ascospores, and we consider sporulation in the common baker's yeast *Saccharomyces cerevisiae* in Section 17.13. Sexual spores produced on the ends of a club-shaped structure (basidium) are *basidiospores* (Figure 17.21 and see Figure 17.30c). *Zygospor*es, produced by zygomycetous fungi such as the common bread mold *Rhizopus* (Section 17.12), are macroscopically visible structures that result from the fusion of hyphae and genetic exchange. Eventually the zygospor maturates and produces asexual spores that are dispersed by air and germinate to form new fungal mycelia. Chytrid fungi produce motile sexual spores called *zoospores*.

Sexual spores of fungi are typically resistant to drying, heating, freezing, and some chemical agents. However, neither sexual nor asexual spores of fungi are as resistant to heat as bacterial endospores (Section 2.16). Both asexual and sexual spores of fungi can germinate and develop into a new hypha.

The Phylogeny of Fungi

Fungi share a more recent common ancestor with animals than does any other group of eukaryotic organisms (Figure 17.3). Fungi and animals are thought to have diverged approximately 1.5 billion years ago. The earliest fungal lineage is thought to be the chytridiomycetes, an unusual group of motile fungi in which cells produce flagellated spores (zoospores, Section 17.11). Thus the lack of flagella in most fungi indicates that motility is a characteristic that has been lost at various times in different fungal lineages.

A detailed picture of fungal phylogeny is shown in the evolutionary tree in Figure 17.23. The phylogeny shown in this figure, based on comparative sequencing of 18S ribosomal RNA (which can be used to resolve fairly close, but not distant, relationships among eukaryotes; see Section 17.2), defines several distinct

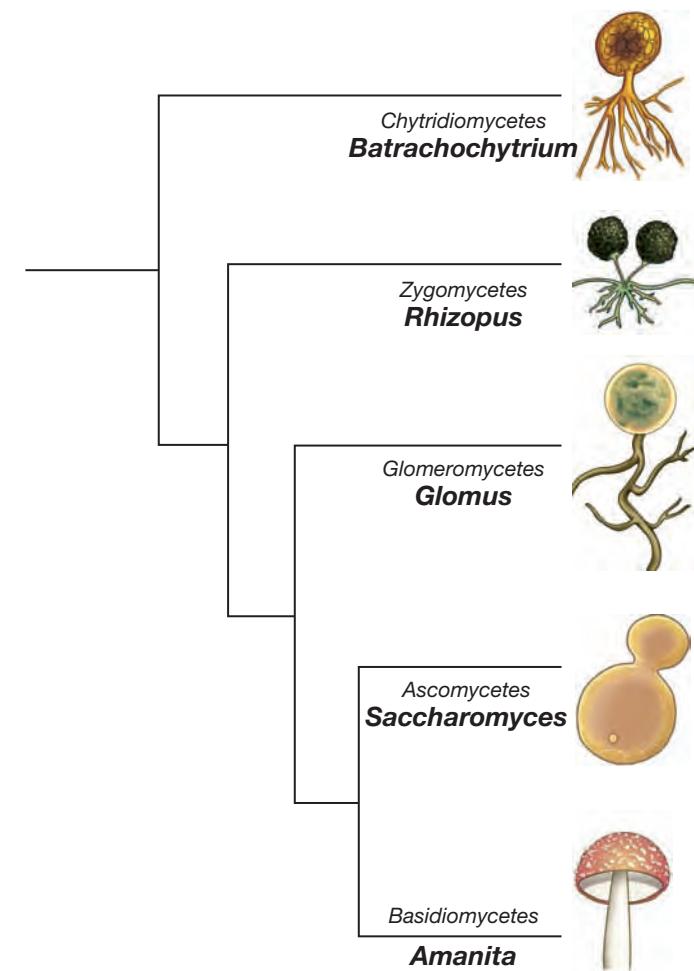

Figure 17.23 Phylogeny of fungi. This generalized phylogenetic tree based on 18S ribosomal RNA gene sequences depicts the relationships among the major groups (phyla) of fungi. A typical genus is listed for each group and depicted in the tree.

fungal groups: the chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes. Figure 17.23 also supports the idea that the chytridiomycetes lie phylogenetically basal to all other fungal groups and that the most derived groups of fungi are the basidiomycetes, which includes the mushrooms (Figure 17.21 and see Figure 17.30), and the ascomycetes, which includes the yeasts such as *Saccharomyces* (Figure 17.22) and molds such as *Aspergillus* (Figure 17.20).

17.11 Chytridiomycetes

Key Genera: *Allomyces*, *Batrachochytrium*

Chytridiomycetes, or *chytrids*, are the earliest diverging lineage of fungi (Figure 17.23), and their name refers to the structure of

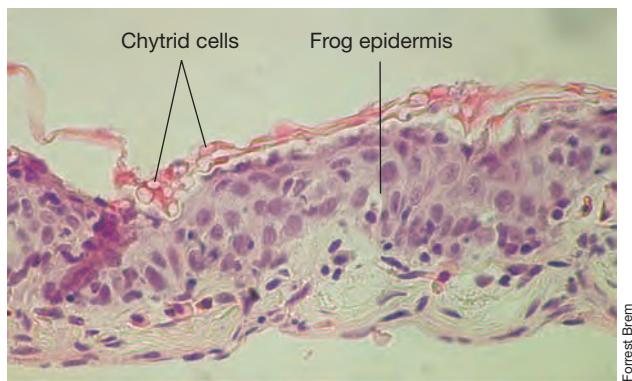

Figure 17.24 Chytridiomycetes. Cells of the chytrid *Batrachochytrium dendrobatidis* stained pink growing on the surface of the epidermis of a frog.

the fruiting body, which contains their sexual spores (zoospores). These spores are unusual among fungal spores in being flagellated and motile, and are ideal for dispersal of these organisms in the aquatic environments, mostly freshwater and moist soils, where they are commonly found.

Many species of chytrids are known and some exist as single cells, whereas others form colonies with hyphae. They include both free-living forms that degrade organic material, such as *Allomyces*, and parasites of animals, plants, and protists. The chytrid *Batrachochytrium dendrobatidis* causes chytridiomycosis of frogs (Figure 17.24), a condition in which the organism infects the frog's epidermis and interferes with the ability of the frog to respire across the skin. Chytrids have been implicated in the massive die-off of frogs and some other amphibians worldwide, probably in response to increases in global temperatures that have stimulated chytrid proliferation and to increased animal susceptibility due to habitat loss and aquatic pollution.

Some chytrids are obligately anaerobic, a highly unusual property for eukaryotic cells, and inhabit the rumen of ruminant animals. The rumen is that part of the ruminant digestive system where the breakdown of cellulose and related polysaccharides occurs (Section 22.7). The chytrid *Neocallimastix*, for example, inhabits the rumen and conserves energy from the fermentation of sugars to acids, alcohol, and H₂. Cells of *Neocallimastix* lack mitochondria and instead contain hydrogenosomes that assist in their fermentative lifestyle by degrading pyruvate to acetate plus CO₂ plus H₂ (Figure 2.64).

Unresolved aspects of the phylogeny of chytrids suggest that this group is not monophyletic. That is, some organisms currently classified as chytrids may actually be more closely related to species of other fungal groups, such as the zygomycetes. As is true for protists, much about the evolution of this and other groups of fungi remains to be learned.

17.12 Zygomycetes and Glomeromycetes

Key Genera: *Rhizopus*, *Encephalitozoon*, *Glomus*

We consider two groups of fungi here, the zygomycetes, known primarily for their role in food spoilage, and the glomeromycetes, important fungi in certain mycorrhizal associations. Zygomycetes are commonly found in soil and on decaying plant material, whereas glomeromycetes form symbiotic relationships with plant roots. All of these fungi are coenocytic (multinucleate), and a unifying feature is the formation of sexual spores called *zygospores* (Section 17.10).

Rhizopus, the Common Bread Mold

The black bread mold *Rhizopus* (Figure 17.25a) is a common zygomycete. This organism undergoes a complex life cycle that includes both asexual and sexual reproduction. In the asexual phase the mycelia form sporangia within which haploid spores are produced. Once released, spores disperse and eventually germinate, giving rise to vegetatively growing mycelia. In the sexual phase, mycelial gametangia of different mating types (analogous to male and female, see Section 17.13) fuse to yield a cell with two nuclei called a *zygosporangium*, which can remain dormant and resist dryness and other unfavorable conditions. When conditions are favorable, the different haploid nuclei fuse to form a diploid nucleus followed by meiosis to yield haploid spores. As in the asexual phase, the release of the spores, in this case genetically nonidentical spores, disperses the organism for vegetative hyphal growth.

Microsporidia and Glomeromycetes

Microsporidia are tiny (2–5 µm) and unicellular parasites of animals and protists. Based on 18S ribosomal RNA gene sequencing and their lack of mitochondria, microsporidia were once thought to form a very early-branching lineage of Eukarya. However, composite gene and protein sequencing has shown the microsporidia to be closely related to the zygomycetes (Figure 17.3).

Microsporidia have adapted to a parasitic lifestyle through the elimination or loss of many key aspects of eukaryotic biology; they are even more structurally stripped down than other amitochondriate eukaryotes. The microsporidium *Encephalitozoon* (Figure 17.25b), for example, lacks mitochondria and hydrogenosomes,

and even lacks the Golgi complex (Figure 2.60). Moreover, the organism contains a very small genome of only 2.9 megabase pairs and contains only about 2000 genes (this is 1.5 megabase pairs and 2600 genes smaller than that of the bacterium *Escherichia coli*!). The *Encephalitozoon* genome lacks genes for major metabolic pathways, such as the citric acid cycle, meaning that this pathogen must depend on its host for even the most basic of metabolic processes. *Encephalitozoon* causes chronic debilitating diseases of the intestine, lung, eye, muscle, and some internal organs but is uncommon among healthy adults with normal immune systems. However, microsporidial diseases have appeared with increasing frequency in immune-compromised individuals, such as those with AIDS or those on long-term administration of immune-suppressing drugs.

The glomeromycetes are a relatively small and unique group of obligately symbiotic fungi in which all known species form associations with plants called *endomycorrhizae* (Section 17.9 and Section 22.5). As many as 80% or more of land plant species form these associations in which the fungal hyphae enters the plant cell and aids the plant's acquisition of minerals from the soil in return for fixed carbon from the plant. As plant symbionts, glomeromycetes are thought to have played a pivotal role in the ability of early vascular plants to colonize land. As far as is known, glomeromycetes reproduce only asexually and are mostly coenocytic in their hyphal morphology. Spores of *Glomus* (Figure 17.23), a major genus of endomycorrhizae, are collected from the roots of cultivated plants and used as an agricultural inoculant to ensure vigorous symbiotic associations.

17.13 Ascomycetes

Key Genera: *Saccharomyces*, *Candida*, *Aspergillus*

The ascomycetes are a large and highly diverse group of fungi that range from single-celled species, such as the baker's yeast *Saccharomyces* (Figure 17.26 and Figure 17.22), to species that grow as filaments, such as the common mold *Aspergillus* (Figure 17.20). The group ascomycetes, species of which are found in aquatic and terrestrial environments, takes its name from the production of

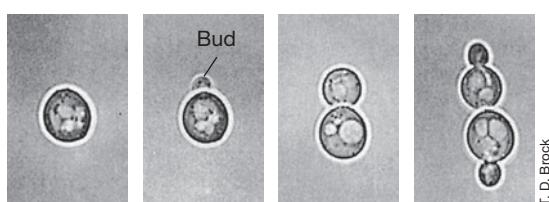

Figure 17.26 Growth by budding division in *Saccharomyces cerevisiae*. A time-lapse series of phase-contrast micrographs shows the budding division process starting from a single cell. Note the pronounced nucleus. A single cell of *S. cerevisiae* is about 6 μm in diameter.

asci (singular, ascus), cells in which two haploid nuclei from different mating types fuse to form a diploid nucleus that eventually undergoes meiosis to form haploid ascospores. In addition to ascospores, ascomycetes reproduce asexually by the production of conidia that form at the tips of specialized hyphae called *conidiophores* (Figure 17.20). Both saprophytic and pathogenic yeasts, such as *Candida albicans*, are common in nature. We focus here on the yeast *Saccharomyces* as a model ascomycete.

Saccharomyces cerevisiae

The cells of *Saccharomyces* and other single-celled ascomycetes are spherical, oval, or cylindrical, and cell division typically takes place by budding. In the budding process, a new cell forms as a small outgrowth of the old cell; the bud gradually enlarges and then separates from the parent cell (Figures 17.22 and 17.26).

Yeast cells are typically much larger than bacterial cells and can be distinguished from bacteria microscopically by their larger size and by the obvious presence of internal cell structures, such as the nucleus or cytoplasmic vacuoles (Figure 17.26). Yeasts flourish in sugar-rich habitats such as fruits, flowers, and the bark of trees. Yeasts are typically facultative aerobes, growing aerobically as well as by fermentation. Several yeasts live symbiotically with animals, especially insects, and a few species are pathogenic for animals and humans (Section 32.2). The most important commercial yeasts are the baker's and brewer's yeasts, which are species of *Saccharomyces*. The yeast *S. cerevisiae* has been studied as a model eukaryote for many years and was the first eukaryote to have its genome completely sequenced (Section 6.6).

Mating Types and Sexual Reproduction in *Saccharomyces*

Saccharomyces can reproduce by sexual means in which two cells fuse. Within the fused cell, called a *zygote*, meiosis occurs and ascospores are eventually formed. The life cycle of *S. cerevisiae* is described in Figure 17.27. Cells of *S. cerevisiae* can grow vegetatively in either a haploid or diploid stage. *S. cerevisiae* forms two different types of haploid cells called *mating types*. These are designated α (alpha) and a (encoded by genes α and a) and are analogous to male and female gametes. The α and a genes regulate the production of the peptide hormones α factor or a factor, which are excreted by yeast cells during mating. The hormones bind to cells of the opposite mating type and bring about changes in their cell surfaces that enable the cells to fuse; once mating has occurred, the nuclei fuse, forming a diploid zygote (Figure 17.28). The zygote grows vegetatively by budding, but under starvation conditions it undergoes meiosis and generates ascospores (Figure 17.27).

Haploid strains of *S. cerevisiae* are genetically predisposed to be either a or α but are able to switch their mating type. This switch occurs when the active mating-type gene is replaced with one of two otherwise "silent" genes, as shown in Figure 17.29. There is a single location on one of the *S. cerevisiae* chromosomes called the *MAT* (for *mating type*) locus, at which either gene a or gene α can be inserted. At this locus, the *MAT* promoter controls transcription of whichever gene is present. If gene a is at that locus, then the cell is mating-type a , whereas if gene α is at that locus, the cell is mating-type α . Elsewhere in the yeast genome are copies of genes a and α that are not expressed, and these are the source of the

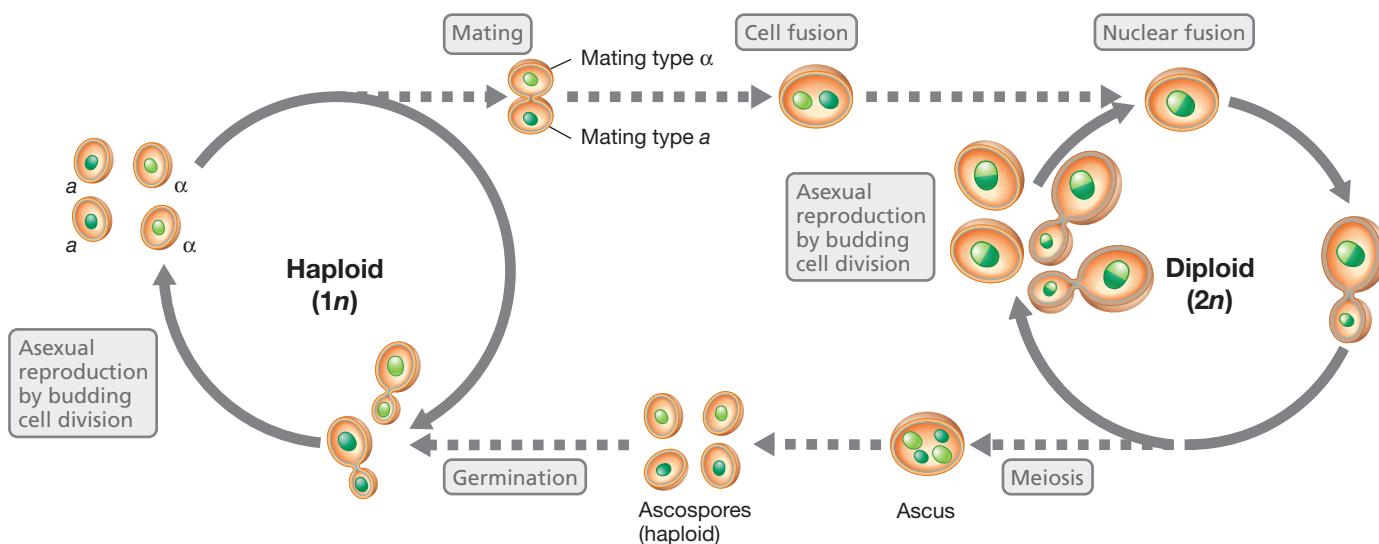

Figure 17.27 Life cycle of a typical ascomycete yeast, *Saccharomyces cerevisiae*. Cells can grow vegetatively for long periods as haploid cells or as diploid cells before life cycle events (dashed lines) generate the alternate genetic form.

inserted gene. In the switch (Figure 17.29), the appropriate gene, *a* or *α*, is copied from its silent site and inserted into the *MAT* location, replacing the gene already present. The old mating-type gene is excised and discarded, and the new gene is inserted. Whichever gene is inserted in the *MAT* locus is the one that will govern the mating type of the strain. It is thus possible for cells from a pure culture of *S. cerevisiae* derived from a single cell to mate, following a mating-type switch in one or more cells in the culture.

17.14 Mushrooms and Other Basidiomycetes

Key Genera: *Agaricus*, *Amanita*

Basidiomycetes are a large group of fungi, with over 30,000 species described. Many are the commonly recognized mushrooms and toadstools, some of which are edible, such as the commercially grown mushroom *Agaricus*. Others, such as the mushroom *Amanita* (Figure 17.30a), are highly poisonous. Other basidiomycetes include puffballs, smuts, rusts, and an important human

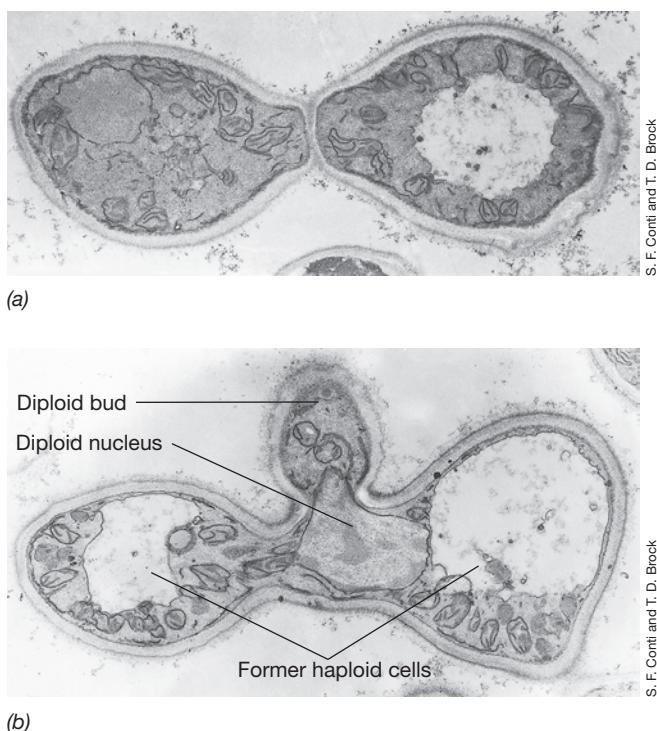

Figure 17.28 Electron micrographs of mating in the ascomycete yeast *Hansenula wingei*. (a) Two cells have fused at the point of contact. (b) Late stage of mating. The nuclei of the two cells have fused, and a diploid bud has formed at a right angle to the mating cells. This bud becomes the progenitor of a diploid cell line. A cell of *Hansenula* is about 10 µm in diameter.

fungal pathogen, *Cryptococcus* (Section 32.2). The defining characteristic of the basidiomycetes is the *basidium* (plural, *basidia*), a structure in which haploid basidiospores are formed by meiosis. The basidium, a word that means “little pedestal” (Figure 17.30c), gives the group its name.

During most of its existence, a mushroom fungus lives as a simple haploid mycelium, growing vegetatively in soil, leaf litter, or decaying logs. It is the sexual reproductive phase of basidiomycetes that produces the visible mushroom structure (Figures 17.21 and 17.30). In this process, mycelia of different mating types fuse, and the faster growth of the dikaryotic (two nuclei per cell) mycelium formed from that fusion overgrows and crowds out the parental haploid mycelia. Then, when environmental conditions are favorable, usually following periods of wet and cool weather, the dikaryotic mycelium develops rapidly into the fruiting body.

A mushroom fruiting body, called a *basidiocarp*, begins as a mycelium that differentiates into a small button-shaped structure underground that then expands into the full-grown basidiocarp that we see aboveground, the mushroom (Figures 17.21 and 17.30). The dikaryotic basidia are borne on the underside of the basidiocarp on flat plates called *gills*, which are attached to the cap of the mushroom (Figure 17.30b, c). The basidia then undergo a fusion of the two nuclei, forming basidia with diploid nuclei. The two rounds of meiotic division generate four haploid nuclei in the basidia, and each of the nuclei becomes a basidiospore. The genetically distinct basidiospores can then be dispersed by wind to new habitats to begin the cycle again, germinating under favorable conditions and growing as haploid mycelia (Figure 17.21).

IV • Red and Green Algae

We conclude our tour of eukaryotic microbial diversity with the **algae**. As we have previously discussed, only the red and green algae originated from primary endosymbiotic events, whereas other protists containing chloroplasts were the result of secondary endosymbioses (Figures 17.2 and 17.3). Here we focus on the red and green algae, a large and diverse group of eukaryotic organisms that contain chlorophyll and carry out oxygenic photosynthesis.

17.15 Red Algae

Key Genera: *Polysiphonia*, *Cyanidium*, *Galdiera*

The red algae, also called *rhodophytes*, mainly inhabit the marine environment, but a few species are found in freshwater and terrestrial habitats. Both unicellular and multicellular species are known, and some of the latter are macroscopic.

Basic Properties

Red algae are phototrophic and contain chlorophyll *a*; their chloroplasts lack chlorophyll *b* but contain phycobiliproteins,

the major light-harvesting pigments of the cyanobacteria (Section 13.2). The reddish color of many red algae (Figure 17.31) results from phycoerythrin, an accessory pigment that masks the green color of chlorophyll. This pigment is present along with phycocyanin and allophycocyanin in structures called *phycobilisomes*, the light-harvesting (antenna) components of cyanobacteria. At greater depths in aquatic habitats, where less light penetrates, cells compensate by producing more phycoerythrin and are a darker red, whereas shallow-dwelling species often have less phycoerythrin and can be green in color (see Figure 17.32).

Most species of red algae are multicellular and lack flagella. Some are considered seaweeds and are the source of agar, the solidifying agent used in bacteriological media, and carrageenans, thickening and stabilizing agents used in the food industry. Other species of red algae, such as the genus *Porphyra*, are harvested and dried and used in making sushi. Different species of red algae are filamentous, leafy, or, if they deposit calcium carbonate, *coralline*

Figure 17.31 *Polysiphonia*, a filamentous marine red alga. Light micrograph. *Polysiphonia* grows attached to the surfaces of marine plants. Cells are about 150 µm wide.

(coral-like) in morphology. Coralline red algae play an important role in the development of coral reefs and help strengthen reefs from wave damage (☞ Section 22.14).

Cyanidium and Relatives

Unicellular species of red algae are also known. One such group, members of the *Cyanidiales* that includes the genera *Cyanidium*, *Cyanidioschyzon*, and *Galdieria* (Figure 17.32), live in acidic hot springs at temperatures from 30 to 60°C and at pH values from 0.5 to 4.0; under these extreme conditions, no other phototrophic microorganisms (including anoxygenic phototrophs) can exist. The unicellular red algae are unusual in other ways as well. For example, cells of *Cyanidioschyzon merolae* are unusually small (1–2 µm in diameter) for eukaryotes, and the genome of this species, approximately 16.5 Mbp, is one of the smallest genomes known for a phototrophic eukaryote.

MINIQUIZ

- What traits link cyanobacteria and red algae?
- What physiological properties would be necessary for *Galdieria* to live in its habitat?

17.16 Green Algae

Key Genera: *Chlamydomonas*, *Volvox*

The green algae, also called *chlorophytes*, have chloroplasts containing chlorophylls *a* and *b*, which give them their characteristic green color, but they lack phycobiliproteins and so do not develop the red or blue-green colors of red algae (Figures 17.31 and 17.32). In the composition of their photosynthetic pigments, green algae are similar to plants and are closely related to plants phylogenetically. There are two main groups of green algae, the chlorophytes, examples of which are the microscopic *Chlamydomonas* and *Dunaliella* (Figure 17.33a), and the charophyceans such as *Chara* (Figure 17.33b), macroscopic organisms that often resemble land plants and are actually most closely related to land plants.

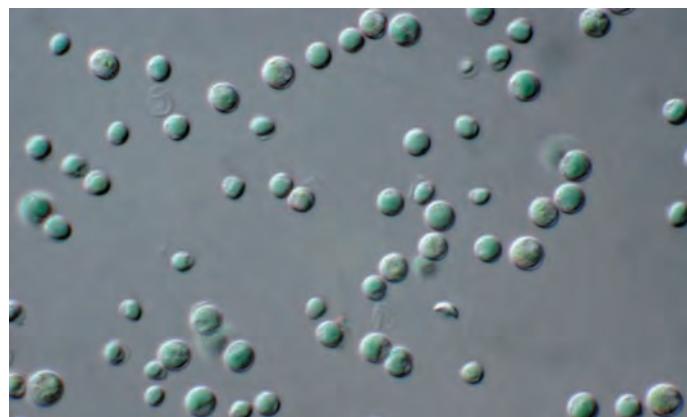

Figure 17.32 *Galdieria*, a unicellular red alga. This alga grows at low pH and high temperature in hot springs. The cells are about 25 µm in diameter and are more blue-green than red in color because *Galdieria* contains mainly phycocyanin rather than phycoerythrin as its phycobilin. See page 543 for interesting features of the genome of *Galdieria*.

Richard W. Castenholz

Most green algae inhabit freshwater while others are found in moist soil or growing in snow, to which they impart a pink color (☞ Figure 5.22). Other green algae live as symbionts in lichens (☞ Section 22.1). The morphology of chlorophytes ranges from unicellular (Figure 17.33a, c) to filamentous, with individual cells arranged end to end (Figure 17.33e), to **colonial**, as aggregates of cells (Figure 17.33f). Even multicellular species exist, an example of which is the seaweed *Ulva*. Most green algae have a complex life cycle, with both sexual and asexual reproductive stages.

Very Small Green Algae and Colonial Green Algae

One of the smallest eukaryotes known is the green alga *Ostreococcus tauri*, a common unicellular species of marine phytoplankton (☞ Section 19.10). Cells of *O. tauri* have a diameter of approximately 2 µm, and the organism contains the smallest genome of any known phototrophic eukaryote, approximately 12.6 Mbp. *Ostreococcus* has thus provided a model organism for research into the evolution of genome reduction and specialization in eukaryotes.

At the colonial level of organization in green algae is *Volvox* (Figure 17.33f). This alga forms colonies composed of several hundred flagellated cells, some of which are motile and primarily carry out photosynthesis, while others specialize in reproduction. Cells in a *Volvox* colony are interconnected by thin strands of cytoplasm that allow the entire colony to swim in a coordinated fashion. *Volvox* has been a long-term model for research on the genetic mechanisms controlling multicellularity and the distribution of functions among cells in multicellular organisms.

Some colonial green algae have potential as sources of biofuels. For example, the colonial green alga *Botryococcus braunii* excretes long-chain (C_{30} – C_{36}) hydrocarbons that have the consistency of crude oil (Figure 17.33g). About 30% of the *B. braunii* cell dry weight consists of this petroleum, and there has been heightened interest in using this and other oil-producing algae as renewable sources of petroleum. Evidence from biomarker studies have shown that some known petroleum reserves originated from green algae such as *B. braunii* that settled in lakebeds in

ancient times. Hence, if the scale-up challenges for commercial algal petroleum production could ever be met, it is possible that some fraction of the world's oil supply could someday come from photosynthesis by green algae.

Endolithic Phototrophs

Some green algae grow inside rocks. These *endolithic* (*endo* means “inside”) phototrophs inhabit porous rocks, such as those containing quartz, and are typically found in layers near the rock surface (Figure 17.34). Endolithic phototrophic communities are most common in dry environments such as deserts or cold dry environments such as Antarctica. For example, in the McMurdo Dry Valleys of Antarctica, where temperatures and humidity are extremely low (Figure 5.21d), life within a rock has its advantages. Rocks in these harsh environments are heated by the sun, and water from snowmelt can be absorbed and retained for relatively long periods, supplying moisture needed for growth.

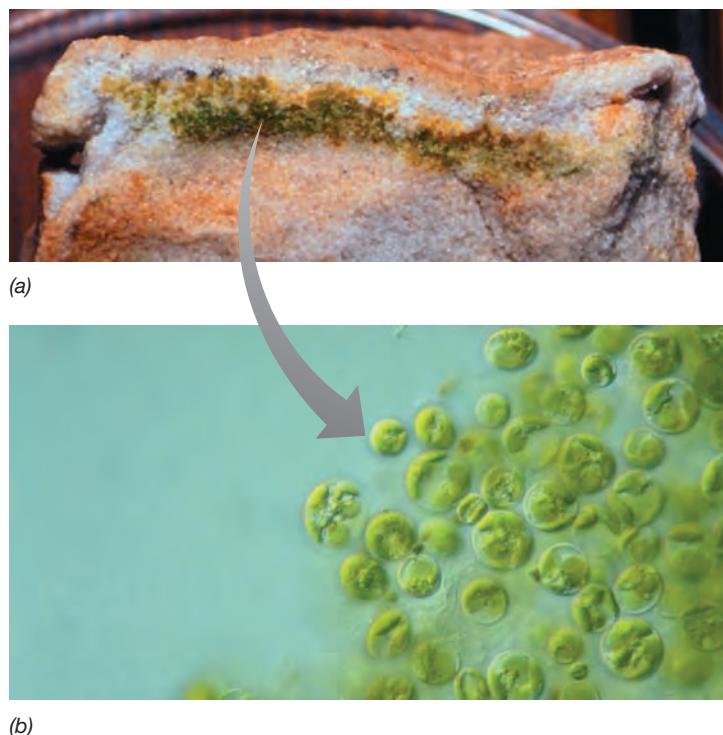

Figure 17.34 Endolithic phototrophs. (a) Photograph of a limestone rock from the Dry Valleys region of Antarctica broken open to show the layer of endolithic green algae. (b) Light micrograph of cells of the green alga *Trebouxia*, a widespread endolithic alga in Antarctica.

Moreover, water absorbed by a porous rock makes the rock more transparent, thus funneling more light to the algal layers.

A wide variety of phototrophs can form endolithic communities, including cyanobacteria and various green algae (Figure 17.34). In addition to being free-living phototrophs, green algae and cyanobacteria coexist with fungi in endolithic lichen communities (see Section 22.1 for discussion of the lichen symbiosis). Metabolism and growth of these internal rock microbial communities slowly weathers the rock, allowing gaps to develop where water can enter, freeze and thaw, and eventually crack the rock, producing new habitats for microbial colonization. The

decomposing rock also forms a crude soil that can support development of plant and animal communities in environments where conditions (temperature, moisture, and so on) permit.

BIG IDEAS

17.1 • Key metabolic organelles of eukaryotes are the chloroplast, which functions in photosynthesis, and the mitochondrion or hydrogenosome, which function in respiration or fermentation. These organelles were originally *Bacteria* that established permanent residence inside other cells (endosymbiosis).

17.2 • Ribosomal RNA gene sequences do not yield as reliable a phylogenetic tree of the *Eukarya* as do other genes and proteins. The modern, multigene tree of eukaryotes shows a major radiation of eukaryotic diversity emerging at some time following symbiotic events that led to the mitochondrion.

17.3 • Diplomonads such as *Giardia* are unicellular, flagellated, nonphototrophic protists. Parabasalids such as *Trichomonas* are human pathogens and contain huge genomes that lack introns.

17.4 • Euglenozoans are unicellular, flagellated protists. Some are phototrophic. This group includes some important human pathogens, such as *Trypanosoma*, and some well-studied nonpathogens, such as *Euglena*.

17.5 • Three groups make up the alveolates: ciliates, dinoflagellates, and apicomplexans. Most ciliates and dinoflagellates are free-living organisms, whereas apicomplexans are obligate parasites of animals.

17.6 • Stramenopiles are protists that bear a flagellum with fine, hairlike extensions. They include oomycetes, diatoms, and brown and golden algae.

17.7 • Cercozoans and radiolarians are two related groups of protists. The cercozoans include the phototrophic chlorarachniophytes and foraminiferans, whereas the radiolarians are chemoorganotrophs.

17.8 • Amoebozoa are protists that use pseudopodia for movement and feeding. Within amoebae are gymnamoebas, entamoebas, and slime molds. Plasmodial slime molds form masses of motile protoplasm, whereas cellular slime molds are individual cells that aggregate to form fruiting bodies from which spores are released.

17.9 • Fungi include the molds, mushrooms, and yeasts. Other than phylogeny, fungi primarily differ from protists by their rigid cell wall, production of spores, and lack of motility.

17.10 • A variety of sexual spores are produced by fungi, including ascospores, basidiospores, and zygospores. From a phylogenetic standpoint, fungi are the closest relatives of animals, and chytridiomycetes are the earliest lineage of fungi.

17.11 • Chytrids are primarily aquatic fungi and are thought to be the most ancient of fungi, lying basal to all other known fungal groups on the 18S rRNA gene tree. Some chytrids are amphibian pathogens.

17.12 • Zygomycetes form coenocytic hyphae and undergo both asexual and sexual reproduction, and the common bread mold *Rhizopus* is a good example. Microsporidia, once thought to be an early lineage of *Eukarya*, are closely related to the zygomycetes. Glomeromycetes are fungi that form endomycorrhizal associations with plants.

17.13 • The ascomycetes are a large and diverse group of saprophytic fungi. Some, such as *Candida albicans*, can be pathogenic in humans. There are two mating types in the yeast *Saccharomyces cerevisiae*, and yeast cells can convert from one type to the other by a genetic switch mechanism.

17.14 • Basidiomycetes include the mushrooms, puffballs, smuts, and rusts. Basidiomycetes undergo both vegetative reproduction as haploid mycelia and sexual reproduction via fusion of mating types and formation of haploid basidiospores.

17.15 • Red algae are mostly marine and range from unicellular to multicellular. Their reddish color is due to the pigment phycoerythrin, a key cyanobacterial pigment, present in their chloroplast.

17.16 • Green algae are common in aquatic environments and can be unicellular, filamentous, colonial, or multicellular. A unicellular green alga, *Ostreococcus*, has the smallest genome known for a phototrophic eukaryote, while the green alga *Volvox* is a model colonial phototroph.

Stitching Together Genomes

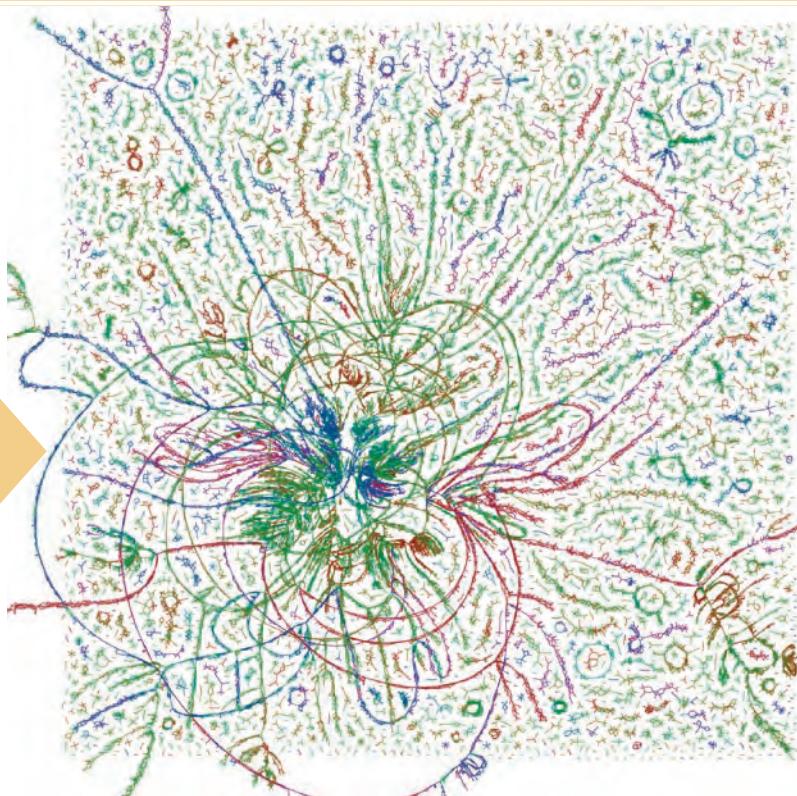

Thus far only a tiny fraction of microbial diversity has been brought into laboratory culture. Although we discuss in this chapter advanced methods that are helping to culture the previously uncultured, sequencing of DNA recovered directly from an environmental sample is an alternative way to evaluate the metabolic capacities of a natural microbial community.

This approach, called *metagenomics*, relates gene sequences to specific biochemical functions, revealing the metabolic and other capabilities of the microbial community. However, microbial communities are not simply a collection of genes; rather, they are a system of interacting organisms, each of which contains a specific complement of genes that determine the properties of that organism. To gain a true understanding of ecosystem function, the assembly of individual genomes is an essential step.

The ability to assemble complete genomes from many hundreds of millions of short bits of sequence (typically 50–200 nucleotides) obtained in a metagenomic analysis has recently become possible using advanced computational methods. The figure here shows a “connection graph” that depicts an assembly of genomes from a coastal marine water sample. A total of 58.5 billion nucleotides in the metagenome were used to stitch together these complete and near-complete genomes.¹ The strands are colored by differences in the percentage of guanine plus cytosine content of their genomic DNAs. Long strands correspond to prokaryotic genomes and the small circular strands are most likely from viruses or plasmids.

This massive metagenomic study paid off handsomely, as it revealed the physiological capacities of an abundant but not yet cultured group of marine *Euryarchaeota* (*Archaea*). The genomes showed these organisms to be motile photoheterotrophs that degrade protein and lipids as carbon sources using light as their energy source.

- IV **Measuring Microbial Activities in Nature 587**

We now begin a new unit devoted to microorganisms in their natural habitats. We learned in Chapter 1 that *microbial communities* consist of cell populations living in association with other populations in nature. The science of **microbial ecology** is focused on how microbial populations assemble to form communities and how these communities interact with each other and their environments.

The major components of microbial ecology are *biodiversity* and *microbial activity*. To study biodiversity, microbial ecologists must identify and quantify microorganisms in their habitats. Knowing how to do this is often helpful for isolating organisms of interest as well, another goal of microbial ecology. To study

microbial activity, microbial ecologists must measure the metabolic processes that microorganisms carry out in their habitats. In this chapter we consider modern methods for assessing microbial diversity and activity. Chapter 19 will outline the basic principles of microbial ecology and examine the types of environments that microorganisms inhabit. Chapters 20, 21, and 22 will complete our coverage of microbial ecology with a consideration of nutrient cycles, applied microbiology, and the role that microorganisms play in symbiotic associations with higher life forms.

We begin with the microbial ecologist's toolbox, which includes a collection of powerful tools for dissecting the structure and function of microbial communities in relation to their natural habitats.

I • Culture-Dependent Analyses of Microbial Communities

The vast majority of microorganisms, more than 99% of all species, have never been grown in laboratory cultures. Recognition of this fact, based on molecular diversity surveys (Sections 18.3–18.7) of microbial habitats, has stimulated the development of new methods for separating out particular microbial species—that is, *isolating* them—to establish pure cultures. Culturing a microorganism remains the only way to fully characterize its properties and predict its impact on an environment.

In the first part of this chapter we cover the enrichment approach, a time-honored and useful method for isolating microorganisms from nature but one with limitations. Enrichment is based on culturing in a selective growth medium, and the tools and methods used in this approach are referred to, collectively, as *culture-dependent* analyses. As we will see, considerable progress has been made in culturing the more elusive microorganisms in natural populations by using robotics to set up large numbers of enrichment cultures that can be monitored using molecular tools. In the second and third parts of this chapter we consider *culture-independent* analyses, techniques that can tell us much about the structure and function of microbial communities in the absence of actual laboratory cultures. In the final part of this chapter, we consider methods for measuring microbial activities in nature and linking them to specific organisms.

18.1 Enrichment

For an **enrichment culture**, a medium and a set of incubation conditions are established that are *selective* for the desired organism and counterselective for undesired organisms. Effective enrichment cultures duplicate as closely as possible the resources and conditions of a particular ecological niche. Literally hundreds of different enrichment strategies have been devised, and **Tables 18.1** and **18.2** provide an overview of some successful ones.

Inocula

Successful enrichment requires an appropriate inoculum containing the organism of interest. Thus, the making of an enrichment culture begins with collecting a sample from the appropriate habitat to serve as the inoculum (Tables 18.1 and 18.2). Enrichment cultures are established by placing the inoculum into selective

media and incubating under specific conditions. In this way, many common prokaryotes can be isolated. For example, the great Dutch microbiologist Martinus Beijerinck, who conceptualized the enrichment culture technique (➡ Section 1.9), used enrichment cultures to isolate for the first time the nitrogen-fixing bacterium *Azotobacter* (**Figure 18.1**). Because *Azotobacter* is a rapidly growing bacterium capable of N₂ fixation in air

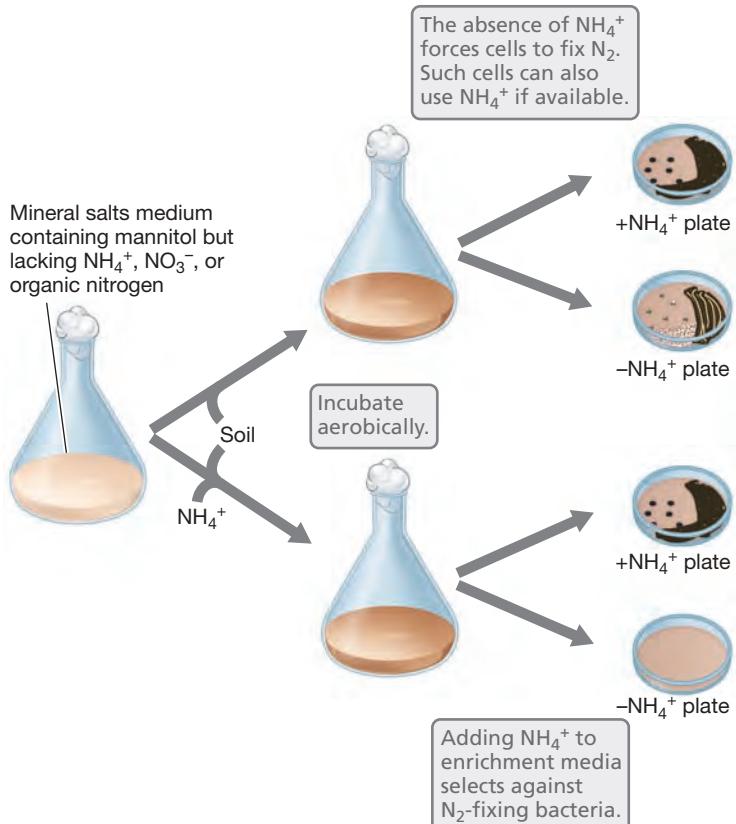

Figure 18.1 The isolation of *Azotobacter*. Selection for aerobic nitrogen-fixing bacteria usually results in the isolation of *Azotobacter* or its relatives. See Section 1.9 and Figure 1.23 for more on the historical importance of *Azotobacter*.

(Section 3.17), enrichment using media devoid of fixed nitrogen, such as ammonia or nitrate, and incubation in air selects strongly for this bacterium and its close relatives. Non-nitrogen-fixing bacteria and anaerobic nitrogen-fixing bacteria are counterselected in this technique.

Enrichment Culture Outcomes

For success with enrichment cultures, attention to both the culture medium and the incubation conditions is important. That is, *resources* (nutrients) and *conditions* (temperature, pH, osmotic considerations, and the like) must mimic those of the habitat to give the best chance of obtaining the organism of interest (Table 19.1). Some enrichment cultures yield nothing. This may be because the organism capable of growing under the enrichment conditions specified is absent from the habitat. Alternatively, even though the organism of interest exists in the habitat sampled, the resources and conditions of the laboratory culture may be insufficient for its growth. Thus enrichment cultures can yield a firm positive conclusion (that an organism with certain capacities exists in a particular environment) but never a firm negative conclusion (that such an organism is not present). Moreover, the

isolation of the desired organism from an enrichment culture says nothing about the ecological importance or abundance of the organism in its habitat; a positive enrichment proves only that the organism was present in the sample, and in theory, this requires only a single viable cell in the enrichment culture inoculum.

The Winogradsky Column

The **Winogradsky column** is an artificial microbial ecosystem and a long-term source of various bacteria for enrichment cultures. Winogradsky columns have been used to isolate phototrophic purple and green bacteria, sulfate-reducing bacteria, and many other anaerobes. Named for the famous Russian microbiologist Sergei Winogradsky (Section 1.9), the column was first used by Winogradsky in the late nineteenth century in his classic studies of soil microorganisms.

A Winogradsky column is prepared by filling a glass cylinder about half full with organically rich, preferably sulfide-containing mud into which carbon substrates have been mixed. The substrates determine which organisms are enriched. Fermentative substrates, such as glucose, that can lead to acidic conditions and excessive gas formation (which can create gas pockets that

^aAll media must contain an assortment of mineral salts including N, P, S, Mg²⁺, Mn²⁺, Fe²⁺, Ca²⁺, and other trace elements (► Sections 3.1–3.2). Certain organisms may have requirements for vitamins or other growth factors. This table is meant as an overview of enrichment methods and does not speak to the effect incubation temperature might have in isolating thermophilic (high temperature), hyperthermophilic (very high temperature), and psychrophilic (low temperature) species, or the effect that extremes of pH or salinity might have, assuming an appropriate inoculum was available. Some enrichment substrates are naturally more specific than others. For example, glucose is quite nonspecific as an enrichment substrate compared with benzoate or methanol.

disrupt the enrichment and let in air) are avoided. The mud is supplemented with small amounts of calcium carbonate (CaCO_3) as a buffer and gypsum (CaSO_4) as a source of sulfate. The mud is packed tightly in the cylinder, taking care to avoid trapping air, and then covered with lake, pond, or ditch water (or seawater if it is a marine column). The top of the cylinder is covered to prevent evaporation, and the container is placed near a window that receives diffuse sunlight for a period of months.

In a typical Winogradsky column a diverse community of organisms develops (Figure 18.2a). Algae and cyanobacteria develop quickly in the upper portions of the water column; by producing O_2 these organisms help to keep this zone of the column oxic. Decomposition processes in the mud lead to the production of organic acids, alcohols, and H_2 , suitable substrates for sulfate-reducing bacteria (Section 13.18). Hydrogen sulfide (H_2S) from the sulfate reducers triggers the development of purple and green sulfur bacteria (anoxygenic phototrophs, Section 13.3) that use sulfide as a photosynthetic electron donor. These organisms typically grow in patches in the mud on the sides of the column but may bloom in the water itself if oxygenic phototrophs are scarce (Figure 18.2b). The pigmented cells of the anoxygenic phototrophs can be sampled with a pipette for microscopy, isolation, and characterization (Table 18.1).

Winogradsky columns have been used to enrich both aerobic and anaerobic prokaryotes. Besides supplying a ready source of inocula for enrichment cultures, columns can also be supplemented with a specific compound to enrich an organism in the inoculum that can degrade it. Once a crude enrichment has been established in the column, culture media can

be inoculated for the isolation of pure cultures, as discussed in the next section.

Enrichment Bias

Although the enrichment culture technique is powerful, there exists a bias, and sometimes a very severe bias, in the outcome of enrichments. This bias is typically most profound in liquid enrichment cultures where the most rapidly growing organism(s) for the chosen set of conditions dominate. However, using molecular techniques to be described later, we now know that the most rapidly growing organisms in laboratory cultures are often only minor components of the microbial community rather than the most abundant and ecologically relevant organisms carrying out the process of interest. This could be for several reasons including the fact that the levels of resources available in laboratory cultures are typically much higher than those in nature, and the conditions in the natural habitat, including both the types and proportions of different organisms present as well as the physical and chemical conditions, are nearly impossible to reproduce and maintain for long periods in laboratory cultures.

This problem of **enrichment bias** can be demonstrated by comparing the results obtained in dilution cultures (Section 18.2) with classical liquid enrichment. Dilution of an inoculum followed by liquid enrichment or plating often yields different organisms than liquid enrichments established with the same but undiluted inocula. It is thought that dilution of the inoculum eliminates quantitatively insignificant but rapidly growing “weed” species, allowing development of organisms that are more abundant in the community but slower growing. Dilution of the

(b) Photo of Winogradsky columns that have remained anoxic up to the top; each column had a bloom of a different phototrophic bacterium. inoculum is thus a common practice in enrichment culture microbiology today. As discussed below, the problem of overgrowth by “weed” species can also be circumvented by physical isolation of the desired organism before introducing it into a growth medium. This is partly accomplished by use of the dilution method. However, more recently, sophisticated methods have been developed to physically isolate single cells of interest (or single cell types) and place them in a growth medium that is free of undesired cells. We consider these techniques in the next section.

18.2 Isolation

A *pure culture*—one containing a single kind of microorganism—can be isolated from an enrichment culture in many ways. Common isolation procedures include the streak plate, the agar dilution, and liquid dilution. For organisms that form colonies on agar plates, the streak plate is quick, easy, and the method of choice (Figure 18.3); if a well-isolated colony is selected and restreaked several successive times, a pure culture can usually be obtained. With proper incubation facilities (for example, anoxic jars or anoxic chambers for anaerobes,  Section 5.16), it is possible to purify both aerobes and anaerobes on agar plates by the streak plate method.

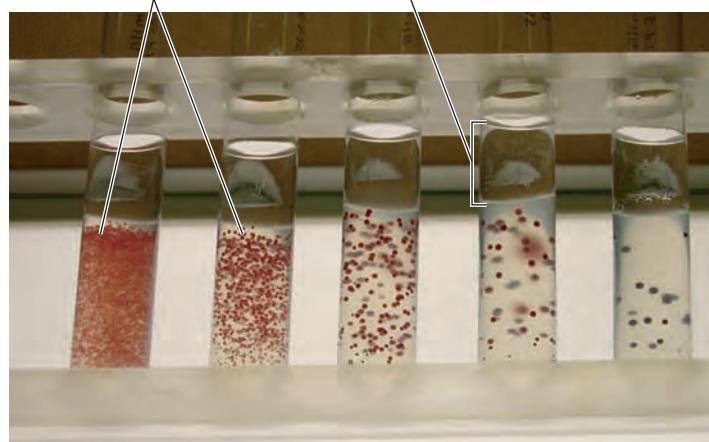

Agar Dilution Tubes and the Most-Probable-Number Technique

In the agar dilution tube method, a mixed culture is diluted in tubes of molten agar medium, resulting in colonies embedded in the agar. This method is useful for purifying anaerobic organisms such as phototrophic sulfur bacteria and sulfate-reducing bacteria from samples taken from Winogradsky columns or other sources. A culture is purified by successive dilutions of cell suspensions in tubes of molten agar medium (Figure 18.3). Repeating this procedure using a colony from the highest-dilution tube as inoculum for a new set of dilutions usually yields pure cultures. A related procedure called the *roll tube method* uses tubes containing a thin layer of agar on their inner surface. The agar can then be streaked for isolated colonies. Because the tubes can be flushed with an oxygen-free gas during streaking, the roll tube method is primarily used for the isolation of anaerobic prokaryotes.

Another purification procedure is the serial dilution of an inoculum in a liquid medium until the final tube in the series shows no growth. When a 10-fold serial dilution is used, for example, the last tube showing growth should have originated from ten or fewer cells. Besides being a method for obtaining pure cultures, serial dilution techniques are widely used to estimate viable cell numbers in the **most-probable-number (MPN) technique** (Figure 18.4). MPN methods have been used for estimating the numbers of microorganisms in foods, wastewater, and other

samples in which cell numbers need to be assessed routinely. An MPN count of a natural sample can be done using highly selective media and incubation conditions to target one or a small group of organisms or a particular pathogen. Alternatively, a count can be done using complex media to get a general estimate of viable cell numbers (but see Section 5.9 for a caveat that applies to such estimates).

Use of several replicate tubes at each dilution improves accuracy of the final MPN obtained.

Criteria for Purity

Regardless of the methods used to purify a culture, once a putative pure culture has been obtained, it is essential to verify its purity. This is typically done through a combination of (1) microscopy, (2) observation of colony characteristics on plates or in dilution

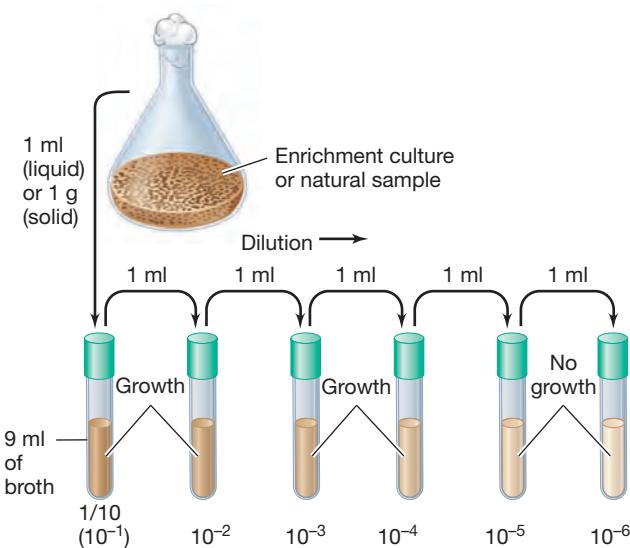

Figure 18.4 Procedure for a most-probable-number (MPN) analysis. Growth in the 10^{-4} but not the 10^{-5} dilution means that cell numbers were at least 10^4 cells/ml in the sample used for inoculation. Since particle-attached microorganisms can skew numbers significantly, gentle methods to disassociate microorganisms from particles are often used prior to dilution.

tubes, and (3) tests of the culture for growth in other media. In the latter, it is important to test the culture for growth in media in which it is predicted that the desired organism will grow poorly or not at all but that contaminants will grow vigorously. In the final analysis, the microscopic observation of a single morphological type of cell that displays uniform staining characteristics (for example, in a Gram stain) coupled with uniform colony characteristics and the absence of contamination in growth tests with various culture media is good evidence that a culture is pure (also called *axenic*).

The molecular methods described in the following sections for characterizing environmental populations can also be applied to verification of culture purity. However, these techniques are generally complementary and do not substitute for the more basic observations of culture characteristics and cellular morphology.

Selective Single-Cell Isolation: The Laser Tweezers and Flow Cytometry

In addition to the methods just described, other more technologically demanding tools for obtaining pure cultures are available, including laser tweezers and flow cytometry. These methods are especially useful for isolating slow-growing microorganisms that would otherwise be overgrown by “weed” species in enrichment cultures or to isolate organisms present in such low numbers that they would be missed using dilution-based enrichment methods.

Laser tweezers consist of an inverted light microscope equipped with a strongly focused infrared laser and a micromanipulation device. Trapping a single cell is possible because the laser beam creates a force that pushes down on a microbial cell (or other small object) and holds it in place (Figure 18.5a). Then when the laser beam is moved, the trapped cell moves along with it. If a mixed sample is in a capillary tube, a single cell can be optically trapped and moved away from contaminating organisms (Figure 18.5b). The cell can

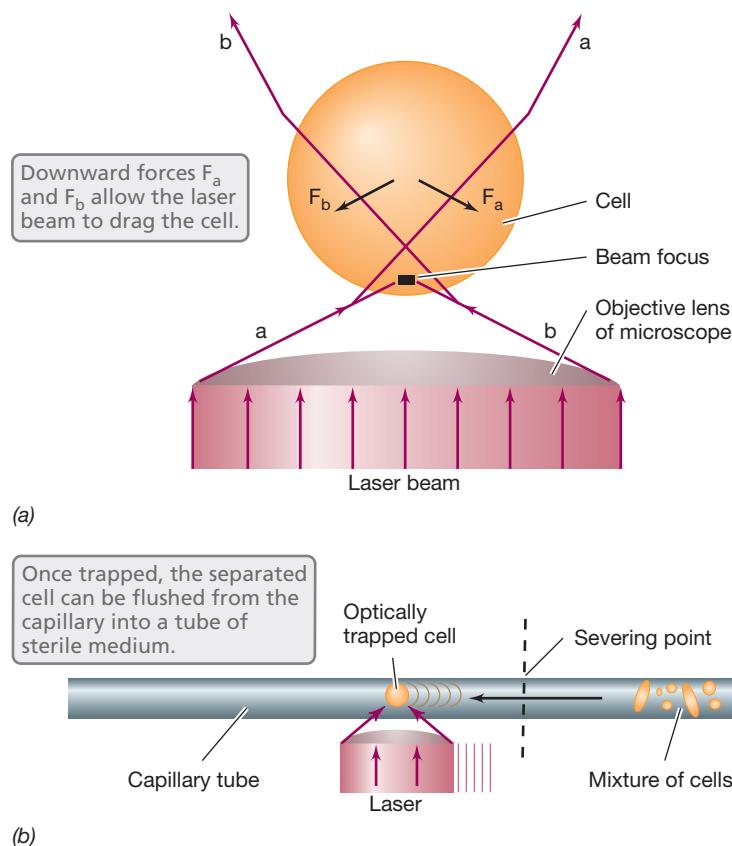

Figure 18.5 The laser tweezers for the isolation of single cells. A technique for physically isolating individual cells for subsequent growth in pure culture.

then be isolated by breaking the tube at a point between the cell and the contaminants and flushing the cell into a small tube of sterile medium. Laser tweezers, when coupled with staining techniques that identify particular organisms (Sections 18.3 and 18.4), can be used to select organisms of interest from a mixture for purification and further laboratory study.

A second method for selective isolation of single cells employs **flow cytometry**, a technique for counting and examining microscopic particles by suspending them in a stream of fluid and passing them through an electronic detector. Flow cytometers assess selected criteria (including size, shape, or fluorescent properties) of single cells as they pass through a detector at rates of many thousands of cells per second, and can also sort out single cells based on measured criteria (see Section 18.10 and Figure 18.29). The latter capacity of the flow cytometer can be used to enrich a particular cell type from a mixture of many types.

Single-cell sorting capacity can arrange single cells on the surface of a solid growth medium or deposit them into individual wells of a multiwelled (microtiter) plate, where each well contains the same growth medium or slightly different growth media. Because the growth requirements of some organisms include organic compounds and metabolites produced by other organisms that share their environment, addition of filter-sterilized source water (for aquatic organisms) or soil water extract (for soil organisms) has been successful for bringing some previously uncultured organisms into laboratory culture.

EXPLORE THE MICROBIAL WORLD

General ecologists refer to two distinct categories of ecological niche, the **fundamental niche** and the **realized niche**. The fundamental niche refers to the range of environments in which a species will be sustained when it is not resource-limited, such as may result from competition with other species. By contrast, the realized niche refers to the range of natural environments supporting a species when it is confronted with factors such as resource limitation, predation, and competition from other species. This distinction between fundamental and realized niches yields a clue as to why some microorganisms are so difficult to isolate from the environment.

Establishing laboratory conditions that fall within the fundamental niche will be sufficient to maintain an organism in pure culture, but those conditions will likely not be adequate to selectively enrich for that species when it must compete with other organisms present in the sample inoculum. Since the realized niche of most microorganisms is unknown, there has been an increasing emphasis on developing high-throughput methods for cultivation, using robotics to set up many cultivation attempts in parallel. High-throughput methods allow for simultaneous investigation of many alternative

growth conditions in an attempt to replicate the realized niche or, alternatively, allow the organism to occupy its fundamental niche by relieving it from competition. The latter approach is more commonly employed, since fewer media need to be prepared to sustain growth.

Methods for collecting and depositing a single cell in nutrient media are well developed, including the established dilution methods, as well as the more recent applications of flow cytometric cell sorting and laser tweezers. When high-throughput cultivation is coupled with molecular probes to screen for growth of novel organisms identified previously by culture-independent methods (Section 18.5), there has been increasing success in isolating some interesting bacteria from the uncultured majority in nature. In fact, this general method was used for the successful isolation of one of the most abundant organisms on Earth, *Pelagibacter ubique* (Figure 1).¹ As discussed in Section 19.10, this bacterium is a species of highly successful marine bacterioplankton (suspended bacterial cells) that thrive on the very dilute pool of dissolved organic matter present in the open oceans.

Dedicated patience is needed in any cultivation effort, as the discovery of slow-growing

Culturing the Uncultured

or dormant organisms may require months of incubation. Also, many or perhaps even most microorganisms in nature are adapted to extremely low nutrient concentrations, being inhibited by nutrient concentrations used to grow organisms commonly studied in the laboratory. In addition, others may depend on complex interspecies relationships that cannot be replaced by a defined growth medium. Thus, high-throughput methods are ideally suited to surveying various combinations of resources to find the set that best supports the laboratory culture of the most interesting and ecologically relevant organisms from nature.

Culture-independent methods have identified over 50 major divisions (phyla) within the domain *Bacteria* alone. Remarkably, only 12 phyla were known in 1987! Among the major bacterial divisions so far identified, only about half now have cultured representatives. Additionally, even when cultures are available for a division, they are generally few in number and therefore do not fully encompass the phylogenetic diversity within the group. Thus, the challenge of obtaining representative cultures is one of both *breadth* of coverage (obtaining at least one member of each division) and *depth* of coverage (developing a culture collection that spans the phylogenetic diversity of each division). The relatively poor representation of the natural diversity of *Bacteria* in culture collections today (Figure 15.1) also applies to microbial eukaryotes and the *Archaea*. However, this situation is not so much a problem as it is a remarkable opportunity for a new generation of microbiologists interested in microbial diversity. We now have the understanding and technology necessary to more fully explore the remarkable diversity of microbial life through culture-based analyses.¹

Following the addition of filter-sterilized seawater and low nutrient concentrations to the individual wells, pure cultures of *Pelagibacter* and other novel marine *Bacteria* were obtained.

Continuing developments of these and related methods for culture screening have spawned a new field of *high-throughput technology* for culturing previously uncultured microorganisms (see Explore the Microbial World, “Culturing the Uncultured”). High-throughput methods also include the use of robotic systems to quickly test hundreds of combinations of nutrients for growth or to assay hundreds or thousands of different wells for DNA sequences that will identify the organisms being enriched, all run simultaneously to yield rapid results (that is, at high throughput).

II • Culture-Independent Microscopic Analyses of Microbial Communities

Microbial ecologists quantify cells in a microbial habitat to estimate relative abundances of different species. Cell stains are necessary to obtain these types of data, and we detail these methods here. Organisms in natural environments can also be detected by assaying their genes. Genes encoding either ribosomal RNA (rRNA, ↗ Section 12.4) or enzymes that support a specific physiology are the usual targets in these studies. *Environmental genomics* (Section 18.7) is a method for assessing the entire gene complement of a habitat, revealing both the biodiversity and metabolic capabilities of the microbial community at the same time.

18.3 General Staining Methods

Several staining methods are suitable for quantifying microorganisms in natural samples. Although these methods do not reveal the physiology or phylogeny of the cells, they are nonetheless reliable and widely used by microbial ecologists for measuring total cell numbers. One method to be described also allows for an assessment of cell viability.

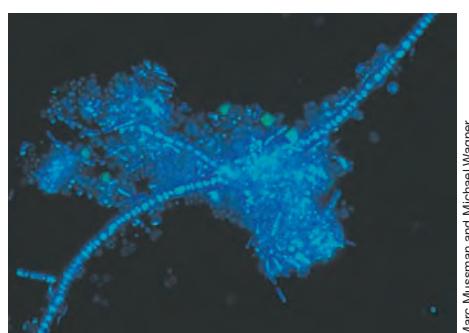

Fluorescent Staining with Dyes That Bind Nucleic Acids

Fluorescent dyes can be used to stain microorganisms from virtually any microbial habitat. **DAPI** (4',6-diamidino-2-phenylindole) is a popular stain for this purpose, as is the dye **acridine orange**.

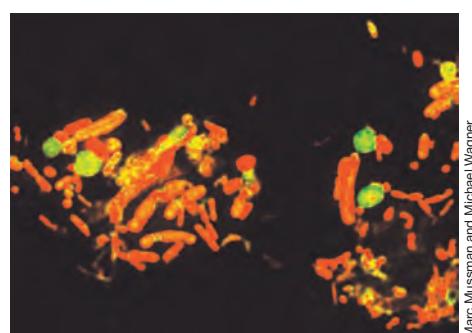

There is also increasing use of **SYBR Green I**, a dye that confers very bright fluorescence to all microorganisms, including viruses. These stains bind to DNA and are strongly fluorescent when exposed to ultraviolet (UV) radiation (DAPI absorption maximum, 400 nm; acridine orange absorption maximum, 500 nm; SYBR Green I absorption maximum, 497 nm), making the microbial cells in the sample readily visible and easy to enumerate. Cells stained with DAPI fluoresce blue, cells stained with acridine orange fluoresce orange or greenish-orange, and cells stained with SYBR Green I fluoresce green (**Figure 18.6**).

Dyes that stain DNA are widely used for the enumeration of microorganisms in environmental, food, and clinical samples. Depending on the sample, background staining is occasionally a problem with fluorescent stains, but because these dyes specifically stain nucleic acids, they are for the most part nonreactive with inert matter. Thus, for many samples, from soil as well as aquatic sources, they can give a reasonable estimate of the cell numbers present. Staining with the brightly fluorescent SYBR Green I also provides excellent enumeration of aquatic virus populations (↗ Section 19.11). For dilute aquatic samples, cells can be stained following collection on a membrane surface by filtration.

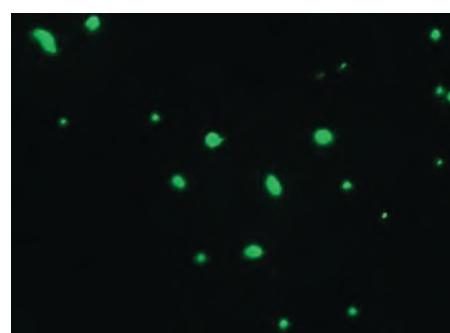

DNA staining is a nonspecific process; *all* microorganisms in a sample are stained. Although this may at first seem desirable, it is not necessarily so. For example, DAPI and acridine orange fail

to differentiate between living and dead cells or between different species of microorganisms, so they cannot be used to assess cell viability or to track species of microorganisms in an environment.

Viability Staining

Viability staining differentiates live cells from dead ones. Hence, viability stains yield both abundance and viability data at the same time. The basis of differentiating between live and dead cells lies with whether a cell's cytoplasmic membrane is intact. Two dyes that fluoresce green and red are added to a sample; the green-fluorescing dye penetrates all cells, viable or not, whereas the red dye, which contains the chemical propidium iodide, penetrates only those cells whose cytoplasmic membrane is no longer intact and that are therefore dead. Thus, when viewed microscopically, green cells are scored as alive and red cells as dead, yielding an instant assessment of both abundance and viability (Figure 18.7).

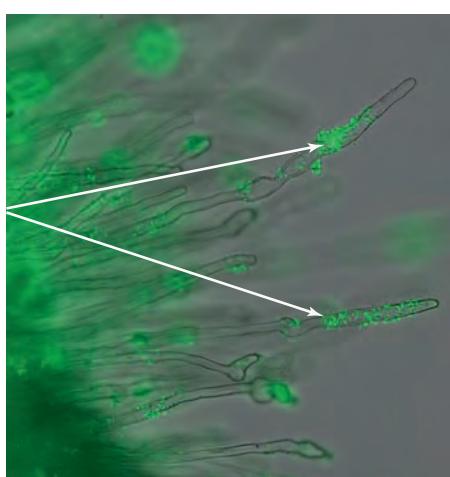

Although useful for research that uses laboratory cultures, the live/dead staining method is not suitable for use in the direct microscopic examination of samples from many natural habitats because of problems with nonspecific staining of background materials. However, procedures have been developed to overcome this problem in analyses of aquatic environments; a water sample is filtered and the filters are stained with the live/dead stain and examined microscopically. Thus in aquatic microbiology, live/dead staining is often used to measure the viability of cell populations in the water column of lakes or oceans, or in the flowing waters of streams, rivers, and other aquatic environments.

Fluorescent Proteins as Cell Tags and Reporter Genes

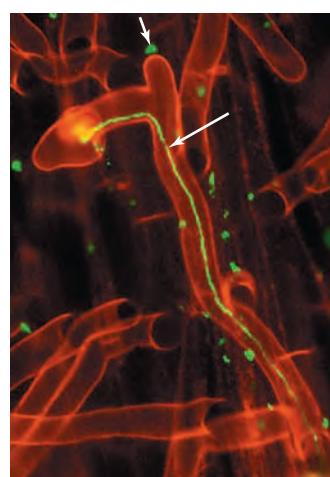

Bacterial cells can be altered by genetic engineering to make them autofluorescent. As discussed earlier (Section 11.6), a gene encoding the green **fluorescent protein** (GFP) can be inserted into the genome of virtually any cultured bacterium. When the GFP gene (*gfp*) is expressed, cells fluoresce green when observed with ultraviolet microscopy (Figure 18.8). Although GFP is not useful for the study of natural populations of microorganisms (because these cells lack the GFP gene), GFP-tagged cells can be introduced into an environment, such as plant roots, and then tracked over time by microscopy. Using this method, microbial ecologists can study competition between the native microflora and a GFP-tagged introduced strain and can assess the effect of perturbations of an environment on the survivability of the introduced strain. GFP tagging is also used extensively in the study of microbial symbiotic associations with plants and animals (Chapter 22). However, GFP requires O₂ to become fluorescent, and thus the GFP method is not suitable for tracking cells introduced into strictly anoxic habitats. The photophysical properties of GFP and other fluorescent proteins isolated from different marine invertebrates (jellyfish, corals, anemones) have since been altered

through mutation to yield a broad palette of fluorescent proteins of varying spectral properties (Figure 18.8a), offering the experimental basis for simultaneous monitoring of multiple species.

The gene *gfp* and those encoding other fluorescent proteins have also been used extensively in laboratory cultures of various bacteria and in controlled environments as a *reporter gene*. When this gene is fused with an operon under the control of a specific regulatory protein, transcription can be studied by using fluorescence as the indicator (a “reporter”) of activity. That is, when genes containing the fused fluorescent protein gene are transcribed and translated, both the protein of interest and the fluorescent protein are made, and cells fluoresce the characteristic color (☞ Section 11.6 and Figures 11.11). For example, expression of *gfp* was used to demonstrate that colonization of alfalfa roots by *Sinorhizobium meliloti* (legume–root nodule symbiosis, ☞ Section 22.3) is promoted by sugars and dicarboxylic acids released by the plant (Figure 18.8b, c).

Limitations of Microscopy

The microscope is an essential tool for exploring microbial diversity and for enumerating and identifying microorganisms in natural samples. However, microscopy alone does not suffice for the study of microbial diversity. Prokaryotes vary greatly in size (☞ Section 2.6 and Table 2.1). Very small cells can be a major problem and can go totally unnoticed, and some cells are near the limits of resolution of the light microscope. Such cells can easily be overlooked in the examination of natural samples, especially if the sample contains high levels of particulate matter or high numbers of large cells. Also, it is often difficult to differentiate live cells from dead cells or cells in general from certain inert materials in natural samples. However, the biggest limitation with the microscopic methods we have discussed thus far is that none of them reveal the phylogenetic diversity of the microorganisms in the habitat under study.

We will see in the next section and get a preview here (Figure 18.9) of powerful staining methods that can reveal the *phylogeny* of organisms observed in a natural sample. These methods

have revolutionized microbial ecology and have helped microbiologists overcome the major limitation of the light microscope in microbial ecology: identifying from a phylogenetic perspective cells observed in a microscopic field. These methods have also taught microbial ecologists an important lesson—when observing unstained or nonspecifically stained natural populations of microorganisms under the microscope, one must remember that the sample almost certainly contains a genetically diverse community, even if many cells “look” the same (Figure 18.9). The simple shapes of bacteria conceal their remarkable diversity.

18.4 Fluorescence In Situ Hybridization (FISH)

Because of their great specificity, nucleic acid probes are powerful tools for identifying and quantifying microorganisms. Recall that a **nucleic acid probe** is a DNA or RNA oligonucleotide complementary to a sequence in a target gene or RNA; when the probe and the target come together, they hybridize (☞ Section 11.2). Nucleic acid probes can be made fluorescent by attaching fluorescent dyes to them. The fluorescent probes can often be used to identify organisms that contain a nucleic acid sequence complementary to the probe. This technique is called **fluorescence in situ hybridization (FISH)**, and different applications are described here, including methods that target phylogeny (Figure 18.10) or gene expression (see Figure 18.12).

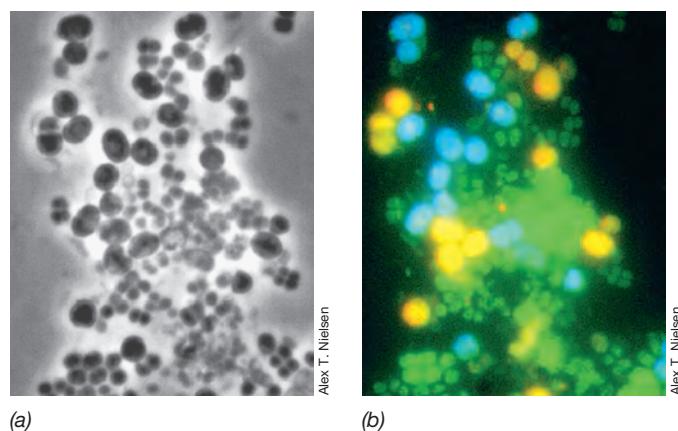

Figure 18.9 Morphology and genetic diversity. The photomicrographs shown here, produced by (a) phase-contrast and (b) a technique called phylogenetic FISH (Section 18.4), are of the same field of cells. Although the large oval cells are of a rather unusual size for prokaryotic cells and all look similar by phase-contrast microscopy, the phylogenetic stains reveal that there are two genetically distinct types (one stains yellow and one stains blue). Both cell types are about 2.25 μm in diameter. The green cells in pairs or clusters are about 1 μm in diameter.

Cells of *B. megaterium* are about 1.5 μm in diameter and cells of *S. cerevisiae* are about 6 μm in diameter.

Phylogenetic Staining Using FISH

Phylogenetic FISH stains are fluorescing oligonucleotides complementary in base sequence to sequences in ribosomal RNA (16S or 23S rRNA in prokaryotes or 18S or 28S rRNA in eukaryotes, [Section 12.4](#)). Phylogenetic stains penetrate cells without lysing them and hybridize with rRNA directly in the ribosomes. The number of fluorescent probes bound to a cell reflects the number of its ribosomes. As single microbial cells can contain tens of thousands of ribosomes, strong signals can be achieved. Because ribosomes are scattered throughout the cell in most prokaryotes, the entire cell becomes fluorescent (Figures 18.9b and 18.10).

By targeting sites in the rRNA that are variable between different organisms, phylogenetic stains can be designed to be very specific and react with only one species or a handful of related microbial species. Alternatively, by targeting conserved stretches in the rRNA they can be made more general and react with, for example, all cells of a given phylogenetic domain. Using FISH, an investigator can identify or track an organism of interest or a domain of interest in a natural sample. For example, if one wishes to determine the percentage of a given microbial population that are *Archaea*, an archaeal-specific phylogenetic stain may be used in combination with DAPI (Section 18.3) to assess *Archaea* and total numbers, respectively, and a percentage could then be derived by calculation.

FISH technology can also employ multiple phylogenetic probes. With a suite of probes, each designed to react with a particular organism or group and each containing its own fluorescent dye, FISH can image multiple taxa in a habitat in a single experiment ([Figure 18.11](#)). If FISH is combined with confocal microscopy ([Section 2.3](#)), it is possible to explore microbial populations with depth, as, for example, in a biofilm ([Section 19.4](#)). In addition to microbial ecology, FISH is also an important tool in the food industry and in clinical diagnostics for the microscopic detection of specific pathogens in food products or clinical specimens.

(b) Confocal laser scanning micrograph of a sewage sludge sample treated with three phylogenetic FISH probes, each containing a fluorescent dye (green, red, or blue) that identifies a particular group of *Proteobacteria*. Green-, red-, or blue-stained cells reacted with only a single probe; other cells reacted with two (turquoise, yellow, purple) or three (white) probes.

CARD-FISH

Besides characterizing the abundance of different taxa in a habitat, FISH can be used to measure *gene expression* in organisms in a natural sample. Because the target in this case is messenger RNA (mRNA), a form of RNA that is much less abundant in the cells than is rRNA, standard FISH techniques cannot be applied. Instead, the signal (fluorescence) must be amplified. A FISH method that enhances the signal is called *catalyzed reporter deposition FISH (CARD-FISH)*.

In CARD-FISH the specific nucleic acid probe contains a molecule of the enzyme peroxidase conjugated to it instead of a fluorescent dye. After there has been time for hybridization, the preparation is treated with a fluorescently labeled soluble compound called *tyramide*, which is a substrate for peroxidase. Within cells containing the nucleic acid probe, the tyramide is converted by the activity of peroxidase into a very reactive intermediate that covalently binds to adjacent proteins; this amplifies the signal sufficiently to be detected by fluorescence microscopy ([Figure 18.12](#)). Each molecule of peroxidase activates many molecules of tyramide so that even mRNAs present at very low abundance can be visualized.

Besides detecting mRNA, CARD-FISH is also useful in phylogenetic studies of prokaryotes that may be growing very slowly, for example organisms inhabiting the open oceans where cold temperatures and low nutrient concentrations limit growth rates ([Figure 18.12](#)). Because such cells have few ribosomes compared with more actively growing cells, standard FISH often yields only a weak signal.

III • Culture-Independent Genetic Analyses of Microbial Communities

Microbial biodiversity studies can forgo isolating organisms or even quantifying or identifying them microscopically using the stains described in the previous sections. Instead, *specific genes* can be used as measures of biodiversity and metabolic capacity. Some genes are unique to particular organisms. Detection of such a gene in an environmental sample implies that the organism is present. The major techniques employed in this type of microbial community analysis are the polymerase chain reaction (PCR), DNA fragment analysis by gel electrophoresis (DGGE, T-RFLP, ARISA) or molecular cloning, and DNA sequencing and analysis. In addition, as we will see in Section 18.7, entire genomes from the cells present in an environmental sample can also be analyzed as a measure of the biodiversity of microbial communities.

18.5 PCR Methods of Microbial Community Analysis

PCR and Microbial Community Analysis

We discussed the principle of PCR in Section 11.3. Recall the major steps in PCR: (1) Two nucleic acid primers are hybridized to a complementary sequence in a target gene; (2) DNA polymerase copies the target gene; and (3) multiple copies of the target gene are made by repeated melting of complementary strands, hybridization of primers, and new synthesis (Figure 11.5). From a single copy of a gene, several million copies can be made.

Which genes are suitable as target genes for microbial community analyses? Because genes encoding the small subunit ribosomal (SSU) rRNAs are phylogenetically informative and techniques for their analysis well developed (Sections 12.4 and 12.5), they are widely used in community analyses. Moreover, because rRNA genes are universal and contain several regions of high sequence conservation, it is possible to amplify them from all organisms using only a few different PCR primers, even though the organisms may be phylogenetically distantly related. In addition to rRNA genes, genes that encode enzymes for metabolic functions unique to a specific organism or group of related organisms can be the target genes (Table 18.3).

Genes such as those encoding rRNAs that have changed in sequence over time as species have diverged are called *orthologs* (Sections 6.11 and 12.5). Organisms that share the same or very closely related orthologous genes are called a **phylotype**. In microbial ecology, the phylotype concept is primarily used to provide a natural (phylogenetic) framework for describing the microbial diversity of a given habitat, regardless of whether the identified phylotypes are cultured organisms or not. Thus, the word *phylotype* is widely used to describe the microbial diversity of a habitat based solely on nucleic acid sequences. It is only when additional physiological and genetic information becomes available, typically after the organism is brought into laboratory culture, that proposing a genus and species name for a phylotype becomes possible.

In a typical community analysis experiment, total DNA is isolated from a microbial habitat (Figure 18.13). Commercially available

kits that yield high-purity DNA from soil and other complex habitats are available for this purpose. The DNA obtained is a mixture of genomic DNA from all of the microorganisms that were in the sample from the habitat (Figure 18.13). From this mixture, PCR is used to amplify the target gene and make multiple copies of each variant (phylotype) of the target gene. If RNA is isolated instead of DNA (to detect those genes being transcribed), the RNA can be converted into complementary DNA (cDNA) by the enzyme reverse transcriptase (Sections 9.11 and 27.10) and the cDNA subjected to PCR as for isolated DNA. However, regardless of whether DNA or RNA is originally isolated, the different phylotypes need to be sorted out following the PCR step before they can be sequenced. Sorting can be accomplished using one of three different methods: (1) physical separation by gel electrophoresis, (2) clone library construction, and (3) next-generation sequencing technology. We consider these methods now.

Denaturing Gradient Gel Electrophoresis: Separating Very Similar Genes

One method to resolve phylotypes is **denaturing gradient gel electrophoresis (DGGE)**, which separates genes of the same size that differ in their melting (denaturing) profile because of differences in their *base sequence* (Figure 18.14a, b). DGGE employs a gradient of a DNA denaturant, typically a mixture of urea and formamide. When a double-stranded DNA fragment moving through the gel reaches a region containing sufficient denaturant, the strands begin to “melt”; at this point, their migration stops (Figures 18.13 and 18.14b). Differences in base sequence cause differences in the melting properties of DNA. Thus, the different

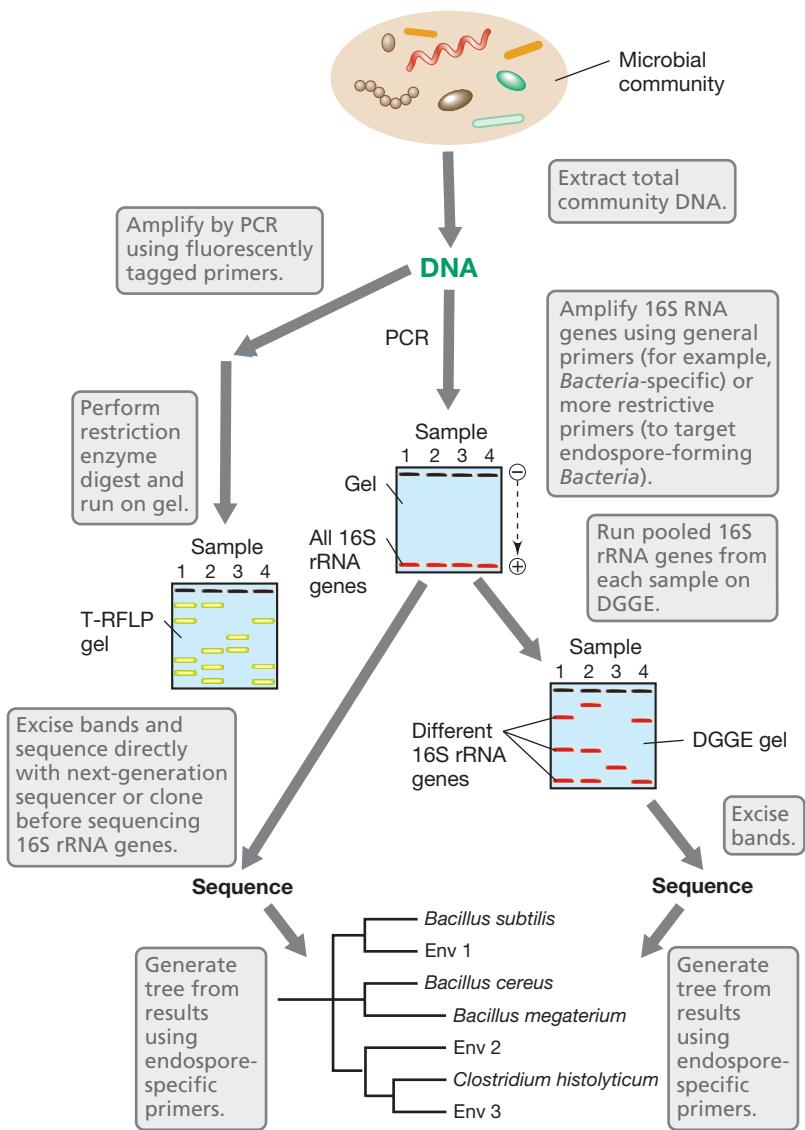

Figure 18.13 Steps in single-gene biodiversity analysis of a microbial community.

From total community DNA, 16S rRNA genes are amplified using, in the DGGE example, primers that target only *Firmicutes*, a group of gram-positive *Bacteria* that includes the endospore-forming genera *Bacillus* and *Clostridium*. The PCR bands are excised and the different 16S rRNA genes separated by either cloning or DGGE. Following sequencing, a phylogenetic tree is generated. "Env" indicates an environmental sequence (phylotype). In T-RFLP analyses, the number of bands indicates the number of phylotypes.

bands observed in a DGGE gel are phylotypes that can differ in base sequence significantly or by as little as a single base change.

Once DGGE has been performed, the individual bands are excised and sequenced (Figure 18.13). With 16S rRNA as the target gene, for example, the DGGE pattern immediately reveals the number of phylotypes (distinct 16S rRNA genes) present in a habitat (Figure 18.14c). The method provides an excellent mechanism to quickly evaluate temporal and spatial shifts in microbial community structure (Figure 18.14c). Following the sequencing of each DGGE band, the actual species present in the community can be determined by phylogenetic analyses (► Sections 12.4 and 12.5; Figure 18.13). If PCR primers specific for genes other than 16S rRNA are used, such as a metabolic gene (Table 18.3),

the variants of this specific gene that exist in the sample can also be assessed. Thus, although the number of bands on a DGGE gel is an overview of the biodiversity in a habitat (Figure 18.14c), sequence analysis is still required for identification and to infer phylogenetic relationship.

T-RFLP and ARISA

Another method for rapid microbial community analysis is *terminal restriction fragment length polymorphism* (*T-RFLP*). In this method a target gene (usually an rRNA gene) is amplified by PCR from community DNA using a primer set in which one of the primers is end-labeled with a fluorescent dye. The PCR products are then treated with a restriction enzyme (► Section 11.1) that cuts the DNA at specific sequences. Restriction enzymes with recognition sites of only four base pairs are commonly used because they cut frequently within a relatively short PCR product. This generates a series of DNA fragments of varying length, the number of which depends on how many restriction cut sites are present in the DNA. The fluorescently labeled terminal fragments are then separated by gel electrophoresis and the digestion products further separated and sized on an automated DNA sequencer that detects fragments based on fluorescence. Therefore, only the terminal dye-labeled fragments are detected. The pattern obtained shows the rRNA sequence variation in the microbial community sampled (Figure 18.13).

DGGE and T-RFLP both measure single-gene diversity, but in different ways. The pattern of bands on a DGGE gel reflects the number of same-length sequence variants of a single gene (Figure 18.14), whereas the pattern of bands on a T-RFLP gel reflects variants differing in DNA sequence of a single gene as measured by differences in restriction enzyme cut sites. The information obtained from a T-RFLP analysis, in addition to providing insight into the diversity and population abundances of a microbial community, can also be used to infer phylogeny. Diagnostic information for each fragment includes knowledge of sequences near both ends (primer sequence and restriction enzyme cut site), knowledge that a second restriction site does not exist within the fragment, and fragment length. Using specialized software, this information can be used to search for matching 16S rRNA sequences in public databases. Although this is of some predictive value, many closely related sequences are often not differentiated by these criteria. Thus, T-RFLP generally underestimates the diversity within a microbial community.

A technique related to T-RFLP that provides more detailed analysis of microbial communities is *automated ribosomal intergenic spacer analysis* (*ARISA*), which exploits the proximity of the 16S rRNA and 23S rRNA genes in prokaryotes. The DNA separating these two genes, called the *internal transcribed spacer* (*ITS*) region, differs in length among species and often also differs in length among the multiple rRNA operons of a single species (Figure 18.15a). The PCR primers for ARISA are complementary to conserved sequences in the 16S and 23S rRNA genes that flank the spacer region. Amplification (Figure 18.15b) and analysis (Figure 18.15c) are conducted as described for T-RFLP, resulting in a complex

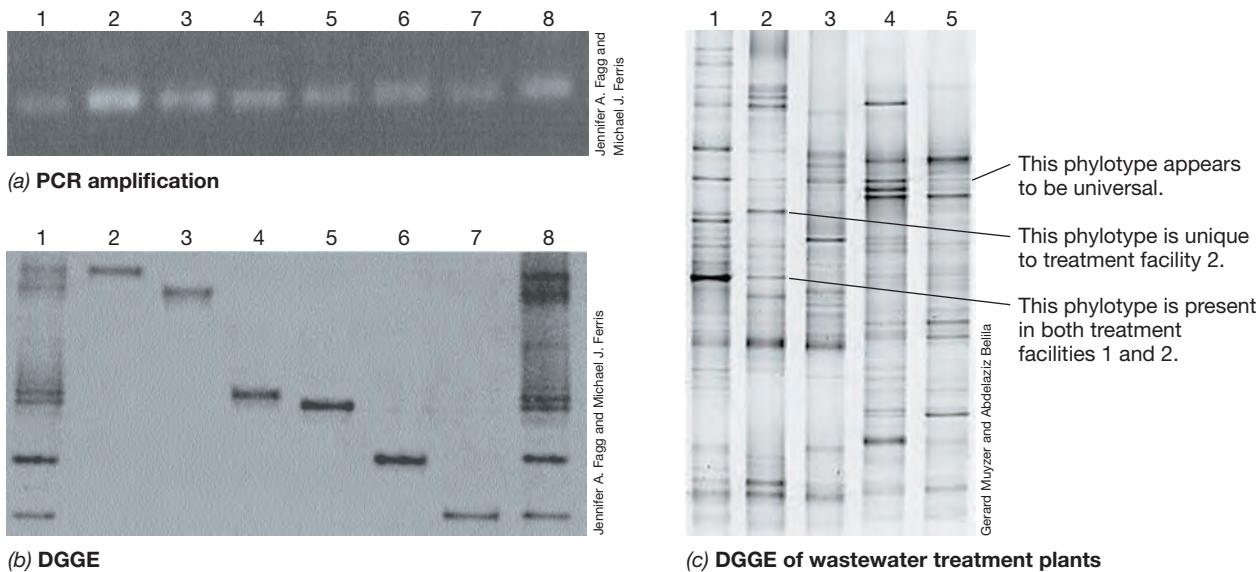

Figure 18.14 **PCR and DGGE gels.** Bulk DNA was isolated from a microbial community and amplified by PCR using primers for 16S rRNA genes of *Bacteria* (a, lanes 1 and 8). Six bands later resolved by DGGE (b, lanes 2–7) were excised and reamplified and each gave a single band at the same location on the PCR gel (a, lanes 2–7). However, by DGGE analysis, each band migrated to a different location on the gel (b, lanes 2–7). Note that all bands migrate to the same location in the nondenaturing PCR gel because they are all of the same size, but migrate to different locations on the DGGE gel because they have different sequences. pattern of bands that can be used for community analysis. However, ARISA differs from T-RFLP in that ARISA does not require a restriction enzyme digestion following PCR amplification. The word “automated” in the ARISA acronym refers to the use of a DNA sequencer that automatically identifies and assigns sizes to each dye-labeled fragment (Figure 18.15c), as can also be done in T-RFLP analyses. ARISA has received greatest application in the study of microbial community dynamics by monitoring, for example, changes in the presence and relative abundance of a specific community member through time and space.

Diversity Studies Using Clone Libraries or Next-Generation Sequencing

Most earlier molecular microbial diversity research relied on the construction of clone libraries to separate individual amplified DNA molecules (*amplicons*); each clone in the library contained a unique sequence that was then used as a template for sequence determination (☞ Section 6.2). Figure 18.14a shows that a 16S rRNA gene amplicon mixture appears as a single band when selected on a nondenaturing gel. However, because the amplified target gene came from a mixture of different cells, the phylotypes need to be sorted out before they are sequenced. This can be accomplished by either DGGE (Figure 18.14b, c), molecular cloning (Figure 18.13, ☞ Section 11.4), or by high-throughput sequencing systems (☞ Section 6.2) that do not require cloning for sequence determination.

Clone library construction and sequencing remains a standard method for analysis of microbial community phylogenetic diversity and for assessing functional potential (Table 18.3). However, since next-generation sequencers do not require a cloning step,

individual DNA fragments are separated and amplified on the sequencing device itself; thus, the PCR products can be used directly for sequencing. Since hundreds of thousands of amplification reactions are conducted simultaneously on next-generation sequencers, the total number of sequencing reads vastly exceeds what is possible by sequencing individual clones obtained in a clone library on a one-by-one basis (Figure 18.16). The tremendous volume of sequence generated by the new sequencing technology provides for extremely *deep sequence analyses*, meaning that minor phylotypes that were possibly missed by the more limited clone library method can now be revealed (Figure 18.16b). For example, imagine that a particular phylotype is present at only 0.01% in a library of cloned sequences. It would then be necessary to sequence well over a thousand clones, on a one-by-one basis, to have any reasonable chance of observing that specific phylotype. By contrast, the power of next-generation sequencing would detect this low-abundance phylotype along with its more abundant neighbors. The collection of minor phylotypes, which represent a substantial fraction of total diversity but only a minor component of total organism abundance in most environments, has been referred to as the *rare biosphere* (Figure 18.16).

Results of PCR Phylogenetic Analyses

Phylogenetic analyses of microbial communities have yielded surprising results. For example, using the gene encoding 16S rRNA as the target, analyses of natural microbial communities typically show that many phylogenetically distinct prokaryotes (phylotypes) are present whose rRNA gene sequences differ from those of all known laboratory cultures (Figure 18.13). Moreover, using additional methods that allow a quantitative assessment of

each phylotype, it has been discovered that with few exceptions, the most abundant phylotypes in a natural microbial community are ones that have thus far defied laboratory culture. These sobering results make it clear that our knowledge of microbial diversity from enrichment cultures is very incomplete and that enrichment bias (Section 18.1) is a serious problem in culture-dependent biodiversity studies. In fact, microbial ecologists estimate that less than 0.1% of the phylotypes revealed by molecular community analyses have ever been grown in laboratory cultures. Clearly there is much work in store for microbiologists who seek to understand microbial diversity.

18.6 Microarrays for Analysis of Microbial Phylogenetic and Functional Diversity

We previously considered the use of DNA chips, a type of *microarray*, for assessing overall gene expression in microorganisms (Section 6.7). More general microarrays can be constructed for rapid analyses of biodiversity and the functional potential of natural communities. Microarrays designed for biodiversity studies, called *phylochips*, have been developed for screening microbial communities for specific groups of prokaryotes. Another type of microarray has been designed to detect genes encoding functions of biogeochemical significance, such as genes encoding proteins required for sulfate respiration, ammonia oxidation, denitrification, or nitrogen fixation (Table 18.3). Because genes encoding functionally comparable enzymes can vary significantly in their primary sequence, arrays of function-specific genes, sometimes referred to as *functional gene microarrays*, must contain many thousands of probes in order to achieve reasonable coverage of natural diversity. Even then, these arrays may only sample a small fraction of natural functional diversity.

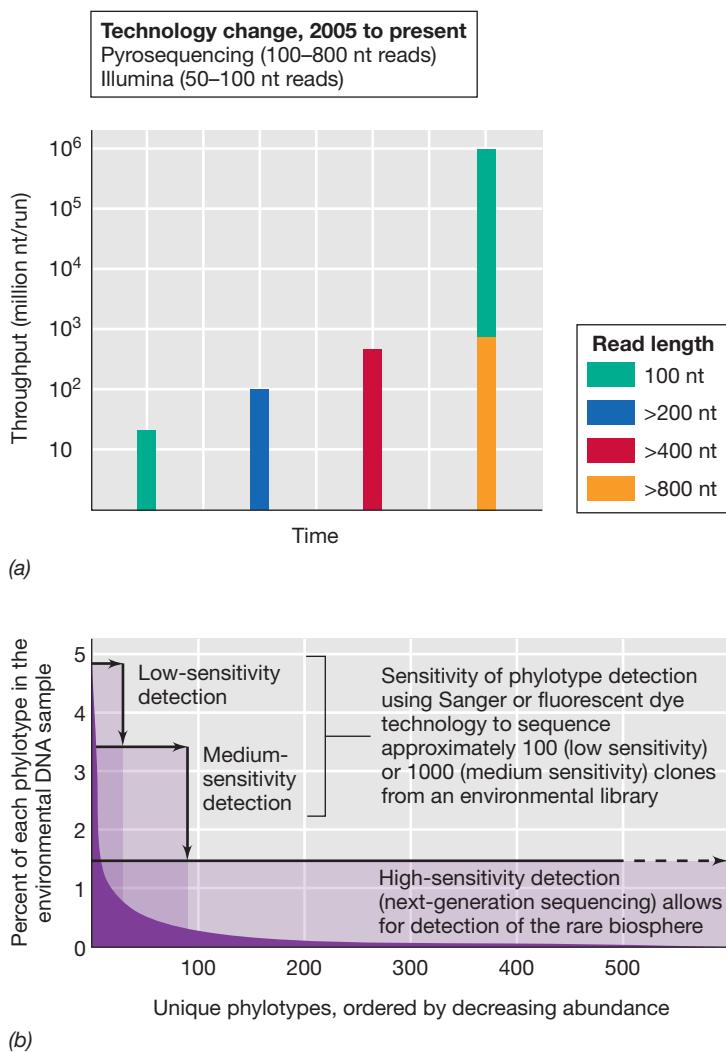

Figure 18.16 Community diversity analyses using next-generation sequencing technology. (a) Current sequencing platforms (Section 6.2) have the capacity to generate 10^{12} nucleotides (nt) of sequence in a single sequencing run (requiring a week or less), with individual read lengths varying from 100 to 800 nucleotides. (b) This enormous sequencing capacity has revealed many unique phylotypes that were not detected using DGGE or clone library sequencing. Fewer than 100 unique phylotypes would be detected by Sanger sequencing of 1000 clones in a library of 16S rRNA gene PCR amplicons. Jed Fuhrman is acknowledged for input to part b.

Phylochips are constructed by affixing rRNA probes or rRNA gene-targeted oligonucleotide probes to the chip surface in a known pattern. Each phylochip can be made as specific or general as required for the study by adjusting the specificity of the probes, and several thousand different probes can be added to a single phylochip. As an example, consider a phylochip designed to assess the diversity of sulfate-reducing bacteria (Sections 13.18 and 14.9) in a sulfidic environment, such as a marine sediment. Arranged in a known pattern on the phylochip are oligonucleotides complementary to specific sequences in the 16S rRNA genes of all known sulfate-reducing bacteria (over 100 species). Then, following the isolation of total community DNA from the sediment and PCR amplification and fluorescence labeling of the 16S rRNA genes, the environmental DNA is hybridized with the probes on the phylochip. The species that are present are determined by assessing

which probes hybridized sample DNA (Figure 18.17). Alternatively, rRNA might be extracted directly from the microbial community, labeled with a fluorescent dye, and hybridized directly to the phylochip without an amplification step. Much more general and inclusive phylochips have also been developed. For example, one such phylochip contains 500,000 rRNA gene-targeted oligonucleotides with coverage of over 8000 individual microbial taxa.

A functional gene microarray called the *GeoChip* contains about 50,000 gene sequences from more than 290 gene categories. The categories encompass very broad metabolic capacities, including the production and consumption of methane, alternative respiratory systems (e.g., dissimilative metal reduction, halo-respiration), heavy metal resistance, degradation of recalcitrant chlorinated pollutants, and common oxidative and reductive steps in the nitrogen, carbon, and sulfur cycles (Chapter 20).

Phylochips and functional gene microarrays like the *GeoChip* circumvent many of the time-consuming steps—PCR, DGGE, cloning, and sequencing—that are done in the microbial community analyses considered earlier (Figure 18.13). An important advantage of these methods compared to sequencing methods is reproducibility, especially for low-abundance taxa. However, an important caveat to interpretation of any gene microarray is the possibility of nonspecific hybridization. That is, gene variants that are closely related in sequence may not be resolved because of overlapping hybridization patterns. Moreover, totally unrelated genes may yield false positive results if they are sufficiently complementary to the probe to cause hybridization. Nevertheless, phylochips and functional gene arrays comprise another important tool for the culture-independent assessment of microbial biodiversity and potential metabolic activities.

MINIQUIZ

- What is a phylochip and what can it tell you?
- What are the advantages and disadvantages of microarray technology compared to sequencing PCR products?
- Why does T-RFLP analysis generally not completely capture the diversity of phylotypes in an environmental sample?

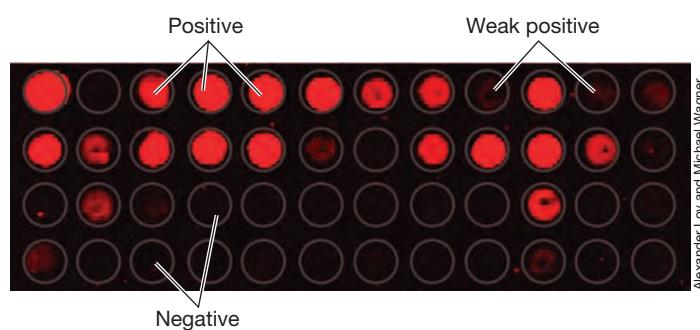

Figure 18.17 Phylochip analysis of sulfate-reducing bacteria diversity.

Each spot on the microarray shown has an oligonucleotide complementary to a sequence in the 16S rRNA of a different species of sulfate-reducing bacteria. After the microarray is hybridized with 16S rRNA genes PCR-amplified from a microbial community and then fluorescently labeled, the presence or absence of each species is signaled by fluorescence (positive or weak positive) or nonfluorescence (negative), respectively.

18.7 Environmental Genomics and Related Methods

A more encompassing approach to the molecular study of microbial communities is **environmental genomics**, also called **metagenomics**. These methods employ the sequencing and analysis of all microbial genomes in a particular environment as a means of characterizing the entire genetic content of that environment. Metagenomics initially focused on capturing random fragments of environmental DNA in small- or large-insert plasmids, which were used to create clone libraries of environmental DNA for sequencing; alternatively, the libraries could be screened for novel genes, such as those that encode antibiotic production. However, the introduction of high-throughput DNA sequencing technology (Sections 6.2 and 18.5) rapidly accelerated this technique and removed the need for cloning DNA. Instead, DNA could now be sequenced directly from total DNA.

Before the metagenomics era, microbial community analyses typically focused on the diversity of a *single* gene in an environmental sample. By contrast, in environmental genomics, *all* genes in a given microbial community can be sampled, and if done with proper experimental design, the information obtained can support a much deeper understanding of the structure and function of the community than can single-gene analyses.

It is not the immediate goal of environmental genomics to generate complete and finished genome sequences, as has been done for many cultured microorganisms (Chapter 6). Instead, the idea is to detect as many genes as possible encoding recognizable proteins and then, if possible, to determine the phylogeny of the organism(s) to which the genes belong. However, this limitation is now being reduced by the increased coverage possible using the latest high-throughput DNA sequencing technology (Figure 18.16) and improved algorithms used for assembly of metagenomic sequence data. These advances have enabled genomes to be routinely reconstructed from community DNA (see the opening page of this chapter).

A problem with genomes assembled from a mixture of environmental DNA sequence reads, however, is that they are unlikely to be clonal, instead being composed of fragments of DNA from closely related strains of a species (Figure 18.18). Of importance to “reassembly” of genomes or near-complete genomic fragments from metagenomic DNA is an assessment of whether all the genes required by any living organism are present (such as all necessary stable RNAs—tRNAs and rRNAs) and therefore diagnostic of a complete genome. In addition, an assessment of the relative abundance of genes encoding specific functions is equally valuable, since abundance changes suggest interactions among species or a common response to a particular environmental variable. For example, if a high number of genes were recovered in the pathway for nitrogen fixation, this would suggest that the environment sampled was limited in NH_4^+ , NO_3^- , and other forms of fixed nitrogen, thus selecting for nitrogen-fixing bacteria. Figure 18.18 contrasts the environmental genomic approach with single-gene analysis of microbial communities.

New Metagenomic Technologies

An early metagenomic study of prokaryotes in the Sargasso Sea (a low-nutrient region of the Atlantic Ocean near Bermuda)

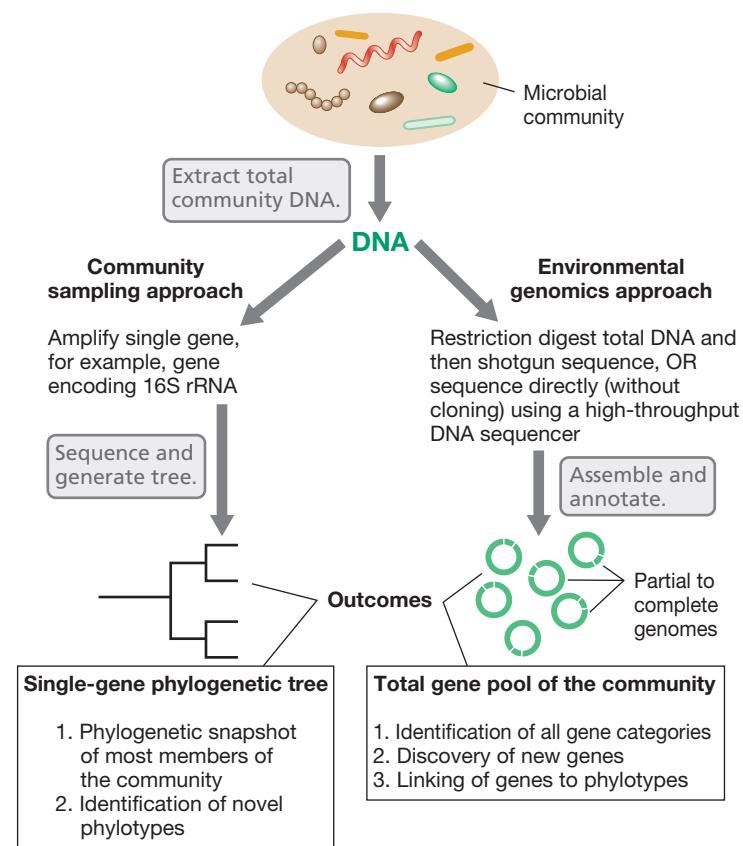

Figure 18.18 Single-gene versus environmental genomic approaches to microbial community analysis. In the environmental genomic approach, all community DNA is sequenced, but the assembled genomes may not all be complete. Total gene recovery is variable and depends on several factors including the complexity of the habitat and the amount of sequence determined. Recovery is typically better when diversity is low and sequence redundancy is high.

revealed remarkable diversity. This study was based on analysis of about one billion bp of sequence data from a random shotgun plasmid library of DNA (Section 6.2) obtained from surface water. The results suggested that at least 1800 bacterial and archaeal species were present, including 148 previously unknown phylotypes and many novel genes. Many of these species had previously been missed by rRNA-based community analyses. This is because the low-sensitivity detection generally afforded by sequencing clone libraries often misses minor species (Figure 18.16) and also because not all of the 16S rRNA genes that were present in the Sargasso Sea microbial community could be amplified with the primers used for PCR amplification. Genes that fail to amplify, of course, remain undetected in community analyses. Metagenomics sidesteps this problem by sequencing DNA *without first amplifying it* by gene-specific PCR (Table 18.3). Thus, genes are sequenced whether they can be amplified by PCR or not.

Although 1 billion base pairs of sequence is an enormous single data set that cost more than US\$1 million with then available technology, it was insufficient to fully describe the microbial species diversity in the Sargasso Sea sample! Indeed, 1 milliliter of seawater contains approximately 5 trillion bp of bacterial genomic DNA (given an average genome size of 5 million bp, and a density

of 1 million cells), and would therefore require 5,000 times that sequencing effort just to cover each base pair once on average. Even with current technology, which can generate over 800 billion bp of sequence in 10 days (Figure 18.16), no one environment has yet been sequenced completely. Moreover, this astonishing sequencing capacity that allows for metagenomic analyses of both the abundant as well as the rare components in a given habitat is also placing unprecedented demands on the computational capacity required for the sequence analyses. Indeed, major leaps in computational efficiency and storage capacities will be needed to keep pace with the volume of metagenomic data of the future.

Some Examples of Environmental Genomics

Environmental genomics can detect both new genes in known organisms and known genes in new organisms. In addition, many of the metagenomic sequence fragments show DNA motifs that suggest they encode proteins, but these proteins have no known homologs in the existing public databases and share no apparent phylogenetic relationship with any known species. These are known as “orphan” or “ORFan” genes, which is a play on the abbreviation for open reading frame (ORF). In the Sargasso Sea study mentioned previously, genes encoding proteins that function in known metabolisms were occasionally found embedded within the genomes of organisms not previously known to carry out such metabolisms. For instance, the discovery of genes related to those encoding ammonia monooxygenase, a key enzyme of ammonia-oxidizing *Bacteria* (Table 18.3; [Sections 13.10, 14.13, and 16.6](#)), on a DNA fragment that also contained archaeal genes suggested the possible existence of ammonia-oxidizing *Archaea*. This was later established when microbiologists were successful in isolating nitrifying *Archaea* from the marine environment (*Nitrosopumilus maritimus*, [Sections 13.10 and 16.6](#)).

In a second example from the Sargasso Sea study, genes encoding *proteorhodopsin*, the light-mediated proton pump present

in certain *Proteobacteria* and related to bacteriorhodopsin of extreme halophiles ([Section 16.1](#)), were found within the genomes of several new phylogenetic lineages of *Bacteria*. The gene for proteorhodopsin had been discovered earlier in an uncultured group of marine *Gammaproteobacteria* by cloning and sequencing large DNA fragments isolated from ocean water. Ongoing metagenomic analyses have since revealed that proteorhodopsin is broadly distributed, including in marine *Archaea* and freshwater *Bacteria*. These discoveries pointed to the importance of light to the physiology and ecology of these organisms and suggested new strategies for how to enrich and isolate them in laboratory culture. Proteorhodopsin has now been identified in a number of cultured microorganisms (including *Alpha-, Beta-, and Gammaproteobacteria*, species of *Bacteroidetes*, and eukaryotic marine dinoflagellates) and is associated primarily with bioenergetic functions.

Genomic approaches have also revealed variations in genes associated with a single phylotype; that is, in strains that contain identical, or nearly identical, rRNA genes. For example, in studies of *Prochlorococcus*, the most abundant cyanobacterium (oxygenic phototroph) in the ocean ([Section 14.3](#)), comparison of the genome sequences of cultured strains with *Prochlorococcus* genes obtained from metagenomic analyses of ocean water identified extensive regions shared between the cultured and environmental populations (Figure 18.19). This high level of gene conservation confirms that the organisms in culture are typical of environmental populations. However, these analyses also identified several highly variable regions in which the genomes of cultured strains differed significantly from environmental populations. These variable regions were clustered in the genome as *genomic islands*, also called *chromosomal islands* ([Section 6.13](#)), and likely encode functions that control the growth response of particular *Prochlorococcus* populations to environmental variables such as temperature or light quality and intensity.

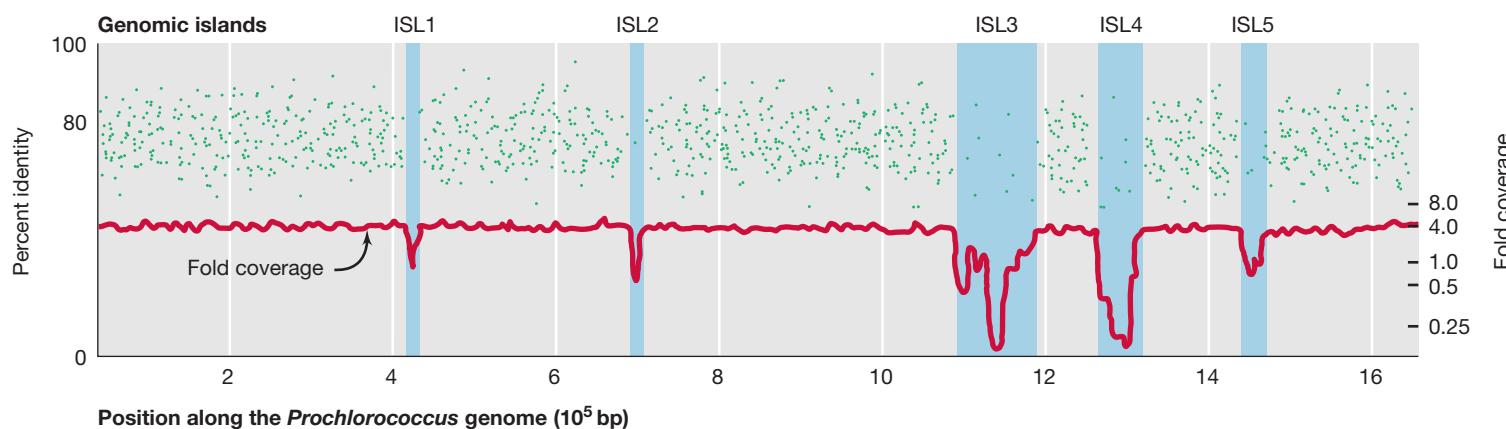

Figure 18.19 Metagenomic analysis. Sequences (represented as green dots) from the Sargasso Sea metagenome that align to the genome sequence of a cultured *Prochlorococcus*, showing regions where the cultured strain has genes of high similarity (high % identity) with sequences in the metagenome, and other regions (shaded) where it lacks genes in common (genomic islands, ISL1–ISL5). Since the DNA sequence contained within the genomic islands is thought to encode niche-specific functions, the cultured strain would likely not exhibit the same environmental distribution as strains containing all the island genes. Fold coverage is a measure of how completely the various regions in the *Prochlorococcus* genome are accounted for by similar sequences in the metagenome.

Metatranscriptomics and Metaproteomics

The application of genomic methods has spawned two related techniques, *metatranscriptomics* and *metaproteomics*. **Metatranscriptomics** is analogous to metagenomics but analyzes the sequences of community RNA, rather than DNA. The isolated RNA is converted into cDNA by reverse transcription (☞ Sections 9.11 and 27.10) before sequencing. Although metagenomics describes the functional capacities of the community (for example, the relative abundance of specific genes), metatranscriptomics reveals which genes in the community are actually being expressed, and the relative level of that expression, at a specific time and place. Because the expression of most genes in prokaryotes is controlled at the level of transcription (☞ Section 7.1), mRNA abundance can be considered a census of individual gene expression levels. Thus, gene transcript abundance determined for an entire community can be used to infer the operation of

major metabolic processes catalyzed by that community at the time of sampling (Figure 18.20).

Metaproteomics, the measure of the diversity and abundance of different *proteins* in a community, is an even more direct measure of cell function than is metatranscriptomics. This is because different mRNAs have different half-lives and efficiencies of translation, and thus will not all yield the same number of protein copies. However, metaproteomics is much more of a technical challenge than is either metagenomics or metatranscriptomics (☞ Section 6.8). Protein identification, usually by mass spectrometric characterization of peptides released from enzymatic digestion of the total protein pool using a protease that cleaves at arginine or lysine residues, relies on naturally available material since it is not possible to amplify protein sequences as one does using PCR to amplify nucleic acids for sequencing. Protein identification also requires at least partial physical separation of the individual

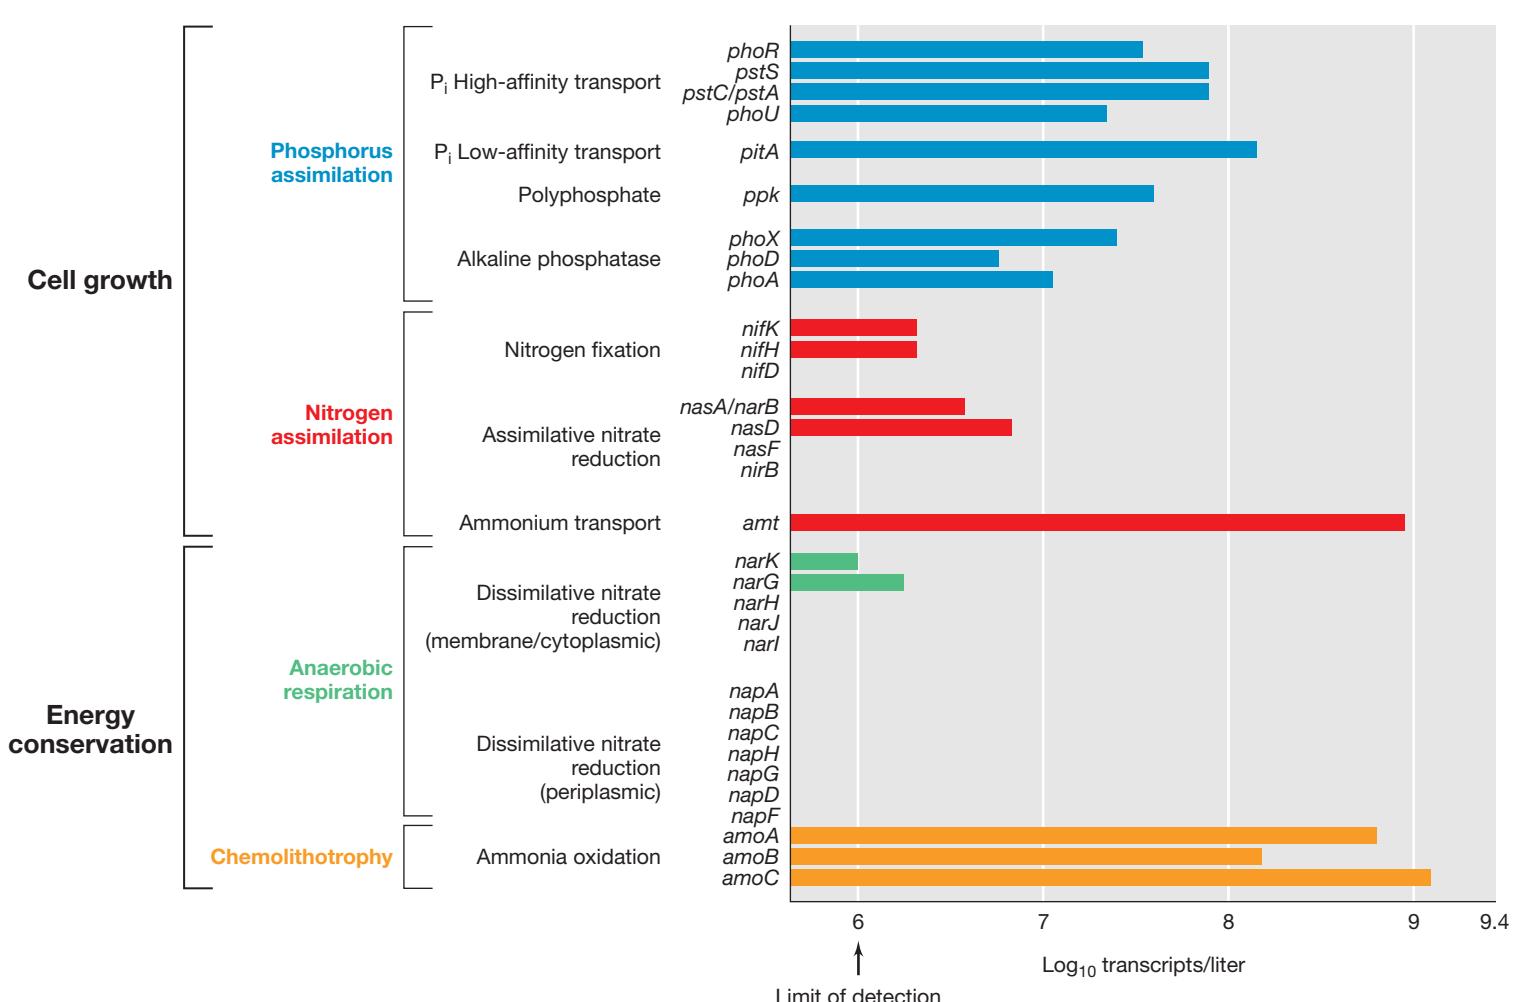

Figure 18.20 Metatranscriptomic analysis of coastal marine surface waters. Expression of genes for key steps in the N and P cycle in a seawater sample determined by sequencing environmental mRNA. These data showed that the microbial community was using both inorganic (high expression of P transporters) and organic (alkaline phosphatase) forms of phosphate (PO_4^{3-}). Low levels of transcripts for genes required for NO_3^- assimilation contrasted with the high expression of genes for NH_3 transport and chemolithotrophic NH_3 oxidation. peptides in order to reduce the complexity of samples analyzed by mass spectrometry. A final complication is the variable recovery of membrane-bound and cytoplasmic proteins. As a consequence, metaproteomics has thus far been restricted mostly to the qualitative characterization of rather simple microbial communities, such as those in some extreme environments, or to the characterization of only very abundant proteins in more complex communities. We discussed how proteins are identified in proteomic analyses and other aspects of metaproteomics in Section 6.8.

IV • Measuring Microbial Activities in Nature

So far in this chapter our discussion has focused on measuring microbial *diversity*. We now turn to how microbial ecologists measure microbial *activity*; that is, what microorganisms are actually *doing* in their environment. The techniques we consider include the use of radioisotopes, microsensors, stable isotopes, and several genomic methods.

Activity measurements in a natural sample are *collective* estimates of the physiological reactions occurring in the entire microbial community, although several techniques to be discussed later (see Sections 18.10 and 18.11) allow for a more targeted assessment of physiological activity. Activity measurements reveal both the types and rates of major metabolic reactions in a habitat, and the various techniques can be used alone or in combination in microbial community analyses. In conjunction with biodiversity estimates and gene expression analyses, these help define the structure and function of the microbial ecosystem, the ultimate goal of microbial ecology. Activity measurements can also provide valuable information for the design of enrichment cultures.

18.8 Chemical Assays, Radioisotopic Methods, and Microsensors

In many studies, direct chemical measurements of microbial reactions are sufficient for assessing microbial activity in an environment. For example, the fate of lactate oxidation by sulfate-reducing bacteria in a sediment sample can be tracked easily. If sulfate-reducing bacteria are present and active in a sediment sample, then lactate added to the sediment will be consumed and SO_4^{2-} will be reduced to H_2S . Since lactate, SO_4^{2-} , and S^{2-} can all be measured with fairly high sensitivity using simple chemical assays, the transformations of these substances relative to one another in a sample can easily be followed (Figure 18.21a).

Radioisotopes

When very high sensitivity is required, or turnover rates need to be determined, or the fate of portions of a molecule needs to be followed, *radioisotopes* are more useful than strictly chemical assays. For instance, if measuring photoautotrophy is the goal, the light-dependent uptake of radioactive carbon dioxide ($^{14}\text{CO}_2$) into microbial cells can be measured (Figure 18.21b). If SO_4^{2-} reduction is of interest, the rate of conversion of $^{35}\text{SO}_4^{2-}$ to H_2^{35}S can be assessed (Figure 18.21c). Heterotrophic activities can

be measured by tracking the release of $^{14}\text{CO}_2$ from ^{14}C -labeled organic compounds (Figure 18.21d), and so on.

Both isotopic and chemical methods are widely used in microbial ecology. To be valid, however, these must employ proper controls because some isotopic transformations might be due to abiotic processes. The *killed cell control* is the key control in such experiments. That is, it is essential to show that the transformation being measured stops when chemical agents or heat treatments that kill microorganisms are applied to the sample. Formalin at a final concentration of 4% is commonly used as a chemical sterilant in microbial ecology studies. This kills all cells, and transformations of radiolabeled materials in the presence of 4% formalin can be ascribed to abiotic processes (Figure 18.21).

Radioisotopic measurements: (b) photosynthesis measured with $^{14}\text{CO}_2$; (c) SO_4^{2-} reduction measured with $^{35}\text{SO}_4^{2-}$; (d) production of $^{14}\text{CO}_2$ from ^{14}C -glucose.

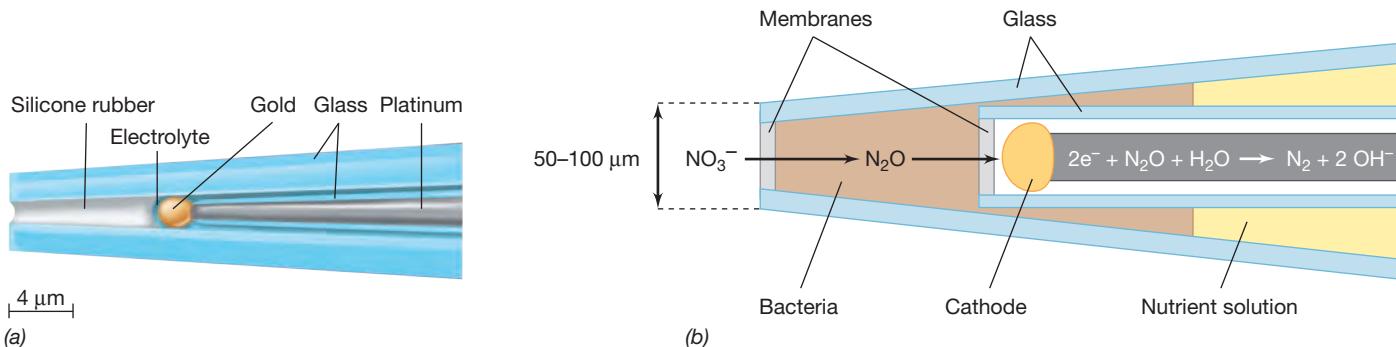

Figure 18.22 **Microsensors.** (a) Schematic drawing of an oxygen (O_2) microsensor. Oxygen diffuses through the silicone membrane in the microsensor tip and reacts with electrons on the gold surface of the cathode, forming hydroxide ions (OH^-); the latter generates a current proportional to the O_2 concentration in the sample. Note the scale of the electrode. (b) Biological microsensor for the detection of nitrate (NO_3^-). Bacteria immobilized at the sensor tip denitrify NO_3^- or NO_2^- to N_2O , which is detected by electrochemical reduction to N_2 at the cathode. Based on drawings by Niels Peter Revsbech.

Microsensors

Microsensors in the form of glass needles containing a sensing mechanism at the tip have been used to study the activity of microorganisms in nature. Microsensors have been constructed that measure many chemical species including pH, O_2 , NO_2^- , NO_3^- , nitrous oxide (N_2O), CO_2 , H_2 , and H_2S . As the name *microsensor* implies, these devices are very small, their tips ranging in diameter from 2 to 100 μm (Figure 18.22). The sensors are carefully inserted into the habitat in small increments to follow microbial activities over very short distances.

Microsensors have many applications. For example, O_2 concentrations in microbial mats (Figure 19.19c), aquatic sediments, or soil particles (Figure 19.3) can be very accurately measured over extremely fine intervals using microsensors. A micro-manipulator is used to insert the sensors gradually through the sample such that measurements can be taken every 50–100 μm (Figure 18.23). Using a bank of microsensors, each sensitive to a different chemical, simultaneous measurements of several transformations in a habitat can be made.

Microbial processes in the sea are extensively studied because they have a profound impact on nutrient cycles and the overall health of the planet. As it is difficult to reproduce in the laboratory the conditions found at great depths, it is useful to use microsensors on robotic devices to analyze microbial activities on the seafloor. Figure 18.24 shows deployment of an instrument “lander” equipped with various microsensors so that the distribution of chemicals in the sediment can be analyzed and compared with that in overlying ocean water. One of the biologically most important chemical species in the oceans is NO_3^- , but electrochemical sensors cannot measure NO_3^- in seawater, as the high concentrations of salts interfere. To circumvent this problem, a “living” microsensor was designed that contains bacteria within its tip that reduce NO_3^- (or NO_2^-) to N_2O . The N_2O produced by the bacteria is then detected following its abiotic reduction to N_2 at the cathode of the microsensor (Figure 18.22b); this provides an electrical impulse signaling the presence of NO_3^- . In the oxic layer of marine sediments, NO_3^- is produced from the oxidation of NH_4^+ (nitrification, Section 13.10), so there is often a peak of NO_3^- in the sediment surface layer (Figure 18.23). In

the deeper, anoxic layers of the sediment, NO_3^- is consumed by denitrification and dissimilative nitrate reduction to ammonia (DRNA) (Section 13.17), and NO_3^- therefore disappears a few millimeters below the oxic-anoxic interface (Figure 18.23).

18.9 Stable Isotopes

For many of the chemical elements different isotopes exist, varying in their number of neutrons. Certain isotopes are unstable and break down as a result of radioactive decay. Others, called *stable isotopes*, are not radioactive, but are metabolized differently by microorganisms and can be used to study microbial transformations in nature. There are two methods in which stable isotopes can yield information on microbial activities. We describe isotopic fractionation in this section and stable isotope probing in Section 18.11.

Isotopic Fractionation

The two elements most useful for stable isotope studies in microbial ecology are carbon (C) and sulfur (S), although the heavy isotope of nitrogen, ^{15}N , is also widely used. Carbon (C) exists in nature primarily as ^{12}C , but about 5% exists as ^{13}C . Likewise, S with its four stable isotopes exists primarily as ^{32}S . Some S is found as ^{34}S and very small amounts as ^{33}S and ^{36}S . The relative abundance of these isotopes changes when C or S is metabolized by microorganisms because enzymes typically favor the *lighter* isotope. That is, relative to the lighter isotope, the heavier isotope

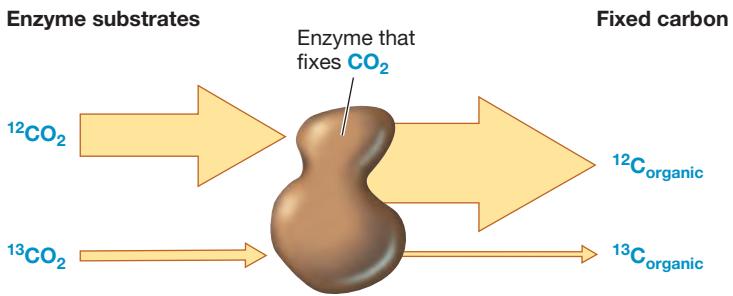

Figure 18.25 Mechanism of isotopic fractionation with C as an example.

Enzymes that fix CO_2 preferentially fix the lighter isotope (^{12}C). This results in fixed carbon being enriched in ^{12}C and depleted in ^{13}C relative to substrate CO_2 . The size of the arrows indicates the relative abundance of each isotope of carbon.

is discriminated against when both are metabolized by an enzyme (Figure 18.25). For example, when CO_2 is fixed into cell material by an autotrophic organism, the cellular C becomes *enriched* in ^{12}C and *depleted* in ^{13}C , relative to an inorganic carbon standard of known isotopic composition. Likewise, the S atom in H_2S produced from the bacterial reduction of SO_4^{2-} is isotopically lighter than H_2S that has formed geochemically. These discriminations are called **isotopic fractionations** (Figure 18.25) and are typically the result of biological activities. Thus this technique can be used as a measure of whether or not a particular transformation has been catalyzed by microorganisms.

The isotopic fractionation of C in a sample is calculated as the extent of ^{13}C depletion relative to a standard having an isotopic composition of geological origin. The standard for C isotope analysis is rocks from a Cretaceous (65- to 150-million-year-old) limestone formation (the Pee Dee belemnite). Because the magnitude of fractionation is usually very small, depletion is calculated as “per mil” (‰, or parts per thousand) and reported as the $\delta^{13}\text{C}$ (pronounced “delta C 13”) of a sample using the following formula:

$$\delta^{13}\text{C} = \frac{(^{13}\text{C}/^{12}\text{C} \text{ sample}) - (^{13}\text{C}/^{12}\text{C} \text{ standard})}{(^{13}\text{C}/^{12}\text{C} \text{ standard})} \times 1000\text{‰}$$

The same formula is used to calculate the fractionation of S isotopes, in this case using iron sulfide (FeS) mineral from the Canyon Diablo meteorite as the standard:

$$\delta^{34}\text{S} = \frac{(^{34}\text{S}/^{32}\text{S} \text{ sample}) - (^{34}\text{S}/^{32}\text{S} \text{ standard})}{(^{34}\text{S}/^{32}\text{S} \text{ standard})} \times 1000\text{‰}$$

Use of Isotopic Fractionation in Microbial Ecology

The isotopic composition of a material can reveal its biological or geological past. For example, plant material and petroleum (which is derived from plant material) have similar isotopic compositions (Figure 18.26). Carbon from both plants and petroleum is isotopically lighter than the CO_2 from which it was formed because the biochemical pathway used to fix CO_2 discriminated against $^{13}\text{CO}_2$ (Figures 18.25 and 18.26). Moreover, methane (CH_4) produced by methanogenic Archaea (► Section 16.2) is isotopically extremely light, indicating that methanogens discriminate strongly against $^{13}\text{CO}_2$ when they reduce CO_2 to CH_4 (► Section 13.20). By contrast, carbon in isotopically heavier marine carbonates is clearly of geological origin (Figure 18.26).

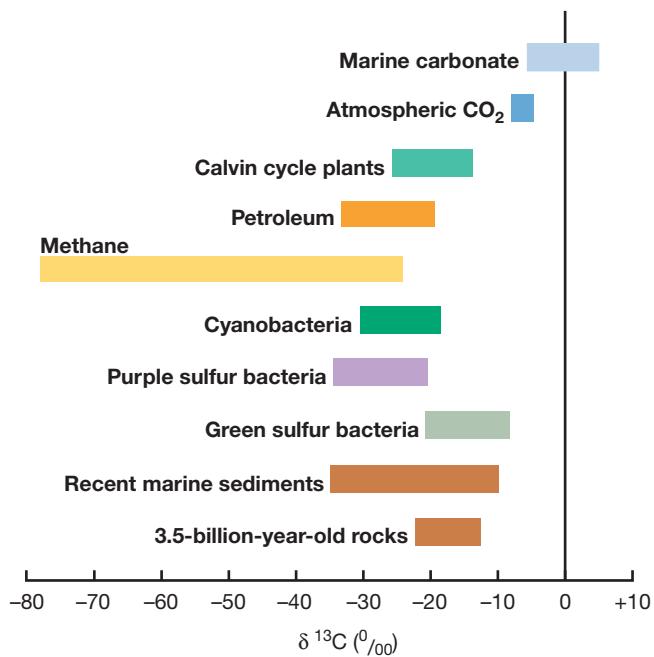

Figure 18.26 Isotopic geochemistry of ^{13}C and ^{12}C . Note that C fixed by autotrophic organisms is enriched in ^{12}C and depleted in ^{13}C . Methane formed from the reduction of CO_2 with H_2 by methanogenic *Archaea* shows extreme isotopic fractionation.

Because of the differences in the proportion of ^{12}C and ^{13}C in carbon of biological versus geological origin, the $^{13}\text{C}/^{12}\text{C}$ ratio of rocks of different ages has been used as evidence for or against past biological activity in Earth's ancient environments. Organic C in rocks as old as 3.5 billion years shows evidence of isotopic fractionation (Figure 18.26), supporting the idea that autotrophic life existed at this time. Indeed, we now believe that the first life on Earth appeared somewhat before this, about 3.8–3.9 billion years ago (Sections 1.3 and 12.1).

The activity of sulfate-reducing bacteria is easy to recognize from their fractionation of stable S isotopes in sulfides (Figure 18.27). As compared with an H_2S standard, sedimentary H_2S is highly enriched in ^{32}S (depleted in ^{34}S , Figure 18.27). Fractionation during sulfate reduction allows one to identify biologically produced S and has been widely used to trace the activities of sulfur-cycling prokaryotes through geological time. Sulfur isotopic analyses have also been used as evidence for the lack of life on the Moon. For example, the data in Figure 18.27 show that the isotopic composition of sulfides in lunar rocks closely approximates that of the H_2S standard, which represents primordial Earth, and differs from that of microbially produced H_2S .

18.10 Linking Genes and Functions to Specific Organisms: SIMS, Flow Cytometry, and MAR-FISH

The isotopic methods described thus far used samples containing large numbers of cells to infer that specific processes such as autotrophy or sulfate reduction were occurring within a community. These methods give an overview of community activities but do not reveal the contribution of individual cells. To do this, new isotopic methods have been developed that can measure the activity and the elemental and isotopic composition of single cells. Coupled with advanced DNA sequencing methods that can determine a genome sequence from the DNA contained in a single cell (Section 6.10 and Chapter 6 Explore the Microbial World, “Genomics, One Cell at a Time”), these techniques are at the cutting edge of microbial ecology today.

Imaging Metabolic Activities of Single Cells by Secondary Ion Mass Spectrometry (SIMS)

Secondary ion mass spectrometry (SIMS) is based on the detection of ions released from a sample placed under a focused high-energy primary ion beam, for example, of cesium (Cs^+); from the data generated, the elemental and isotopic composition of released materials can be obtained. When the primary ion beam impacts the sample, most chemical bonds are broken and atoms or polyatomic fragments are ejected from a very thin layer (1–2 nm) of the surface as either neutral or charged particles (secondary ions), a process called *sputtering*. These secondary ions are directed to a mass spectrometer, an instrument that can determine their mass-to-charge ratio.

NanoSIMS instruments are SIMS devices designed to yield information on single cells. The instrument is equipped with Cs^+ and O_2 primary beam sources with a resolution of 50 nm for the Cs^+ ion beam and 200 nm for the O_2 beam. The O_2 beam generates positive secondary ions and is used to analyze metals (e.g., Fe, Na, Mg) while the Cs^+ beam generates negative secondary ions for the analysis of major cellular elements (C, N, P, S, O, H) and halogens. The NanoSIMS instrument also records where on the specimen

the ion beam is directed such that a two-dimensional image of the distribution of specific ions on the sample surface is obtained. In addition, by focusing the ion beam on the same spot during repeated cycles of sputtering, material can be slowly burned away to expose deeper regions of the sample. This high-resolution SIMS analysis is where the term *NanoSIMS* got its name. NanoSIMS instruments have multiple detectors that provide for the simultaneous analysis of ions of different mass-to-charge ratios originating from the same sample location (Figure 18.28).

When combined with FISH (Section 18.4), NanoSIMS can be used to track the incorporation of different elements, natural isotopes, or isotope-labeled substrates into individual cells of specific cell populations. An initial application of the pairing of these two technologies (FISH-SIMS) was to characterize the composition of C isotopes in structured aggregates of anaerobic methane-oxidizing prokaryotes. A form of anaerobic methane oxidation widespread in marine sediments is the result of a syntrophic association between sulfate-reducing *Bacteria* and methane-oxidizing (methanotrophic) *Archaea* that form aggregates, with the metabolically coupled sulfate reducers surrounding an interior core of the archaeal methanotrophs (Sections 13.15, 13.24, and 20.1). Because biogenic CH₄ is highly depleted in ¹³C, NanoSIMS technology could be used to confirm incorporation of the lighter (¹²C) methane carbon into archaeal methanotrophs.

A variation on the FISH-SIMS method that greatly simplifies the identification of cells scanned by NanoSIMS uses probe-conferred deposition of a halide (Br, Fl, I), either through direct incorporation of the halide into an oligonucleotide probe (SIMS-*in situ* hybridization or SIMSISH) or by using a halide-containing tyramide substrate (see CARD-FISH, Section 18.4). This method is referred to as “elemental FISH” (EL-FISH) and also as “halogen *in situ* hybridization-SIMS” (HISH-SIMS). Halogens possess a high ionization yield compared with other elements and are thus easy to detect, and are typically of low natural abundance. Thus, one of the NanoSIMS detectors is

dedicated to identifying cells to which the probe has hybridized (Figure 18.28d) by halogen ionization while the remaining detectors are used for assessing elemental composition (Figure 18.28c).

Having excellent spatial resolution, NanoSIMS are increasingly used to examine metabolite transfer among single cells of interacting microorganisms. For example, labeling with ¹⁵N₂ followed by NanoSIMS was used to demonstrate the transfer of N₂ fixed by methanotrophic *Archaea* to the surrounding sulfate-reducing bacteria in the aggregates mentioned previously, and to demonstrate transfer of N₂ fixed by filamentous cyanobacteria to attached heterotrophic bacteria (Figure 18.28). Labeling with ¹⁵NH₄ and ¹³C-labeled CO₂ or organic substrates is also being used to explore the assimilation of key nutrients and the transfer of metabolites among microbial species in both aquatic and soil environments.

Flow Cytometry and Multiparametric Analyses

Because of the large population sizes of natural microbial communities—typically well in excess of 10⁶ cells per milliliter of water or per gram of soil—methods that rely on microscopy can examine only a very small part of a whole community. Although image analysis software can help automate the process, most microscopic analyses still rely on the practiced eye of the investigator. It is particularly difficult to assess cell numbers by counting cells microscopically, and this problem is compounded if populations are present in low numbers. However, a technique called flow cytometry offers an alternative to more labor-intensive microscopic methods. Flow cytometers can examine specific cell parameters such as size, shape, or fluorescent properties as the cells pass through a detector at rates of many thousands of cells per second (Figure 18.29). Fluorescence may be intrinsic (for example, chlorophyll fluorescence of phototrophic microorganisms; or it may be conferred by DNA staining, or by differential staining of live versus dead cells (vital stains), or by fluorescent DNA probes (FISH), all methods discussed in this chapter. A major advantage of flow cytometry is the ability to carry

out *multiparametric analyses*, that is, the capacity to combine multiple parameters in the analysis of a microbiological sample or to find a specific population. A remarkable example of this was the discovery in the late 1980s of a novel and abundant community of marine cyanobacteria, all species of the genus *Prochlorococcus*. *Prochlorococcus* cells are smaller and have different fluorescent properties than another common marine cyanobacterium, *Synechococcus*. Based on differences in size and fluorescence, flow cytometry resolved these two populations and *Prochlorococcus* was subsequently shown to be the predominant oxygenic phototroph in ocean waters between 40°S and 40°N latitude, reaching concentrations greater than 10^5 cells/ml. Based on this finding, it can be said that *Prochlorococcus* is the most abundant phototrophic organism on Earth. We discuss the biology of *Prochlorococcus* in more detail in Section 19.10 and Figure 18.19.

Radioisotopes in Combination with FISH: Microautoradiography-FISH

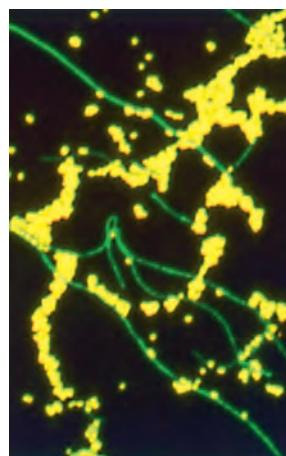

Radioisotopes are used as measures of microbial activity in a microscopic technique called **microautoradiography (MAR)**. In this

method, cells from a microbial community are exposed to a substrate containing a radioisotope, such as an organic compound or CO_2 . Heterotrophs take up the radioactive organic compounds and autotrophs take up the radioactive CO_2 . Following incubation in the substrate, cells are affixed to a slide and the slide is dipped in photographic emulsion. While the slide is left in darkness for a period, radioactive decay from the incorporated substrate induces formation of silver grains in the emulsion; these appear as black dots above and around the cells. **Figure 18.30a** shows a MAR experiment in which an autotrophic cell has taken up $^{14}\text{CO}_2$.

Microautoradiography can be done simultaneously with FISH (Section 18.4) in **MAR-FISH**, a powerful technique that combines identification with activity measurements. MAR-FISH allows a microbial ecologist to determine (by MAR) which organisms in a natural sample are metabolizing a particular radiolabeled substance while at the same time identifying these organisms (by FISH) (Figure 18.30). MAR-FISH thus goes a step beyond phylogenetic identification by revealing physiological information on the organisms, as is also true of NanoSIMS. Such data are useful not only for understanding the activity of the microbial ecosystem but also for guiding enrichment cultures. For example, knowledge of the phylogeny and morphology of an organism metabolizing a particular

substrate in a natural sample can be used to design an enrichment protocol to isolate the organism. In addition, MAR-FISH results can be quantified by counting the silver grains as a measure of the amount of substrate consumed by single cells, allowing the activity distribution in a community to be described. The technique is limited only by the availability of suitable radioactive isotopes. For example, although C-labeled substrates work well, it is not feasible to track N incorporation using MAR-FISH, since the radioactive isotope ^{13}N has a very short half-life. However, it is feasible to track N incorporation using the nonradioactive ^{15}N with NanoSIMS, as we saw earlier (Figure 18.28).

- Compared with microscopy, what are the advantages and disadvantages of flow cytometry for characterizing a microbial community?
- How does MAR-FISH link microbial diversity and activity?

18.11 Linking Genes and Functions to Specific Organisms: Stable Isotope Probing and Single-Cell Genomics

We have seen in the previous section how the combination of FISH with MAR or FISH with NanoSIMS allows for analyses of both microbial diversity and activity. These are powerful methods for connecting specific microbial populations with a specific activity or ecological niche, but in both cases, the phylogeny of the organisms of interest must be known for the FISH probe to be developed (Section 18.4). An alternative method of coupling diversity to activity is **stable isotope probing** (SIP), a method that employs stable isotopes such as ^{13}C or ^{15}N or even ^{18}O to label DNA of organisms in a community. In addition to SIP, improvements in DNA sequencing technology allow genomics to be performed on single cells obtained from the environment. We look at the power of both of these methods here.

Stable Isotope Probing

How is a SIP experiment done? Let's say the goal of a research project was to characterize organisms capable of catabolizing aromatic compounds in lake sediment. Using benzoate as a model aromatic compound, ^{13}C -enriched benzoate would be added to a sediment sample, the sample incubated for an appropriate period, and then total DNA extracted from the sample (Figure 18.31). As shown in Figure 18.13, such DNA originates from *all* of the organisms in the microbial community. However, organisms that incorporate ^{13}C -benzoate will synthesize DNA containing ^{13}C . ^{13}C -DNA is heavier, albeit only slightly heavier, than ^{12}C -DNA, but the difference is sufficient to separate the heavier DNA from the lighter DNA by a special type of centrifugation technique (Figure 18.31). Once the ^{13}C -DNA is isolated, it can be analyzed using various genomics techniques for genes of interest.

If the goal of the benzoate study was to characterize the phylogeny of the organism(s) catabolizing the benzoate, PCR amplification and analysis of 16S rRNA genes from the ^{13}C -DNA could be used to do so (Figures 18.13 and 18.14). However, in addition to phylogenetic analyses, functional genes could also be targeted once the ^{13}C -DNA was obtained. For example, SIP has been employed in studies of the phylogeny and metabolism of methylotrophs, organisms that specialize in the catabolism of C_1 compounds (► Section 13.23), in natural environments. In these studies, $^{13}\text{CH}_4$ or ^{13}C -labeled methanol ($^{13}\text{CH}_3\text{OH}$) was used to label the methylotrophs' DNA followed by PCR amplification of 16S rRNA genes and genes encoding specific methane oxidation functions (Table 18.3) from the ^{13}C -DNA. Whole genome analyses are also possible using SIP. For example, in a second methylotroph study, SIP was used in combination with metagenomic analyses (Section 18.7), and the results pointed to a previously unsuspected methylotroph as being a key species for the catabolism of C_1 compounds in that particular environment.

SIP can also be done with labeled N. In this case, the isotopically heavy isotope of N, ^{15}N , competes with the more abundant and lighter isotope, ^{14}N . To study nitrogen fixation, for example, a sample would be supplied with $^{15}\text{N}_2$, and those organisms that can fix N_2 (► Section 3.17) will incorporate some of the $^{15}\text{N}_2$. Some of the ^{15}N will end up in the organism's DNA, making it isotopically "heavy"; such DNA can be separated from isotopically lighter (^{14}N) DNA by ultracentrifugation (Figure 18.31) and then analyzed for specific genes.

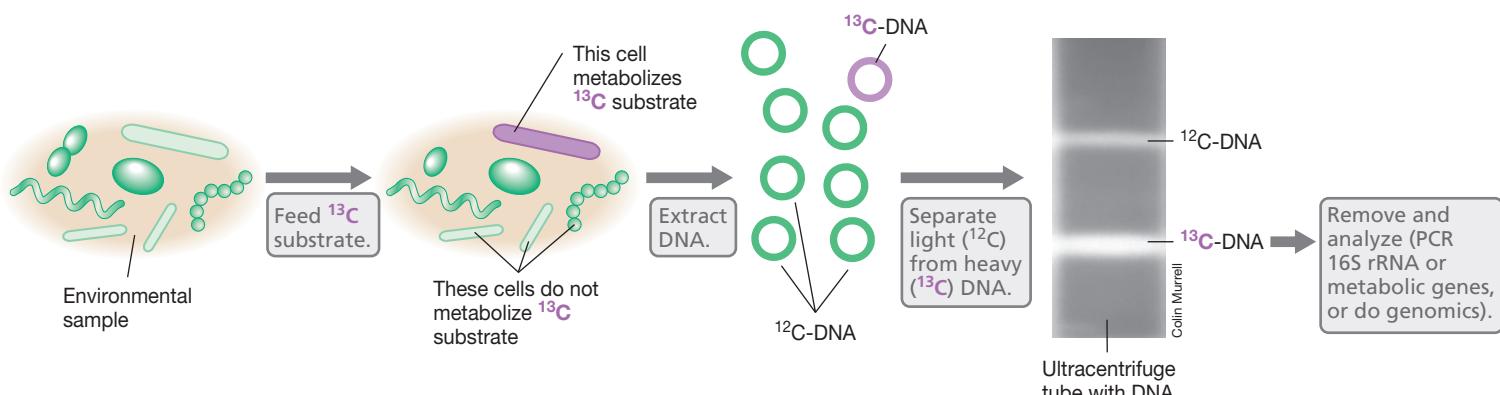

Figure 18.31 **Stable isotope probing.** The microbial community in an environmental sample is fed a ^{13}C -substrate. Organisms that can metabolize the substrate produce ^{13}C -DNA as they grow and divide; ^{13}C -DNA can be separated from lighter ^{12}C -DNA by density gradient centrifugation (photo). The isolated DNA is then subjected to specific gene analysis or entire genomic analysis.

Single-Cell Genomics

A major stumbling block in PCR-based gene recovery method is the requirement that a specific gene that will react with the primers used in the amplification be identified prior to analysis. Newer methods of DNA amplification now provide an alternative method for associating specific genes with a specific organism without the problems and biases associated with PCR. These methods employ *single-cell genomics* (➡ Section 6.10 and Chapter 6 Explore the Microbial World, “Genomics, One Cell at a Time”), one of the most recent tools to enter the microbial ecologist’s toolbox. **Multiple displacement amplification (MDA)** (Figure 18.32) is key to single-cell genomics and is used to amplify chromosomal DNA from a single cell isolated from a natural environment using a cell sorting technique, such as flow cytometry (Figure 18.29).

MDA uses a DNA polymerase from a specific bacteriophage to initiate replication of cell DNA at random points in the chromosome, displacing the complementary strand as each polymerase molecule synthesizes new DNA. This polymerase has strong strand displacement activity, resulting in the synthesis of numerous high-molecular-weight DNA products. The number of genome copies produced by amplification is sufficient to determine the complete, or nearly complete, genome sequence using next-generation sequencing platforms. In this way, both phylogenetic and metabolic functions can be inferred from the genome sequence and PCR is not required.

MDA requires stringent control over purity to eliminate contaminating DNA, but when combined with high-throughput DNA sequencing methods, MDA provides a powerful tool for linking specific metabolic functions to individual cells that have never been grown in laboratory culture. Information about the metabolic capacities of these uncultured organisms can then be used to develop strategies to recover them by enrichment culture methods and get them growing in laboratory culture.

MINIQUIZ

- How can stable isotope probing reveal the identity of an organism that carries out a particular process?
- What key method is required to do genomics on a single cell?
- When grown on $^{15}\text{N}_2$, would the DNA of a nitrogen-fixing bacterium be lighter or heavier than that of a bacterium unable to fix nitrogen?

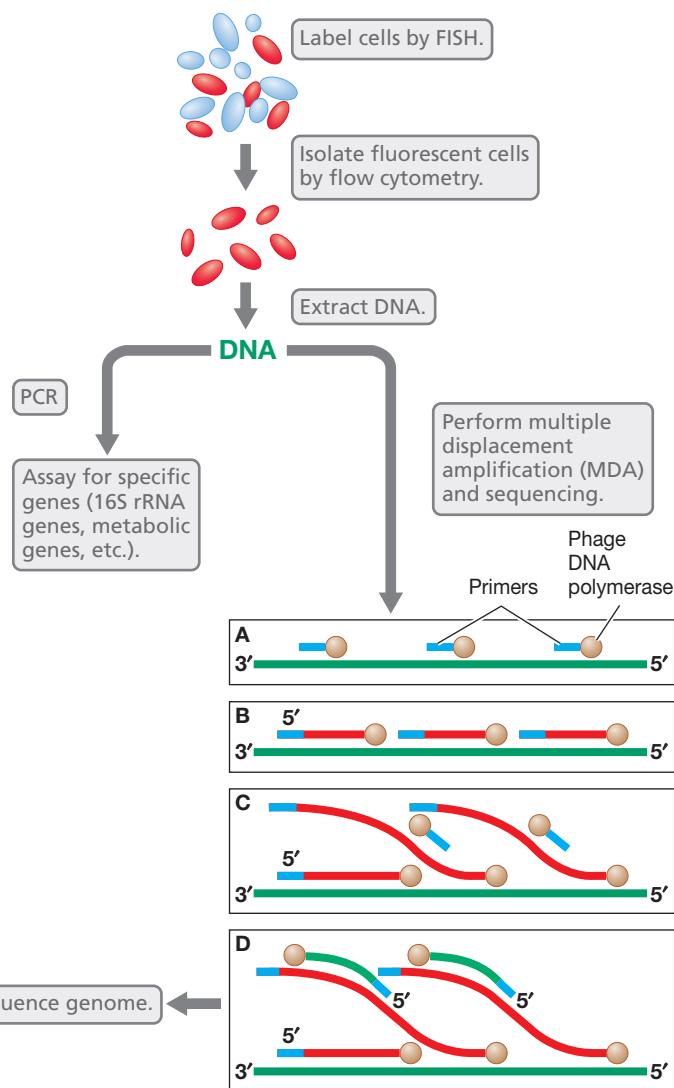

Figure 18.32 **Genetic analysis of sorted cells.** DNA is recovered from a specific population of cells following FISH labeling and flow cytometric sorting (Figure 18.29). DNA is characterized by PCR amplification and sequencing of specific genes, or by amplification of the entire genome by MDA followed by sequencing. For MDA, an amount of DNA sufficient for full genome sequence determination is produced using short DNAs of random sequence as primers (A) to initiate genome replication by a bacteriophage DNA polymerase. The bacteriophage polymerase copies DNA from multiple points in the genome and also displaces newly synthesized DNA (B, C), thereby freeing additional DNA for primer annealing and (D) initiation of polymerization.

BIG IDEAS

18.1 • The enrichment culture technique is a means of obtaining microorganisms from natural samples. Successful enrichment and isolation prove that an organism of a specific metabolic type was present in the sample, but does not indicate its ecological importance or abundance.

18.2 • Once a successful enrichment culture has been established, pure cultures can often be obtained by conventional microbiological procedures, including streak plates, agar dilution, and liquid dilution methods. Laser tweezers and flow cytometry allow one to isolate a cell from a microscope field and move it away from contaminants.

18.3 • DAPI, acridine orange, and SYBR Green are general stains for quantifying microorganisms in natural samples. Some stains can differentiate live versus dead cells. The GFP makes cells autofluorescent and is a means for tracking cells introduced into the environment and reporting gene expression. In natural samples, morphologically identical cells may actually be genetically distinct.

18.4 • FISH methods have combined the power of nucleic acid probes with fluorescent dyes and are thus highly specific in their staining properties. FISH methods include phylogenetic stains and CARD-FISH.

18.5 • PCR can be used to amplify specific target genes such as rRNA genes or key metabolic genes. DGGE can identify the different variants of these genes present in different species in a community.

18.6 • Phylochips combine microarray and phylogenetic technologies and are used to screen microbial communities for specific groups of prokaryotes.

18.7 • Environmental genomics (metagenomics) is based on cloning, sequencing, and analysis of the collective genomes of the organisms present in a microbial community. Metatranscriptomics and metaproteomics are offshoots of metagenomics whose focus is mRNA and proteins, respectively.

18.8 • The activity of microorganisms in natural samples can be assessed very sensitively using radioisotopes or microsensors, or both. The measurements obtained give the net activity of the microbial community.

18.9 • Isotopic compositions can reveal the biological origin and/or biochemical mechanisms involved in the formation of various substances. Isotopic fractionation is a result of the activity of enzymes that discriminate against the heavier form of an element when binding their substrates.

18.10 • A variety of advanced technologies such as NanoSIMS and MAR-FISH make it possible to examine metabolic activity, gene content, and gene expression in natural microbial communities. NanoSIMS employs secondary ion mass spectrometry technology while MAR-FISH combines the uptake of radiolabeled substrates (MAR) along with phylogenetic identification (FISH).

18.11 • SIP employs substrates labeled with heavy isotopes to generate “heavy” DNA that can be separated from the remaining (“light”) DNA. Genomic analyses of the heavy DNA allow processes to be linked to specific organisms. Single-cell genomics incorporates methods for analyzing the genome of individual cells isolated from a natural microbial community.

Acridine orange a nonspecific fluorescent dye used to stain DNA in microbial cells in a natural sample

DAPI a nonspecific fluorescent dye that stains DNA in microbial cells; used to obtain total cell numbers in natural samples

Denaturing gradient gel electrophoresis (DGGE) an electrophoretic technique capable of separating nucleic acid fragments of the same size that differ in base sequence

Enrichment bias a problem with enrichment cultures in which “weed” species tend to dominate in the enrichment, often to the exclusion of the most abundant or ecologically significant organisms in the inoculum

Enrichment culture highly selective laboratory culture methods for obtaining microorganisms from natural samples

Environmental genomics (metagenomics) the use of genomic methods (sequencing and

analyzing genomes) to characterize natural microbial communities

Flow cytometry a technique for counting and examining microscopic particles by suspending them in a stream of fluid and passing them by an electronic detection device

Fluorescence in situ hybridization (FISH) a method employing a fluorescent dye covalently bonded to a specific nucleic acid probe for identifying or tracking organisms in the environment

Fluorescent protein any of a large group of proteins that fluoresce different colors, including the green fluorescent protein, for tracking genetically modified organisms and determining conditions that induce the expression of specific genes

Fundamental niche the range of environments in which a species will be sustained when it is

not resource-limited, such as may result from competition with other species

Isotopic fractionation the discrimination by enzymes against the heavier isotope of the various isotopes of C or S, leading to enrichment of the lighter isotopes

Laser tweezers a device for obtaining pure cultures by optically trapping a single cell with a laser beam and moving it away from surrounding cells into sterile growth medium

MAR-FISH a technique that combines identification of microorganisms with measurement of metabolic activities

Metatranscriptomics the measurement of whole-community gene expression using RNA sequencing

Metaproteomics the measurement of whole-community protein expression using mass spectrometry to assign peptides to the amino acid sequences coded by unique genes

Microautoradiography (MAR) the measurement of the uptake of radioactive substrates by visually observing the cells in an exposed photographic emulsion

Microbial ecology the study of the interaction of microorganisms with each other and their environment

Microsensor a small glass sensor or electrode for measuring pH or specific compounds such as O₂, H₂S, or NO₃⁻ that can be immersed into a microbial habitat at microscale intervals

Most-probable-number (MPN) technique the serial dilution of a natural sample to

determine the highest dilution yielding growth

Multiple displacement amplification (MDA)

a method to generate multiple copies of chromosomal DNA from a single organism

Nucleic acid probe an oligonucleotide, usually 10–20 bases in length, complementary in base sequence to a nucleic acid sequence in a target gene or RNA

Phylotype one or more organisms with the same or related sequences of a phylogenetic marker gene

Realized niche the range of natural environments supporting a species when

that organism is confronted with factors such as resource limitation, predation, and competition from other species

Stable isotope probing (SIP) a method for characterizing an organism that incorporates a particular substrate by supplying the substrate in ¹³C or ¹⁵N form and then isolating heavy isotope-enriched DNA and analyzing the genes

Winogradsky column a glass column packed with mud and overlaid with water to mimic an aquatic environment, in which various bacteria develop over a period of months

REVIEW QUESTIONS

APPLICATION QUESTIONS

- Design an experiment for measuring the activity of sulfur-oxidizing bacteria in soil. If only certain species of the sulfur oxidizers present were metabolically active, how could you tell this? How would you prove that your activity measurement was due to biological activity?
- You wish to know whether *Archaea* exist in a lake water sample but are unsuccessful in culturing any. Using techniques described in this chapter, how could you determine whether *Archaea* existed in the sample, and if they did, what proportion of the cells in the lake water were *Archaea*?
- Design an experiment to solve the following problem. Determine the rate of methanogenesis (CO₂ + 4 H₂ → CH₄ + 2H₂O) in

anoxic lake sediments and whether or not it is H₂-limited. Also, determine the morphology of the dominant methanogen (recall that these are *Archaea*, Section 16.2). Finally, calculate what percentage the dominant methanogen is of the total archaeal and total prokaryotic populations in the sediments. Remember to specify necessary controls.

- Design a SIP experiment that would allow you to determine which organisms in a lake water sample were capable of oxidizing the hydrocarbon hexane (C₆H₁₄). Assume that four different species could do this. How would you combine SIP with other molecular analyses to identify these four species?

Living in a World of Extreme Energy Limitation

Cold anoxic marine sediments comprise the largest organic carbon sink on Earth and are one of the most significant of all microbial habitats, harboring an estimated 3×10^{29} cells; this is similar to the total number of microbial cells in seawater.

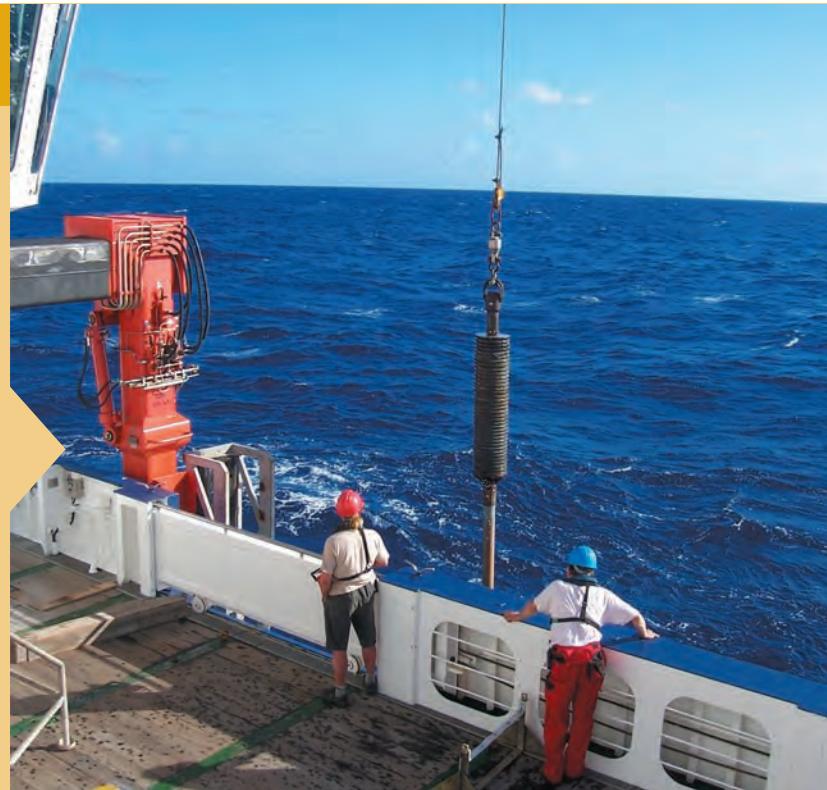

Organic matter enters the sediments when cells and organic particles sink through the water column. Easily degraded components are removed by microbial processes in the water column or in surface sediments, leaving behind a dilute pool of deeply buried organic matter that is not readily degradable. Because of this poor nutrient quality, most of the deep-sediment microbial community exists in a state of metabolic slow motion, with populations doubling every one hundred to one thousand years.

Archaea are abundant in this energy-starved environment, and it is thought they may be better adapted than *Bacteria* to energy limitation.¹ However, since the major sediment populations also represent novel archaeal lineages that have not yet been cultured, insight into their physiology has only recently emerged from the application of molecular and analytical tools suited to the analysis of single cells.

Several partial genome sequences have been determined from single cells of Archaea plucked from sediments collected by coring the seafloor (photo). Genomic analyses confirmed their affiliation with the novel archaeal groups and revealed a physiological capacity to degrade and assimilate protein. Thus, these organisms apparently specialize in the degradation and assimilation of proteins buried by sedimentation or released when other sediment microorganisms die.

Since sediment microorganisms largely control the fate of carbon in this vast subsurface reservoir of organic matter, the discovery of these archaeal protein eaters living at the thermodynamic edge of life has given microbial ecologists a new perspective on carbon cycling in marine sediments.

Microorganisms do not live alone in nature but instead interact with other organisms and with their environment. In so doing, microorganisms carry out many essential activities that support all life on Earth. In this chapter we explore some of the major habitats of microorganisms; these include soil, freshwater, and

the oceans. In addition to these, microorganisms have also established more specific, and often very intimate, associations with plants and animals. We examine a few examples of such microbial partnerships and symbioses in Chapter 22.

I • Microbial Ecology

We begin with a broad overview of the science of microbial ecology, including ways that organisms interact with each other and their environments and the difference between species *diversity* and species *abundance*. These basic ecological concepts pervade this and the next two chapters.

19.1 General Ecological Concepts

The distribution of microorganisms in nature resembles that of macroorganisms in the sense that a given species resides in certain places but not others; that is, everything is not everywhere. Also, environments differ in their abilities to support diverse microbial populations. We examine these concepts here.

Ecosystems and Habitats

An **ecosystem** is a dynamic complex of plant, animal, and microbial communities and their abiotic surroundings, all of which interact as a functional unit. An ecosystem contains many different **habitats**, parts of the ecosystem best suited to one or a few populations. Although microorganisms are present in any habitat containing plants and animals, many microbial habitats are unsuitable for plants and animals. For example, microorganisms are ubiquitous on Earth's surface and even deep within it; they inhabit boiling hot springs and solid ice, acidic environments near pH 0, saturated brines, environments contaminated with radionuclides and heavy metals, and the interior of porous rocks that contain only traces of water. So some ecosystems are mostly or even exclusively microbial.

Collectively, microorganisms show great metabolic diversity and are the primary catalysts of nutrient cycles in nature (Chapter 20). The *types* of microbial activities possible in an ecosystem are a function of the species present, their population sizes, and the physiological state of the microorganisms in each habitat. By contrast, the *rates* of microbial activities in an ecosystem are controlled by the nutrients and growth conditions that prevail. Depending on several factors, microbial activities in an ecosystem can have minimal or profound impacts and can diminish or enhance the activities of both the microorganisms themselves and the macroorganisms that may coexist with them.

Species Diversity in Microbial Habitats

A group of microorganisms of the same species that reside in the same place at the same time constitutes a microbial **population**. A microbial population may be descended from a single cell. As noted in earlier chapters, a microbial **community** consists of populations of one species living in association with populations of one or more other species. The mix of species that are found in a certain habitat are those best able to grow with the nutrients and conditions that prevail there.

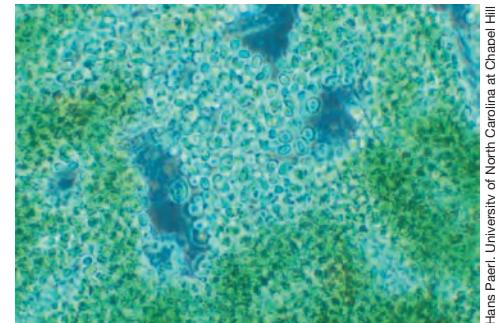

The diversity of microbial species in a community can be expressed in two ways (Figure 19.1). One is **species richness**, the total *number* of different species present. Identifying cells is, of course, basic to determining microbial species richness, but this need not require their isolation and culture. Species richness may also be expressed in molecular terms by the diversity of phylotypes (for example ribosomal RNA genes, [Section 18.5](#)) observed in a given community. **Species abundance**, by contrast, is the *proportion* of each species in the community. abundance can change quickly over a short time as shown in Figure 19.1. One goal of microbial ecology is to understand species richness and abundance in microbial communities along with the community's associated activities and the abiotic environment. Once all of these factors are known, microbial ecologists can model the ecosystem by perturbing it in some way and observing whether predicted changes match experimental results.

The microbial species richness and abundance of a community are functions of the conditions that prevail and the kinds and amounts of nutrients available in the habitat. **Table 19.1** lists common nutrients and conditions relevant to microbial growth. In some microbial habitats, such as undisturbed organic-rich soils, high species richness is common (see Figure 19.14), with most species present at only moderate abundance. Nutrients in such a habitat are of many different types, and this helps select for high species richness. In other habitats, such as some extreme environments, species richness is often very low and abundance of one or a few species very high. This is because the conditions in the environment exclude all but a handful of species, and key nutrients are present at such high levels that the highly adapted species can grow to high cell densities. Bacteria that catalyze acid mine runoff from the oxidation of iron are a good example. These organisms thrive in highly acidic, iron-rich but organic-poor waters, where the acidic conditions and the dearth of organic carbon limit species richness. However, the elevated levels of ferrous iron (Fe²⁺) present, which is oxidized to Fe³⁺ in energy-yielding reactions (Section 13.9), fuel high species abundance. We examine the activities of acidophilic iron-oxidizing microorganisms in Sections 20.5 and 21.1.

19.2 Ecosystem Service: Biogeochemistry and Nutrient Cycles

In any ecosystem whose resources and growth conditions are suitable, microorganisms will grow to form populations. Metabolically similar microbial populations that exploit the same resources in a similar way are called **guilds**. A habitat that is shared by a guild and supplies the resources and conditions the cells require for growth is called a **niche**. Sets of guilds form microbial communities (Figure 19.2). Microbial communities interact with macroorganisms and abiotic factors in the ecosystem in a way that defines the workings of that ecosystem.

Energy Inputs to the Ecosystem

Energy enters ecosystems as sunlight, organic carbon, and reduced inorganic substances. Light is used by phototrophs to make ATP and synthesize new organic matter (Figure 19.2). In addition to carbon (C), new organic matter contains nitrogen (N), sulfur (S), phosphorus (P), iron (Fe), and the other elements of life (Section 3.1). This newly synthesized organic material along with organic matter that enters the ecosystem from the outside (called *allochthonous* organic matter) fuels the catabolic activities of chemoorganotrophic organisms. These activities oxidize the organic matter to CO₂ by respiration or ferment it to various reduced substances. If chemolithotrophs are present and metabolically active in the ecosystem, they can conserve energy from

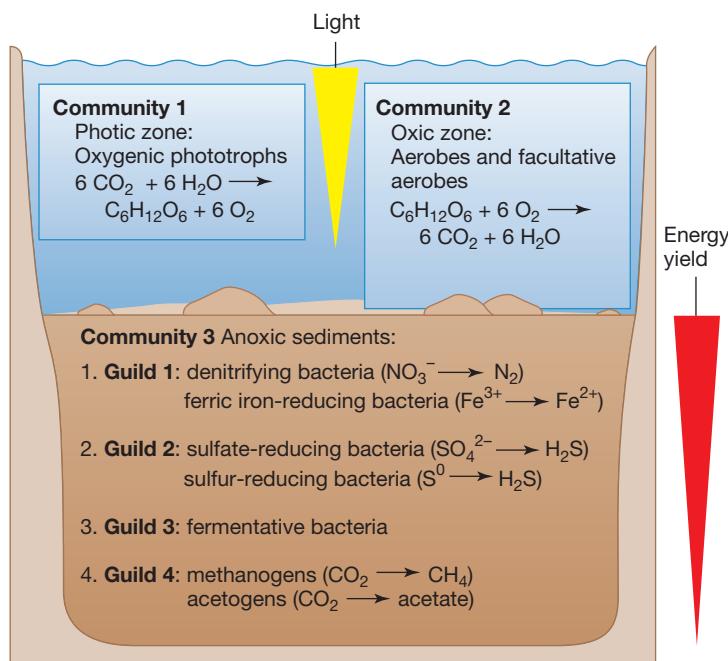

Figure 19.2 Populations, guilds, and communities. Microbial communities consist of populations of cells of different species. A freshwater lake ecosystem would likely have the communities shown here. The reduction of NO₃⁻, Fe³⁺, SO₄²⁻, S⁰, and CO₂ are examples of anaerobic respirations. The region of greatest activity for each of the different respiratory processes would differ with depth in the sediment. As more energetically favorable electron acceptors are depleted by microbial activity near the surface, less favorable reactions occur deeper in the sediment.

the oxidation of inorganic electron donors, such as H_2 , Fe^{2+} , S^0 , or NH_3 (Chapters 13 and 14), and contribute new organic matter through their autotrophic activities (Figure 19.2).

Biogeochemical Cycling

Microorganisms play an essential role in cycling elements, in particular C, N, S, and Fe, between their different chemical forms. The study of these transformations is part of **biogeochemistry**, an interdisciplinary science that includes biology, geology, and chemistry. Figure 19.2 shows how the activities of different guilds of microorganisms influence the chemistry of one environment, a lake ecosystem. The sequence of changing chemistry with increasing depth in the sediments corresponds to the layers of different microbial guilds. The location of each guild in the ecosystem is primarily determined by the availability of electron donors and acceptors, both of which tend to decrease with increasing depth in the sediments.

A *biogeochemical cycle* defines the transformations of an element that are catalyzed by either biological or chemical means (or both). Many different microorganisms participate in biogeochemical cycling reactions, and in many cases, microorganisms are the *only* biological agents capable of regenerating forms of the elements needed by other organisms, particularly plants. Thus, biogeochemical cycles are often also *nutrient cycles*, reactions that generate important nutrients for other organisms.

Most biogeochemical cycles proceed by oxidation–reduction reactions as the element moves through the ecosystem and are often tightly *coupled*, with transformations in one cycle impacting one or more other cycles. For example, hydrogen sulfide (H_2S) is oxidized by phototrophic and chemolithotrophic microorganisms to sulfur (S^0) and sulfate (SO_4^{2-}), the latter being a key nutrient for plants. Phototrophs and chemolithotrophs are autotrophic organisms, and thus impact the carbon cycle by producing new organic carbon from CO_2 . However, SO_4^{2-} can be reduced to H_2S by activities of the sulfate-reducing bacteria, organisms that consume organic carbon, and this reduction closes the biogeochemical sulfur cycle while regenerating CO_2 . The cycling of nitrogen is also a microbial process and is key to the regeneration of forms of nitrogen usable by plants and other organisms. The nitrogen cycle is driven by both chemolithotrophic and chemoorganotrophic bacteria, organisms that produce and consume organic carbon, respectively. We consider the theme of biogeochemical cycles and their coupled nature in more detail in Chapters 13, 14, and 20.

II • The Microbial Environment

Microorganisms define the limits of life throughout aquatic and terrestrial environments on our planet. Specific conditions required by a particular organism or group of organisms may be subject to rapid change due to inputs to and outputs from their habitat and to microbial activities or physical disturbance. Thus, within one environment there can be multiple habitats, some of which are relatively stable and others that change rapidly over time and space.

19.3 Environments and Microenvironments

Besides living in the common habitats of soil and water, microorganisms thrive in extreme environments and also reside on and within the cells of other organisms. The intimate associations developed between microorganisms and other organisms will be presented in Chapter 22. Here we focus on terrestrial and aquatic microbial habitats.

The Microorganism, Niches, and the Microenvironment

The habitat in which a microbial community resides is governed by physical and chemical (physicochemical) conditions that are determined in part by the metabolic activities of the community. For example, the organic material used by one species may have been a metabolic by-product of a second species. Another example is oxygen (O_2), which can become limiting if biological consumption exceeds the rate at which it is supplied.

Because microorganisms are very small, they directly experience only a tiny local environment; this small space is called their **microenvironment**. For example, for a typical 3- μm rod-shaped

bacterium, a distance of 3 mm is equivalent to that which a human would experience over a distance of 2 km! As a consequence of the smallness of microorganisms, the variable metabolic activities of nearby microorganisms, and the changes in physicochemical conditions over short intervals of time and distance, numerous microenvironments can exist within a given habitat. The conditions supporting growth within a microenvironment correspond to the general requirements for growth we considered in Chapter 5.

Ecological theory states that for every organism there exists at least one niche, the *realized niche* (also called the *prime niche*), where it will be most successful. The organism dominates the realized niche but may also inhabit other niches; in other niches it is less ecologically successful than in its realized niche but it may still be able to compete. The full range of environmental conditions under which an organism can exist is called its *fundamental niche*. The word “niche” should not be confused with the word “microenvironment” because the microenvironment describes conditions at a specific location and can change rapidly. In other words, the general conditions that describe a specific niche may be transient at many places in a microenvironment.

Another important consequence for microorganisms of being small is that diffusion often determines the availability of resources. Consider, for example, the distribution of an important microbial nutrient such as O_2 in a soil particle. Microsensors (🔗 Section 18.8) can be used to measure oxygen concentrations throughout small soil particles. As shown in the data from an actual microsensor experiment (Figure 19.3), soil particles are not homogeneous in terms of their O_2 content but instead contain many adjacent

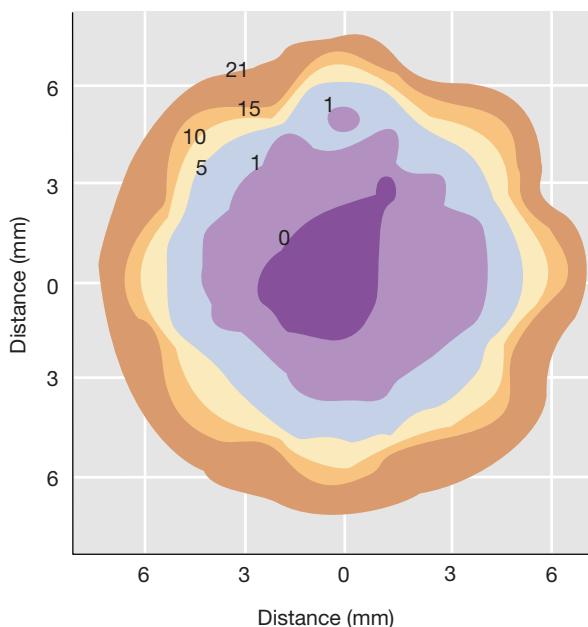

Figure 19.3 Oxygen microenvironments. Contour map of O_2 concentrations in a small soil particle as determined by a microsensor (Section 18.8). The axes show the dimensions of the particle. The numbers on the contours are percentages of O_2 concentration (air is 21% O_2). Each zone can be considered a different microenvironment.

microenvironments. The outer layer of the soil particle may be fully oxic (21% O_2) while the center, only a very short distance away (in human terms, but of course a great distance from a microbial standpoint), may be anoxic (O_2 -free). The microorganisms near the outer edges consume all of the O_2 before it can diffuse to the center of the particle. Thus, anaerobic organisms could thrive near the center of the particle, microaerophiles (aerobes that require very low oxygen levels) farther out, and obligately aerobic organisms in the outermost region of the particle. Facultatively aerobic bacteria (organisms that can grow either aerobically or anaerobically) could be distributed throughout the particle (Section 5.16). Nutrient transfer is particularly important in thick assemblages of cells, such as biofilms and microbial mats, and we explore this in the next section.

Physicochemical conditions in a microenvironment are subject to rapid change in both time and space. For example, the O_2 concentrations shown in the soil particle in Figure 19.3 represent “instantaneous” values. Measurements taken in the same particle following a period of intense microbial respiration or disturbance due to wind, rain, or disruption by soil animals could differ dramatically from those shown. During such events certain populations may temporarily dominate the activities in the soil particle and grow to high numbers, while others remain dormant or nearly so. However, if the microenvironments shown in Figure 19.3 are eventually reestablished, the various microbial activities characteristic of different regions of the soil particle will eventually return as well.

Nutrient Levels and Growth Rates

Resources (Table 19.1) typically enter an ecosystem intermittently. A large pulse of nutrients—for example, an input of leaf

litter or the carcass of a dead animal—may be followed by a period of nutrient deprivation. Because of this, microorganisms in nature often face a “feast-or-famine” existence. It is thus common for them to produce storage polymers as reserve materials when resources are abundant and draw upon these reserves in periods of starvation. Examples of storage materials are poly- β -hydroxyalkanoates, polysaccharides, and polyphosphate (Section 2.14).

Extended periods of exponential microbial growth in nature are probably rare. Microorganisms typically grow in spurts, linked closely to the availability and nature of resources. Because all relevant physicochemical conditions in nature are rarely optimal for microbial growth at the same time, growth rates of microorganisms in nature are usually well below the maximum growth rates recorded in the laboratory. For instance, the generation time of *Escherichia coli* in the intestinal tract of a healthy adult eating at regular intervals is about 12 h (two doublings per day), whereas in pure culture it can grow much faster, with a minimum generation time of about 20 min under optimal conditions. In addition, research-based estimates indicate that most cultured soil bacteria typically grow in nature at less than 1% of the maximal growth rate measured in the laboratory.

These slower growth rates in nature than in laboratory culture reflect the facts that (1) resources and growth conditions (Table 19.1) are frequently suboptimal; (2) the distribution of nutrients throughout the microbial habitat is not uniform; and (3) except in rare instances, microorganisms in nature grow in mixed populations rather than pure culture. An organism that grows rapidly in pure culture may grow much slower in a natural environment where it must compete with other organisms that may be better suited to the resources and growth conditions available.

Microbial Competition and Cooperation

Competition among microorganisms for resources in a habitat may be intense, with the outcome dependent on several factors, including rates of nutrient uptake, inherent metabolic rates, and ultimately, growth rates. A typical habitat contains a mixture of different species (Figures 19.1 and 19.2), with the density of each population dependent on how closely its niche resembles its realized niche.

Some microorganisms work together to carry out transformations that neither can accomplish alone—a process called *syntrophy*—and these microbial partnerships are particularly important for anoxic carbon cycling (Sections 13.15 and 20.2). Metabolic cooperation can also be seen in the activities of organisms that carry out complementary metabolisms. For example, we have previously considered metabolic transformations that are carried out by two distinct groups of organisms, such as those of the nitrifying prokaryotes (Sections 13.10, 14.13, and 16.6). Together, the nitrifying prokaryotes oxidize ammonia (NH_3) to nitrate (NO_3^-), although neither the ammonia oxidizers (having both archaeal and bacterial representatives) nor the nitrite-oxidizing bacteria are capable of doing this alone. Because nitrite (NO_2^-), the product of the ammonia-oxidizing microorganisms, is the substrate for the nitrite-oxidizing bacteria, the two groups of organisms often live in nature in tight association within their habitats (Figure 18.11).

MINIQUIZ

- What characteristics define the realized niche of a particular microorganism?

19.4 Surfaces and Biofilms

Surfaces are important microbial habitats, typically offering greater access to nutrients, protection from predation and physicochemical disturbances, and a means for cells to remain in a favorable habitat and not be washed away. Moreover, flow across a colonized surface increases transport of nutrients to the surface, providing more resources than are available to planktonic cells (cells that live a floating existence) in the same environment. A surface may also be provided by another organism or by a nutrient such as a particle of organic matter. For example, plant roots become heavily colonized by soil bacteria living on organic exudates from the plant, as revealed when fluorescent stains are used (Figure 19.4a).

Virtually any natural or artificial surface exposed to microorganisms will be colonized. For example, microscope slides have been used as experimental surfaces to which organisms can attach and grow. A slide can be immersed in a microbial habitat, left for a period of time, and then retrieved and examined microscopically (Figure 19.4b). Clusters of a few cells that develop from a single colonizing cell, called *microcolonies*, form readily on such surfaces, much as they do on natural surfaces in nature. In fact, periodic microscopic examination of immersed microscope slides has been used to measure growth rates of attached organisms in nature. Surface colonization may be sparse, consisting only of microcolonies and not visible to the eye, or may consist of so many cells that microbial accumulation becomes visible as, for example, in a stagnant toilet bowl. Surface growth can be particularly problematic in the hospital setting where microbial colonization of indwelling devices such as catheters and intravenous lines can cause serious infection. In a few extreme environments that lack small animal grazers (for example, hot springs), microbial accumulation on a surface can be many centimeters in thickness. Called **microbial mats**,

such accumulations often contain highly complex yet very stable assemblages of phototrophic, autotrophic, and heterotrophic microorganisms (Section 19.5).

Biofilms

As bacterial cells grow on surfaces they commonly form **biofilms**—assemblages of bacterial cells attached to a surface and enclosed in an adhesive matrix that is the product of excretion by cells and cell death (Figure 19.5). The matrix is typically a mixture of polysaccharides, proteins, and nucleic acids that bind the cells together. Biofilms trap nutrients for microbial growth and help prevent the detachment of cells on dynamic surfaces, such as in flowing systems (Figure 19.5c). We examined some of the genetic regulatory features of biofilm microbial communities in Section 7.9.

Biofilms typically contain multiple layers of cells embedded in the porous matrix material, and the cells in each layer can be examined by confocal scanning laser microscopy (Section 2.3; Figure 19.5b). Biofilms may contain only one or two species or, more commonly, many species of bacteria. The biofilms that form on tooth and soft surfaces of the mouth, for example, contain between 100 and 200 different phylotypes (Section 18.5), including species of both *Bacteria* and *Archaea*; in total, the human mouth is a habitat for approximately 700 phylotypes. Biofilms are

thus functional and growing microbial communities and not just cells trapped in a sticky matrix. We contrasted microbial growth in biofilms with that of planktonic (suspended) growth in Chapter 5 Explore the Microbial World, “Stick or Swim.”

Wherever submerged surfaces are present in natural environments, biofilm growth is almost always more extensive and diverse than the planktonic growth in the liquid that surrounds the surface. Biofilms differ from planktonic communities in supporting critical transport and transfer processes, which generally control growth in biofilm environments. For example, if consumption of O₂ by populations near the surface exceeds diffusion of O₂ into deeper regions of the biofilm, the deeper regions will become anoxic, opening up new niches for colonization by obligate anaerobes or facultative aerobes. This is similar to the depletion of O₂ in the interior of a soil particle that was depicted in Figure 19.3.

One of the most clinically and industrially relevant properties of biofilm microbial communities is their inherent tolerance to antibiotics and other antimicrobial stressors. A given species growing in a biofilm can be up to 1000 times more tolerant of an antimicrobial substance than planktonic cells of the same species. Reasons for the greater tolerance include slower growth rates in biofilms, reduced penetration of antimicrobial substances through the extracellular matrix, and the expression of genes that increase tolerance to stress. Their tolerance of antimicrobial substances may explain why biofilms are responsible for many untreatable or difficult-to-treat chronic infections and are also hard to eradicate in industrial systems where surface growth (fouling) by microorganisms may impair important processes.

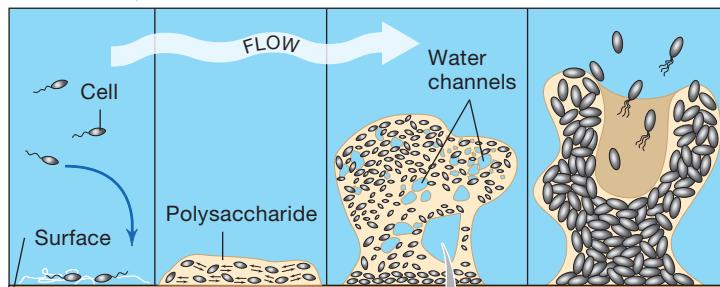

Biofilm Formation

How do biofilms form? Random collision of cells with a surface accounts for initial cell attachment, with adhesion promoted by interaction between one or more cellular structures and the surface. Cellular structures promoting attachment include protein appendages (pili, flagella) and cell surface proteins (for example, the large protein LapA exposed on the cell surface is required for attachment and biofilm formation by *Pseudomonas fluorescens*, as we will see later in this section).

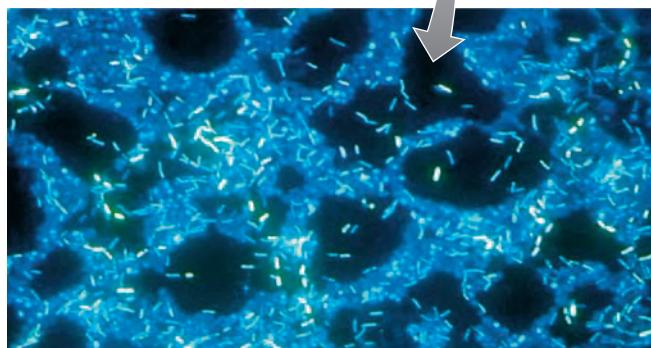

Attachment of a cell to a surface is a signal for the expression of biofilm-specific genes. These include genes encoding proteins that synthesize intercellular signaling molecules and production of extracellular polysaccharides that initiate matrix formation (Figure 19.6a). Once committed to biofilm formation, a previously planktonic cell typically loses its flagella and becomes nonmotile. However, biofilms are not static entities and cells may also be released from the biofilm matrix through an active process of dispersal (Figure 19.6a).

Although the mechanism remains to be discovered, bacteria somehow “sense” a suitable surface and this coordinates events that lead to the biofilm growth mode. How surface sensing takes place is an area of active research, but the actual switch from planktonic to biofilm growth is triggered by the production of the chemical *cyclic di-guanosine monophosphate* (*c-di-GMP*) (Figure 19.7). We examined this second messenger as a regulator of biofilm formation in Section 7.9, showing that *c-di-GMP* signaling operates at multiple levels to modulate gene expression and enzyme activity, such as by binding to transcriptional regulators,

mRNA (riboswitches, [Section 7.15](#)), and specific proteins to alter enzyme activity. For example, *c-di-GMP* binds to proteins that reduce the activity of the flagellar motor, regulates cell surface proteins required for attachment, and mediates the biosynthesis of extracellular matrix polysaccharides of the biofilm.

Pseudomonas aeruginosa and Biofilms

Besides the intracellular activities triggered by *c-di-GMP*, intercellular communication is required for the development and maintenance of bacterial biofilms. For example, in *Pseudomonas aeruginosa*, a notorious biofilm former (Figure 19.8), the major intercellular signaling molecules are *acyl homoserine lactones*. As these molecules accumulate, they signal adjacent *P. aeruginosa* cells that the population of this species is enlarging (that is, they are a signal in quorum sensing, [Section 7.9](#)). The signaling lactones then control expression of genes that contribute to biofilm formation. Genes turned on at this time include, in particular, those that increase the intracellular levels of *c-di-GMP*.

Elevated *c-di-GMP* levels initiate the production of extracellular polysaccharide and decrease flagellar function. Over time, in nutrient-rich conditions, *P. aeruginosa* cells can develop mushroom-shaped microcolonies that can be over 0.1 mm high

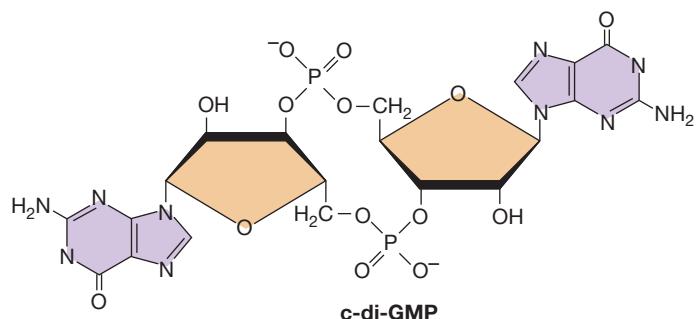

Figure 19.7 Molecular structure of the second messenger cyclic di-guanosine monophosphate. This is used as an intracellular signaling molecule by many bacteria to control specific physiological processes.

and contain millions of cells enmeshed in a sticky polysaccharide matrix (Figure 19.8). The final architecture of the biofilm is determined by multiple factors in addition to signaling molecules, including nutritional factors and local flow environment.

P. aeruginosa biofilms form in human lungs in patients with the genetic disease *cystic fibrosis*. In the biofilm state, *P. aeruginosa* is difficult to treat with antibiotics and the biofilm appears to help the bacteria persist in individuals with this disease. Like most biofilms, that which develops in the lungs of cystic fibrosis patients contains more than one bacterial species (Explore Chapter 5 Explore the Microbial World, “Stick or Swim”). So, in addition to *intraspecies* signaling, *interspecies* signaling is probably also occurring in the events that initiate and maintain biofilms containing more than one species.

In *P. fluorescens*, a related biofilm-forming organism, increases in c-di-GMP also promote biofilm formation. However, the biofilm machinery regulated by c-di-GMP in this species is very different from that of *P. aeruginosa*. In *P. fluorescens*, changes in c-di-GMP affect secretion and cell surface localization of a large adhesion protein called LapA that helps stick the cell to surfaces. For example, in response to low extracellular phosphate, *P. fluorescens* cells maintain a low c-di-GMP level that prevents localization of LapA to the outer membrane, thereby disabling the attachment mechanism required to initiate biofilm formation. If phosphate levels continue to fall within the biofilm, the associated reduction in c-di-GMP levels also results in the activation of a protease that cleaves LapA; this releases already attached cells and promotes their dispersal to explore nearby habitats for nutrients

(Figure 19.6). Other environmental cues for *P. fluorescens* dispersal include carbon or oxygen depletion and changes in temperature or iron availability.

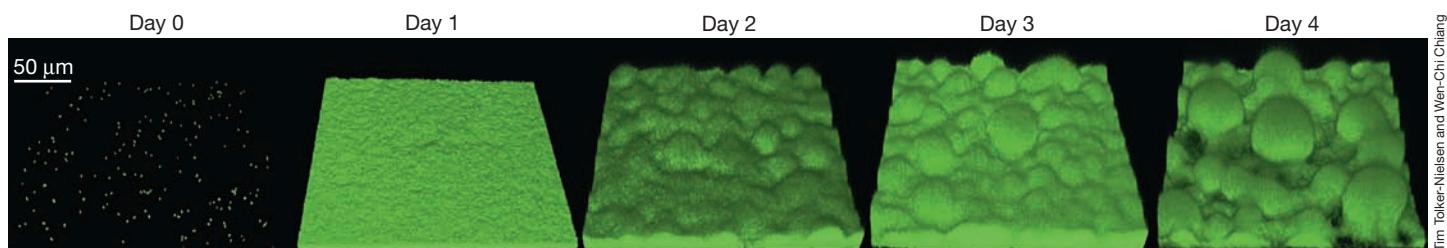

Although quorum sensing–based signaling has been primarily associated with biofilm formation, the quorum-sensing system of *Staphylococcus aureus* plays a role in dispersal. Thus, no single developmental program for biofilm formation is shared among species. This lack of unity has greatly complicated the development of biofilm control strategies, as discussed at the end of this section.

Why Bacteria Form Biofilms

At least four reasons have been proposed for the formation of biofilms. First, biofilms are a means of microbial self-defense that increase survival. Biofilms resist physical forces that could otherwise remove cells only weakly attached to a surface. Biofilms also resist phagocytosis by protozoa and cells of the immune system, and retard the penetration of toxic molecules such as antibiotics. These advantages improve the chances for survival of cells in the biofilm. Second, biofilm formation allows cells to remain in a favorable niche. Biofilms attached to nutrient-rich surfaces, such as animal tissues, or to surfaces in flowing systems (Figure 19.5c) fix bacterial cells in locations where nutrients may be more abundant or are constantly being replenished. Third, biofilms form because they allow bacterial cells to live in close association with each other. As we have already seen for *P. aeruginosa* and the biofilm that forms in cystic fibrosis patients, this facilitates cell-to-cell communication and increases chances for survival. Moreover, when cells are in close proximity to one another, there are more opportunities for nutrient and genetic exchange. Finally, biofilms seem to be the typical way bacterial cells grow in nature. The biofilm may be the “default” mode of growth for prokaryotes in natural environments, which differ dramatically in nutrient levels from the rich liquid culture media used in the laboratory. Planktonic growth may be the norm only for those bacteria adapted to life at extremely low nutrient concentrations (discussed in Sections 19.9 and 19.11).

Biofilm Control

Biofilms have significant implications in human medicine and commerce. In the body, bacterial cells within a biofilm are protected from attack by the immune system, and antibiotics and other antimicrobial agents sometimes fail to penetrate the biofilm. Besides

cystic fibrosis, biofilms have been implicated in several medical and dental conditions, including periodontal disease, chronic wounds, kidney stones, tuberculosis, Legionnaires' disease, and *Staphylococcus* infections. Medical implants are ideal surfaces for biofilm development. These include both short-term devices, such as a urinary catheter, as well as long-term implants, such as artificial joints. It is estimated that 10 million people a year in the United States experience biofilm infections from implants or intrusive medical procedures. Biofilms explain why routine oral hygiene is so important for maintaining dental health. Dental plaque is a typical biofilm and contains acid-producing bacteria responsible for dental caries (☞ Section 23.3).

In industrial situations biofilms can slow the flow of water, oil, or other liquids through pipelines and can accelerate corrosion of the pipes themselves. Biofilms also initiate the degradation of submerged objects, such as structural components of offshore oil platforms, boats, and shoreline installations. The safety of drinking water may be compromised by biofilms that develop in water distribution pipes (Figure 19.6b), many of which in the United States are nearly 100 years old (☞ Section 21.9). Water-pipe biofilms mostly contain harmless microorganisms, but if pathogens successfully colonize a biofilm, standard chlorination practices may fail to kill them. Periodic releases of pathogenic cells can then lead to outbreaks of disease. For example, there is concern that *Vibrio cholerae*, the causative agent of cholera (☞ Section 31.3), may be propagated in this manner.

Biofilm control is big business, and thus far, only a limited number of tools exist to fight biofilms. Collectively, industries commit huge financial resources to treating pipes and other surfaces to keep them free of biofilms. New antimicrobial agents that can penetrate biofilms, as well as drugs that eliminate biofilm formation by interfering with intercellular communication, are being developed. A class of chemicals called *furanones*, for example, has shown promise as biofilm preventives on abiotic surfaces.

19.5 Microbial Mats

Microbial mats are among the most visibly conspicuous of microbial communities and can be considered extremely thick biofilms. Built by phototrophic or chemolithotrophic bacteria, these layered microbial communities can be several centimeters thick (Figure 19.9). The layers are composed of species of different microbial guilds whose activities are governed by light availability and other resources (Table 19.1). The combination of microbial metabolism and nutrient transport controlled by diffusion results in steep concentration gradients of different microbial nutrients and metabolites, creating unique niches at different depth intervals in the mats. The most abundant and versatile phototrophic mat builders are filamentous cyanobacteria, oxygenic phototrophs many of which grow under extreme environmental conditions. For example, some species of cyanobacteria grow in waters as hot as 73°C or as cold as 0°C, and others tolerate salinities in excess of 12% and pH values as high as 10.

Cyanobacterial Mats

Cyanobacterial mats are complete microbial ecosystems, containing large numbers of **primary producers** (cyanobacteria and other phototrophic bacteria) that use light energy to synthesize new organic material from CO₂. These along with populations of

consumers in the mat community mediate all key nutrient cycles. Although microbial mat ecosystems have existed for over 3.5 billion years, the evolution of metazoan grazers and competition with macrophytes (aquatic plants) triggered their decline about a billion years ago.

Microbial mats develop today only in aquatic environments where specific environmental stresses restrict grazing and competition, conditions most commonly found in hypersaline or geothermal habitats. Well-studied microbial mats are found in hypersaline solar evaporation basins, either formed naturally, such as Solar Lake (Sinai, Egypt), or those constructed for the recovery of sea salt (Figure 19.9a). Because microbial mats are restricted to extreme environments, most are found in remote locations and many are not readily accessible to study. In contrast, however, the cyanobacterial mats that colonize the outflow channels of hot springs in Yellowstone National Park (USA) and many other thermal regions in the world are easily accessible to scientific research (Figure 19.9b, c).

The chemical and biological structure of a microbial mat can change dramatically during a 24-h period (called a *diel cycle*) as a consequence of changing light intensity. Using microsensors (➡ Section 18.8) it is possible to measure pH, H₂S, and O₂ repeatedly over a diel cycle in zones in the mat separated vertically by only a few micrometers. During the day, there is intense oxygen production in the photic surface layer of microbial mats and active sulfate reduction throughout the lower regions. Near the zone where O₂ and H₂S begin to mix, intense metabolic activity by phototrophic and chemolithotrophic sulfur bacteria may consume these substrates rapidly over very short vertical distances. Detecting the rate of these changes reveals the zones of greatest microbial activity (Figure 19.9c). These gradients disappear at night when the entire mat turns anoxic and H₂S accumulates. Some mat organisms rely on motility to follow the shifting chemical gradients. For example, sulfur-oxidizing filamentous phototrophic bacteria such as *Chloroflexus* and *Roseiflexus* (➡ Section 14.7) follow the up-and-down movement of the O₂-H₂S interface on a diel basis.

(a, c) Filaments of the large sulfur-oxidizing chemolithotroph *Thioploca* extend into the water above the sediment (87 m depth) in the Bay of Concepción off the Chilean coast. (b) From 10 to 20 filaments (trichomes) are bundled together by a gelatinous sheath, each bundle approximately 1.5 mm in diameter and 10–15 cm in length. Two species of *Thioploca* commonly inhabit the same bundle: *T. chileae*, about 20 µm in diameter, and *T. araucae*, about 40 µm in diameter. Individual trichomes glide independently within the sheaths and can extend up to 3 cm into the water. See page 631 for another example of filamentous sulfide-oxidizing bacteria and their unique metabolic strategy.

Chemolithotrophic Mats

The most common types of chemolithotrophic mats are composed of filamentous sulfur-oxidizing bacteria, such as *Beggiatoa* and *Thioploca* species, which grow on marine sediment surfaces at the interface between O₂ supplied from the overlying water and H₂S produced by sulfate-reducing bacteria living in the sediment. In these habitats the bacteria oxidize H₂S to support energy conservation and autotrophic reactions (☞ Sections 13.8 and 14.11).

Chemolithotrophic mats composed of sulfur-oxidizing *Thioploca* species on sediments of the Chilean and Peruvian continental shelf are thought to be the most extensive microbial mats on Earth (Figure 19.10). *Thioploca* has developed a remarkable strategy to bridge spatially separated resources. These chemolithotrophic mat organisms contain large internal vacuoles that store high concentrations of nitrate (NO₃⁻) as an electron acceptor to support anaerobic respiration. Much like a scuba diver filling tanks with oxygen to dive into the water, cells of *Thioploca* migrate up to the sediment surface to charge internal vacuoles

with NO₃⁻ from the water column (Figure 19.10a, b). They then return (“dive”) to the anoxic depths of the sediment (gliding at speeds of 3–5 mm per hour) to use their stored NO₃⁻ as an electron acceptor for H₂S oxidation.

The physical and biological structures of both biofilms and microbial mats are determined by metabolic interactions among microorganisms and the diffusion of nutrients. Thus, as biofilms form on a surface they become increasingly more complex, and in so doing generate new niches for organisms of differing physiologies. This diversity reaches its maximum in mature microbial mats (Figure 19.9), as these structures have been shown to be among the most complex microbial communities characterized thus far by molecular community sampling (☞ Section 18.5).

III • Terrestrial Environments

Extensive microbial habitats on Earth are in two terrestrial environments that are similar in lacking sunlight, being periodically or permanently anoxic, and having other physicochemical conditions in common. The two terrestrial environments are soils and water enclosed in soils and bedrock. In each of the next two sections we cover these microbial habitats, and in each case we begin with the abiotic part of the environment and conclude with a discussion of the microbial communities that live there.

19.6 Soils

The word *soil* refers to the loose outer material of Earth’s surface, a layer distinct from the bedrock that lies underneath (Figure 19.11). Soil develops over long periods of time through complex interactions among the parent geological materials (rock, sand, glacial drift materials, and so on), the topography, climate, and the presence and activities of living organisms.

Soils can be divided into two broad groups: *mineral soils* are derived from the weathering of rock and other inorganic materials, and *organic soils* are derived from sedimentation in bogs and marshes. Most soils are a mixture of these two basic types. Although mineral soils, which are the primary focus of this section, predominate in most terrestrial environments, there is increasing interest in the role that organic soils play in carbon storage. A detailed understanding of carbon storage (sinks) and sources (such as release of CO₂) is of great relevance to the science of climate change. The carbon cycle is considered in Chapter 20.

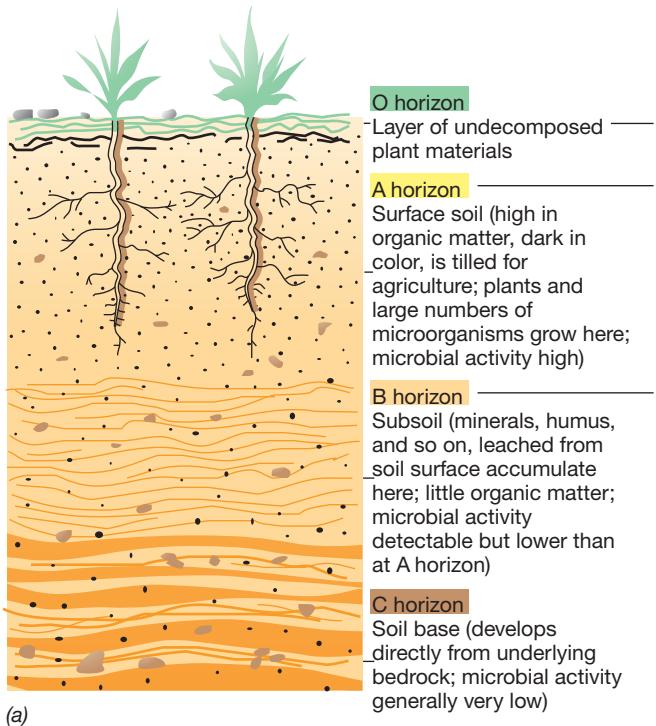

Soil Composition and Formation

Vegetated soils have at least four components. These include (1) inorganic mineral matter, typically 40% or so of the soil volume; (2) organic matter, usually about 5%; (3) air and water, roughly

50%; and (4) microorganisms and macroorganisms, about 5%. Particles of various sizes are present in soil. Soil scientists classify soil particles on the basis of size: Those in the range of 0.1–2 mm in diameter are called *sand*, those between 0.002 and 0.1 mm *silt*, and those less than 0.002 mm *clay*. Different textural classes of soil are then given names such as “sandy clay” or “silty clay” based on the percentages of sand, silt, and clay they contain. A soil in which no one particle size dominates is called a *loam*.

Physical, chemical, and biological processes all contribute to the formation of soil. An examination of almost any exposed rock reveals the presence of algae, lichens, or mosses. These organisms are phototrophic and produce organic matter, which supports the growth of chemoorganotrophic bacteria and fungi. More complex chemoorganotrophic communities composed of *Bacteria*, *Archaea*, and eukaryotes then develop as the extent of the earlier colonizing organisms increases. Carbon dioxide produced during respiration becomes dissolved in water to form carbonic acid (H₂CO₃), which slowly dissolves the rock, especially rocks containing limestone (CaCO₃). In addition, many chemoorganotrophs excrete organic acids, which also promote the dissolution of rock into smaller particles.

Freezing, thawing, and other physical processes assist in soil formation by forming cracks in the rocks. As the particles generated combine with organic matter, a crude soil forms in these crevices, providing sites needed for pioneering plants to become established. The plant roots penetrate farther into the crevices, further fragmenting the rock; the excretions of the roots promote development in the **rhizosphere** (the soil that surrounds plant roots and receives plant secretions) of high microbial cell abundance (Figure 19.4a). When the plants die, their remains are added to the soil and become nutrients for more extensive microbial development. Minerals are rendered soluble, and as water percolates, it carries some of these substances deeper into the soil.

Michael T. Madigan

Figure 19.11 Soil. (a) Profile of a mature soil. The soil horizons are zones defined by soil scientists. (b) Photo of a soil profile, showing O, A, and B horizons. This soil from Carbondale, Illinois (USA), is rich in clay and very compact. Such soils are not as well drained as those rich in sand. Note the clear color delineation between the organic-rich A horizon and the less-organic-rich B horizon.

As weathering proceeds, the soil increases in depth and becomes able to support the development of larger plants and small trees. Soil animals such as earthworms colonize the soil and play an important role in keeping the upper layers of the soil mixed and aerated. Eventually, the movement of materials downward results in the formation of soil layers, called a *soil profile* (Figure 19.11). The rate of development of a typical soil profile depends on climatic and other factors, but it can take hundreds to thousands of years.

Water Availability: Vegetated and Dryland Soils as Microbial Habitats

The limiting nutrients in soils are often inorganic nutrients such as phosphorus and nitrogen, key components of several classes of macromolecules. Another major factor affecting microbial activity in soil is the availability of water, and we have previously emphasized the importance of water for microbial growth (Section 5.15).

Water is a highly variable component of soil, and a soil's water content depends on soil composition, rainfall, drainage, and plant cover. Water is held in the soil in two ways—by adsorption onto surfaces or as free water in thin sheets or films between soil particles (Figure 19.12). The water present in soils has materials dissolved in it, and the mixture is called the *soil solution*. In well-drained soils, air penetrates readily, and the oxygen concentration of the soil solution can be high, similar to that of the soil surface. In waterlogged soils, however, the only oxygen present is that dissolved in water, and this can be rapidly consumed by the resident microflora. Such soils then become anoxic, and, as described for freshwater environments (Section 19.8), show profound changes in their biological activities.

There is also water in the larger channels in soil, where bulk flow is important for rapid transport of microorganisms and their substrates and products.

Arid Soils

The greatest microbial activity in soils is in the organic-rich surface layers in and around the rhizosphere (Figure 19.4a). However, some soils are so dry that plant coverage is greatly limited and only special microbial communities can thrive.

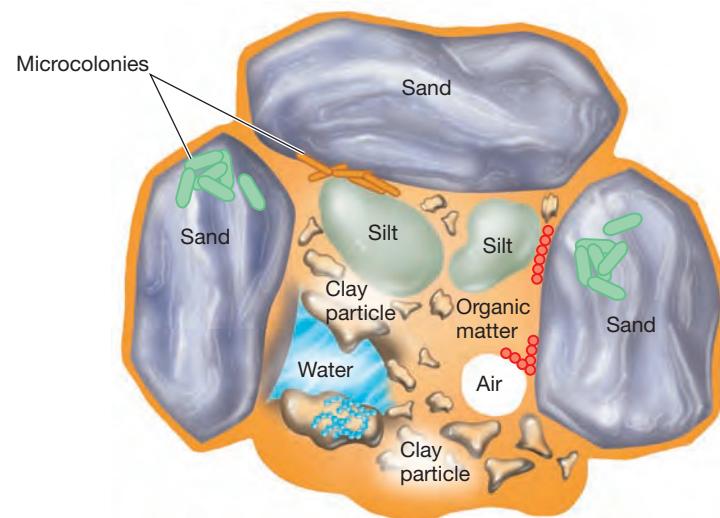

Figure 19.12 A soil microbial habitat. Very few microorganisms are free in the soil solution; most of them reside in microcolonies attached to the soil particles. Note the relative size differences among sand, clay, and silt particles.

These are *arid soils*, and approximately 35% of Earth's landmass is permanently or seasonally arid. Aridity can be defined by the *aridity index*, expressed as the ratio of precipitation to potential evapotranspiration (P/PET). Evapotranspiration is the sum of water loss through evaporation and plant transpiration. A region is classified as arid when there is a P/PET of less than 1; that is, water entering through precipitation (and fog and dew) is less than that lost through evapotranspiration.

Arid soils are among the most extreme environments on Earth, with temperature highs in excess of 60°C and lows of -24°C, high insolation (exposure to solar rays), and low water activity. Although arid regions are typically nearly devoid of leafy plants, they sustain important microbial communities that assemble in and stabilize the near-soil surface and reside within and on the surfaces of rocks. The dominant microorganisms present in these carbon-limited environments are cyanobacteria, with lesser numbers of green algae, fungi, heterotrophic bacteria, lichens, and mosses.

Dryland microbial habitats include *biological soil crusts* (BSCs) (Figure 19.13), ventral surfaces of translucent stones (*hypolithic colonists*), exposed rock surfaces (*epilithic colonists*), and the interior pore spaces, cracks, and fissures of rocks (*endolithic colonists*). The soil crusts are dominated by cyanobacterial *Microcoleus* species (Figure 19.13b, c), whereas coccoid *Chroococcidiopsis* species are the predominant endolithic population. The rock colonists play an important role in weathering and soil formation as described above; here we primarily consider the BSC communities.

The BSC serves a critical function in soil stabilization of desert ecosystems. Stabilization is critical because of the very slow rate of desert soil formation (<1 cm per 1000 years). Here, the

filamentous cyanobacteria (*Microcoleus*) and fungi provide soil cohesion, which is further stabilized aboveground by lichens and mosses when present. Importantly, this microbial network functions to eliminate soil erosion from wind and water. The BSCs are major determinants of water infiltration and influence local hydrological cycles and water availability to vegetation. Remarkably, when moisture and temperature conditions are optimal, the photosynthetic rates of BSC are comparable to those of vascular plant leaves. Cyanobacteria and other nitrogen-fixing bacteria (Sections 3.17, 7.13, and 14.3) provide nitrogen, and much of the fixed nitrogen is released immediately and made available to other soil biota.

The disruption of BSCs is a major contributor to *desertification*, a process exacerbated by climate change and human activities. Dust storms resulting from BSC destruction reduce soil fertility, and when heavy dust is deposited on nearby snowfields it accelerates melt and evapotranspiration rates, thereby reducing freshwater inputs to rivers. Once compromised, soil crusts have recovery times varying from 15 to 50 years. Given the expansive terrestrial presence of BSCs, their importance to human and ecosystem function, and the projected increase in aridity associated with climate change, a better understanding of BSC formation and the rehabilitation of compromised BSCs is important for a healthy planet Earth.

A Phylogenetic Snapshot of Soil Prokaryotic Diversity

As we saw in Figure 19.3, even a single soil particle can contain many different microenvironments and can thus support the growth of several physiological types of microorganisms. To examine soil particles directly for microorganisms, fluorescence microscopes are often used, the organisms in the soil having been

previously stained with a fluorescent dye. To visualize a specific microorganism in a soil particle, fluorescent antibody staining or gene probes (► Sections 18.3, 18.4) can also be used. Microorganisms can also be observed on soil surfaces directly by scanning electron microscopy (Figure 19.13*b*, *c*).

We learned in Chapter 18 that sequence analyses of 16S ribosomal RNA (rRNA) genes obtained from the environment can be used as a measure of prokaryotic diversity (► Section 18.5). As yet, no natural communities have been so thoroughly characterized by these techniques that all resident species have been

identified. However, within limits, the method is widely considered to be a valid measure of microbial diversity and avoids the more serious problems of enrichment bias that plague culture-dependent diversity studies (► Section 18.1). Here and in later sections of this chapter we present a “phylogenetic snapshot” of major microbial habitats, with the goal of emphasizing trends and patterns rather than absolute details.

Molecular community sampling of a typical vegetated surface has shown typically *thousands* of different species of *Bacteria* and *Archaea* in a single gram of soil, likely reflecting the numerous

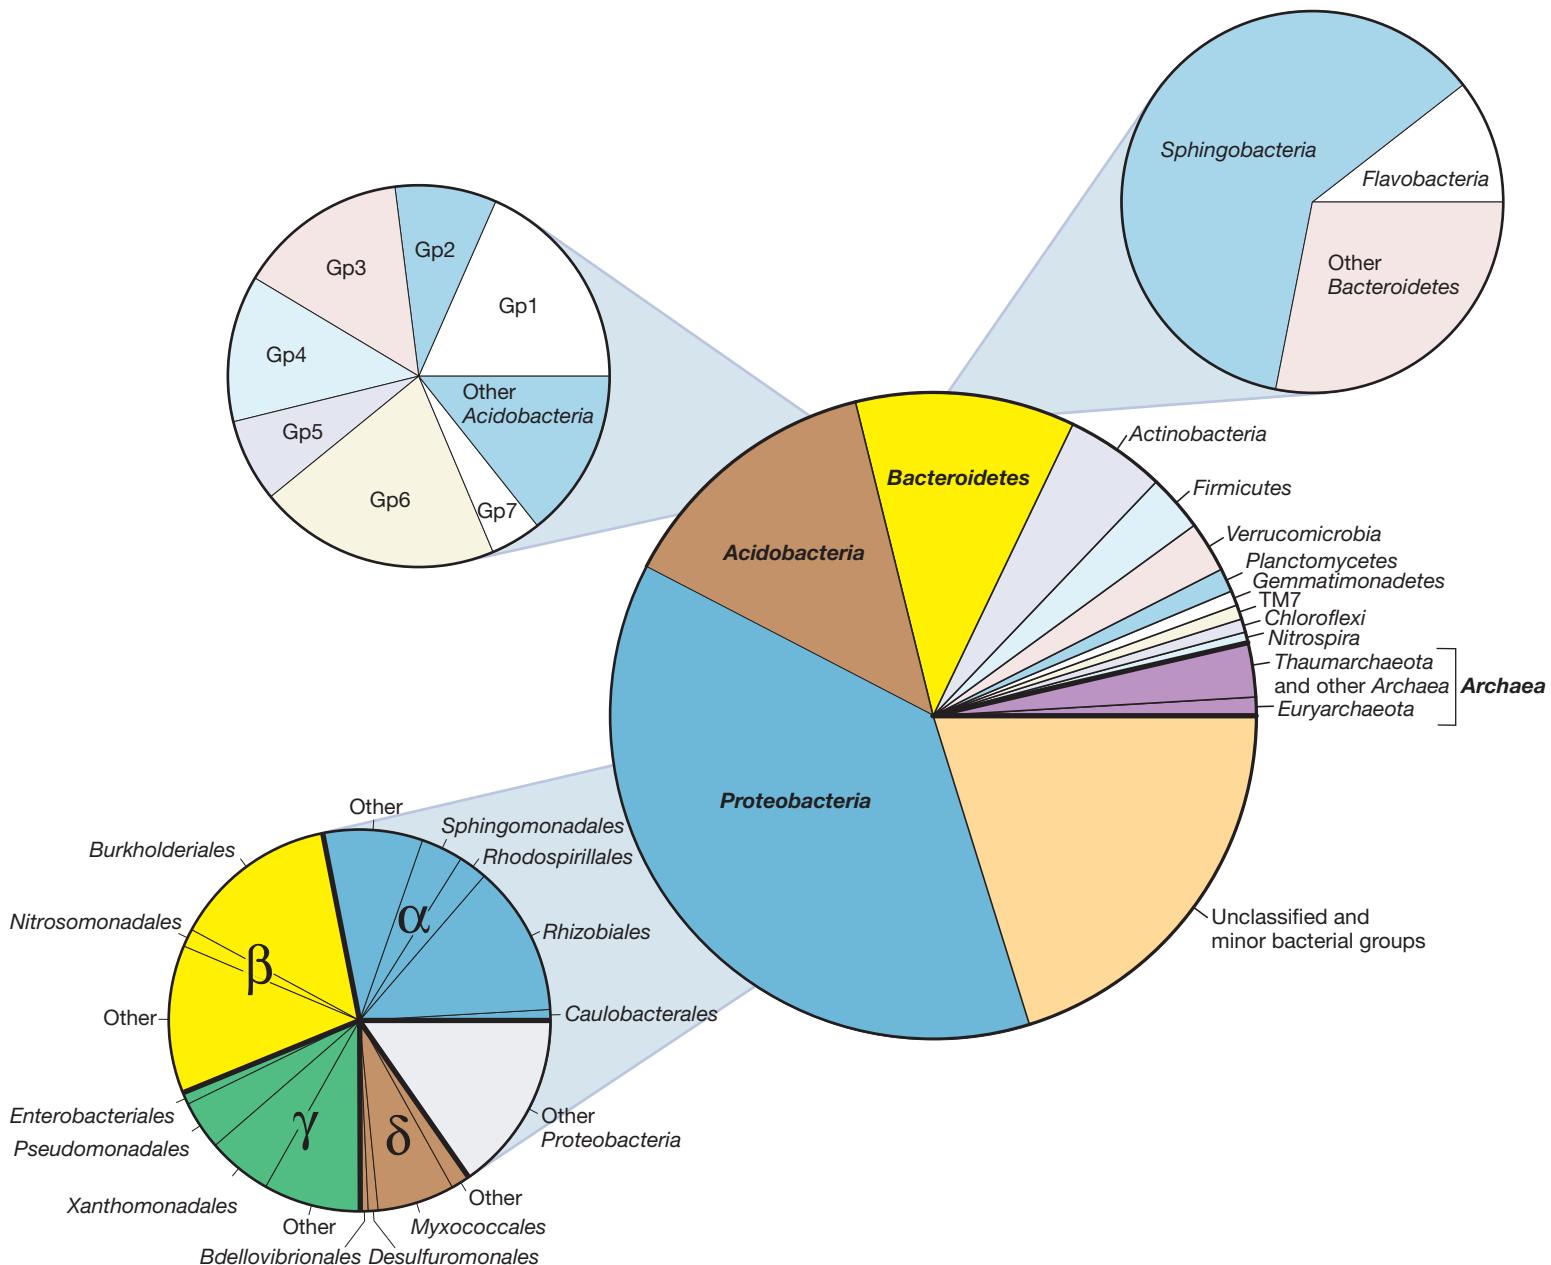

Figure 19.14 Soil prokaryotic diversity. The results are pooled analyses of 287,933 sequences from several studies of the 16S rRNA gene content of soil environments. Many of these groups are covered in Chapters 14 and 15 (*Bacteria*) or 16 (*Archaea*). For *Proteobacteria*, *Acidobacteria*, and *Bacteroidetes*, major subgroups are indicated (Gp, group). Note high species richness as indicated by the large proportion of the total community composed of unclassified and minor bacterial groups. Also note the relatively low proportion of the total prokaryotic soil community that consists of *Archaea* and that many soil *Archaea* are not close relatives of known *Euryarchaeota* or *Crenarchaeota*. Data assembled and analyzed by Nicolas Pinel.

microenvironments present there. A “species” is operationally defined here as a 16S rRNA gene sequence obtained from a microbial community that differs from all other sequences by more than 3% (☞ Section 12.8). Such an environmental sequence is called a *phylotype*. Besides very large species numbers, soil microbial diversity studies have also showed that diversity varies with soil type and geographical location. For example, analysis of an Alaska forest soil, an Oklahoma prairie soil, and a Minnesota farm soil (all sites in the USA) revealed approximately 5000, 3700, and 2000 different phylotypes, respectively. The Alaska and Minnesota soils showed similar distributions at the phylum level of taxonomy (for example, *Proteobacteria*, *Acidobacteria*, *Bacteroidetes*, *Actinobacteria*, *Verrucomicrobia*, and *Planctomyces*) but shared only about 20% of their species in common. This indicates that although the *proportions* of the dominant phyla in different soils are relatively constant, the *actual species present* within a phylum may vary considerably between different soils. In addition, lower bacterial diversity was observed in the farm soil than the Alaska soil, probably because modern intensive agricultural practices rely heavily on fertilization, low plant diversity, and the chemical suppression of unwanted plants and animals.

Figure 19.14 shows the general composition of prokaryotic soil communities based on pooled 16S rRNA sequence data taken from several soils. As can be seen, *Proteobacteria* (Chapters 14 and 15) make up nearly half of the total phylotypes recovered, with all major subgroups except for *Epsilonproteobacteria* well represented. *Acidobacteria* and *Bacteroidetes* are also abundant groups; *Actinobacteria* and *Firmicutes* are less so. In addition to these, a major proportion of soil phylotypes are unclassified species or members of minor bacterial groups. This underscores the high bacterial diversity typical of soil ecosystems. In contrast to *Bacteria*, the diversity of *Archaea* in soil is minimal, with relatively few sequences within each major phylum of *Archaea* (*Euryarchaeota*, *Thaumarchaeota*, and *Crenarchaeota*) represented. However, since there have been fewer selective surveys of archaeal diversity in soils, their diversity may be greater than now recognized.

A similar study to that shown in Figure 19.14 but performed on hydrocarbon-polluted soil showed that the general taxonomic makeup of polluted and unpolluted soils is similar: *Proteobacteria* comprise the largest fraction in both soil types, followed by significant representation of *Acidobacteria*, *Bacteroidetes*, *Actinobacteria*, and *Firmicutes*. However, there was a significant shift in fractional representation of these taxa in the two soils. Polluted soils are enriched in *Actinobacteria* and *Euryarchaeota* but diminished in *Bacteroidetes*, *Acidobacteria*, and unclassified *Bacteria* relative to nonpolluted soils. Notably, *Crenarchaeota* are absent from all surveys of hydrocarbon-polluted soils, suggesting that hydrocarbon pollutants suppress the *Crenarchaeota* and the ammonia-oxidizing *Thaumarchaeota* (*Archaea*, ☞ Sections 16.6, 16.9). The impact of hydrocarbon pollution on *Bacteria* was reflected by a greater proportion of *Gammaproteobacteria* and a single dominant *Bacteroidetes* phylotype. By contrast, unpolluted soils contained several phylotypes of *Bacteroidetes* (Figure 19.14). The diversity of *Acidobacteria*, a major group in unpolluted soils, is also significantly reduced in polluted soils (Figure 19.14).

Although the *functional* significance of the observed diversity of microbial communities in polluted versus unpolluted soils is unknown, the shifts observed signal that the two soils will likely differ in their capacity to process carbon and nitrogen and to carry out other important nutrient cycling events. However, despite this lack of a functional connection, different 16S rRNA gene surveys of soils agree on two things: (1) undisturbed, unpolluted soils support very high prokaryotic diversity, and (2) perturbations in a soil trigger measurable shifts in community composition—presumably toward species that are more competitive in the disturbed soil environment—and an overall reduction in prokaryotic diversity.

19.7 The Subsurface

In the soils and rocks of Earth’s subsurface, there is water. This underground water, called *groundwater*, is a vast but little-explored microbial habitat (see MicrobiologyNow, page 379). As recently as three decades ago most microbiologists were of the opinion that significant microbial numbers were limited to the top 100 m or so of Earth’s crust. However, from research made possible by the development of improved drilling and aseptic sampling technology, it is now known that microbial life extends down at least 3 kilometers into the Earth in regions containing trapped water. The microbiology of relatively shallow groundwater is quite similar to the microbiology of soils. However, microorganisms in deep subsurface waters exist at temperatures that can exceed 50°C and in anoxic and nutrient-depleted surroundings. What do we know about these organisms?

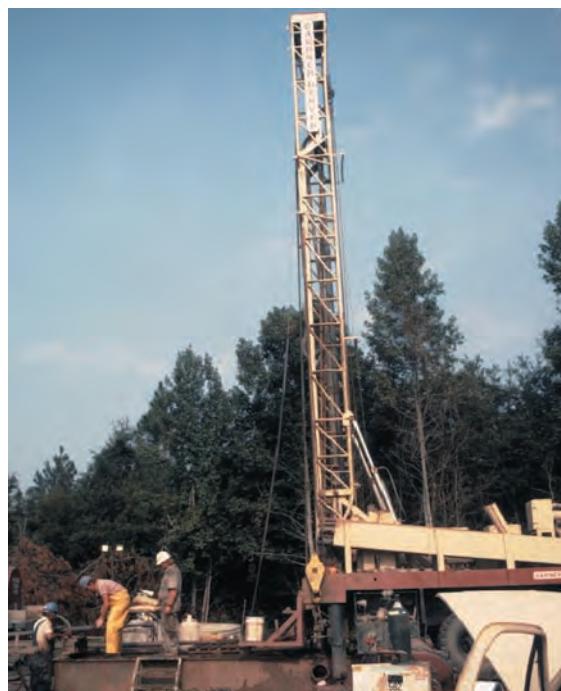

Microbiology of the Deep Subsurface

Subsurface microbiology initially focused on relatively shallow and easily accessible aquifer systems, revealing diverse populations of *Archaea* and *Bacteria* and a limited presence of protozoa and fungi. An *aquifer* is an underground layer of water-bearing permeable material, such as fractured rock or gravel. Microorganisms in aquifers are metabolically active and greatly influence the chemistry of groundwater. For example, the presence of ferrous iron (Fe^{2+}) in groundwater is largely attributable to the activity of microorganisms such as *Geobacter* that reduce ferric iron (Fe^{3+}) as an electron acceptor (☞ Section 13.21).

The period of time a water mass remains within a region of the subsurface varies from weeks to millions of years, depending on its proximity to the surface and the rate of recharge (movement of surface water into groundwater). The long-term isolation of microorganisms in deep subsurface groundwater that is not recharged has been suggested as a mechanism for *allopatric* speciation (the emergence of new microbial species as a consequence of geographic isolation). However, the microbial diversity discovered in the subsurface thus far using culture-independent

techniques (Chapter 18) has for the most part been unremarkable; the organisms closely resemble surface or near-surface species.

Research on the deep microbial biosphere has been facilitated by mining and drilling operations that expose water in fractured rock at great depths. For example, samples collected from a nearly 3-km-deep gold-mining operation in South Africa (**Figure 19.15**) revealed chemolithotrophic and autotrophic *Bacteria* and *Archaea*. DNA extracted from fissure water showed that an H₂-oxidizing, sulfate-reducing bacterium was virtually the only organism present. Genome analysis of the organism, as yet uncultured but given the provisional name *Desulforudis audaxviator*, indicated that it should be thermophilic and should be capable of autotrophic growth using H₂ as the electron donor for respiration and CO₂ fixation. In addition, the organism contained genes encoding nitrogen fixation proteins (➡ Section 3.17), meaning that it could live on a diet of a few minerals, CO₂, SO₄²⁻, N₂, and H₂. Such an organism would be well suited to long-term isolation in the deep subsurface and could be a model for the types of physiologies one would expect in such a nutrient-deficient environment.

Possible sources of H₂ for chemolithotrophs in the deep subsurface include the radiolysis of water by uranium, thorium, and other radioactive elements, and geochemical processes such as the release of H₂ from the oxidation of iron silicate minerals in aquifers. As an electron donor, H₂ can satisfy the needs of bacteria that carry out many different anaerobic respirations, including sulfate reduction, methanogenesis, acetogenesis, and ferric iron reduction (Chapter 13), and examples of all these physiologies have been identified in various subsurface microbiology research

projects. Thus the current consensus is that these types of chemolithotrophs likely dominate the deep subsurface.

Growth Rates and the Future of Subsurface Microbiology

Bacterial numbers in uncontaminated groundwater vary by several orders of magnitude (10²–10⁸ per ml), reflecting primarily nutrient availability, mostly in the form of dissolved organic carbon. Measured and estimated generation times for deep subsurface bacteria vary by many orders of magnitude, from days to centuries, as determined by the physicochemical environment, the physiology of the resident populations, and nutrient availability. However, relevant data are scarce and our knowledge about the microbial ecology of the subsurface will be greatly advanced by emerging technologies such as single-cell genomics for characterizing individual cells in their natural environment (➡ Chapter 6 Explore the Microbial World, “Genomics, One Cell at a Time,” and Section 18.11). For example, microorganisms appear to be attached to surfaces or within biofilms in the nutrient-depleted subsurface, but it is unknown whether these are genetically or physiologically distinct from microorganisms in planktonic populations.

These many unanswered questions in subsurface microbiology have supported the establishment of permanent science laboratories at great depths in the Earth. For example, the Sanford Underground Research Facility in Lead, South Dakota (USA), is being constructed at a depth of 2400 m in the former Homestake gold mine with government and private support for research in physics, geology, and microbiology. The Integrated Ocean Drilling Program, an international effort, has probed for microbial populations at great depths below the seafloor. Results thus far have

shown *Archaea* and *Bacteria* as far down as 1600 m below the seafloor in rocks more than 100 million years old. Although this may sound ancient, such ages are relatively young compared with viable bacteria that have been recovered from salt crystals nearly a half billion years old. Obviously, prokaryotic cells can remain viable for enormously long periods of time.

IV • Aquatic Environments

Freshwater and marine environments differ in many ways including salinity, average temperature, depth, and nutrient content, but both provide many excellent habitats for microorganisms. In this unit we focus first on freshwater microbial habitats. We then consider two marine environments: (1) coastal and ocean waters, and (2) the deep sea. Much new information is emerging about marine microorganisms from studies using the molecular tools of microbial ecology, especially genetic stains, microbial community sampling, and metagenomics (Chapter 18).

19.8 Freshwaters

Freshwater environments are highly variable in the resources and conditions (Table 19.1) available for microbial growth. Both oxygen-producing and oxygen-consuming organisms are present in aquatic environments, and the balance between photosynthesis and respiration (Figure 19.2) controls the natural cycles of oxygen, carbon, and other nutrients (nitrogen, phosphorus, metals).

Among microorganisms, oxygenic phototrophs include the algae and cyanobacteria. These can either be *planktonic* (floating) and distributed throughout the water columns of lakes, sometimes accumulating in large numbers at a particular depth, or *benthic*, meaning they are attached to the bottom or sides of a lake or stream. Oxygenic phototrophs, which obtain their energy from light and use water as an electron donor to reduce CO_2 to organic matter (Chapter 13), are the main primary producers in freshwater aquatic ecosystems.

The activity and diversity of chemoorganotrophic aquatic microbial communities depend to a major extent on primary production, in particular its rates and temporal and spatial distributions. Oxygenic phototrophs produce new organic material as well as O_2 . If primary production rates are very high, the resultant excessive organic matter production can lead to bottom-water O_2 depletion from respiration and the development of anoxic conditions. This in turn stimulates anaerobic metabolisms, including anaerobic respirations and fermentations (Chapter 13). Like oxygenic phototrophs, anoxygenic phototrophs can also fix CO_2 into organic material. But these organisms use reduced substances other than water, such as H_2S or H_2 , as electron donors in photosynthesis (Section 13.3). Organic matter produced by anoxygenic phototrophs can also support and enhance respiration, accelerating the spread of anoxia.

Oxygen Relationships in Freshwater Environments

The biological and nutrient structure of lakes is greatly influenced by seasonal changes in physical gradients of temperature and salinity. In many lakes in temperate climates the water column

becomes stratified, separated into layers of differing physical and chemical characteristics that constitute a **stratified water column**. During the summer, warmer and less dense surface layers, called the **epilimnion**, are separated from the colder and denser bottom layers (the **hypolimnion**). The **thermocline** is the transition zone from epilimnion to hypolimnion (Figure 19.16).

In the late fall and early winter, lake surface waters become colder and thus more dense than the bottom layers. This, combined with wind-driven mixing, causes the cooled surface water to sink and the lake to “turn over,” mixing surface and bottom waters and their nutrients. The separation of a relatively well-mixed surface layer from a relatively static bottom layer limits the transfer of nutrients between layers until fall turnover once again mixes the water column.

During periods of stratification, transfer between surface and bottom waters is controlled not by mixing but by the much slower process of diffusion. As a result, bottom waters can experience seasonal periods of either low or no dissolved O_2 . Although O_2 is one of the most plentiful gases in the atmosphere (21% of air), it has relatively limited solubility in water, and in a large body of water its exchange with the atmosphere is slow. Whether a body of water actually becomes O_2 -depleted depends on several factors, including the amount of organic matter present and the

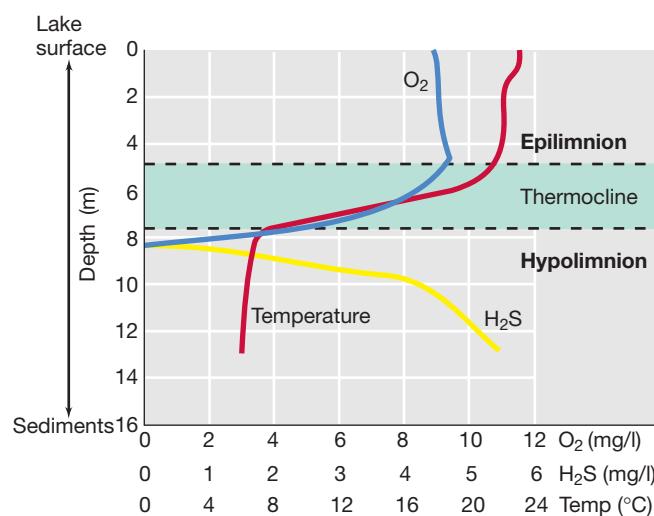

Figure 19.16 Development of anoxic conditions in a temperate lake due to summer stratification. The colder bottom waters are more dense and contain H_2S from bacterial sulfate reduction. The thermocline is the zone of rapid temperature change. As surface waters cool in the fall and early winter, they reach the temperature and density of hypolimnetic waters and sink, displacing bottom waters and effecting lake turnover. Data from a small freshwater lake in northern Wisconsin (USA).

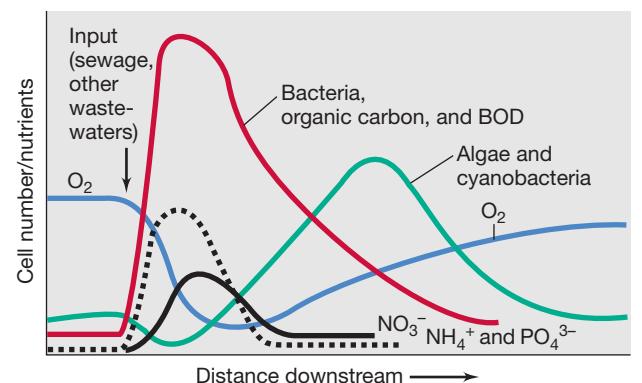

degree of mixing of the water column. Organic matter that is not consumed in surface layers sinks to the depths and is decomposed by anaerobes (Figure 19.2). Lakes may contain high levels of dissolved organic matter because inorganic nutrients that run off the surrounding land can trigger algal and cyanobacterial blooms; these organisms typically excrete various organic compounds and also release complex organic compounds when they die and decay. The combination of water body stratification during early summer, high organic loading, and limited O₂ transfer results in O₂ depletion of the bottom waters (Figure 19.16), making them unsuitable for aerobic organisms such as plants and animals.

The annual turnover cycle allows the bottom waters of a lake to pass from oxic to anoxic and back to oxic. Microbial activity and community composition is altered with these changes in oxygen content, but other factors that accompany fall turnover of the water column, especially changes in temperature and nutrient levels, govern microbial diversity and activity as well. If organic matter is sparse, as it is in pristine lakes or in the open ocean, there may be insufficient substrate available for chemoorganotrophs to consume all the oxygen. The microorganisms that dominate such environments are typically **oligotrophs**, organisms adapted to growth under very dilute conditions (Section 19.11). Alternatively, where currents are strong or there is turbulence because of wind mixing, the water column may be well mixed, and consequently oxygen may be transferred to the deeper layers.

Oxygen levels in rivers and streams are also of interest, especially those that receive inputs of organic matter from urban, agricultural, or industrial pollution. Even in a river well mixed by rapid water flow and turbulence, large organic inputs can lead to a marked oxygen deficit from bacterial respiration (Figure 19.17a). As the water moves away from a point source input, for example, from an input of sewage, organic matter is gradually consumed, and the oxygen content returns to previous levels. As in lakes, nutrient inputs to rivers and streams from sewage or other pollutants can trigger massive blooms of cyanobacteria and algae (Figure 19.17b), thereby diminishing overall water quality and growth conditions for aquatic animals.

Biochemical Oxygen Demand

The microbial oxygen-consuming capacity of a body of water is called its **biochemical oxygen demand (BOD)**. The BOD of water is determined by taking a sample, aerating it well to saturate the water with dissolved O₂, placing it in a sealed bottle, incubating it in the dark (usually for 5 days at 20°C), and determining the residual oxygen in the water at the end of incubation. A BOD determination gives a measure of the amount of organic material in the water that can be oxidized by the microorganisms present in the water. As a lake or river recovers from an input of organic matter or from excessive primary production, the initially high BOD becomes lower and is accompanied by a corresponding increase in dissolved oxygen in the ecosystem (Figure 19.17a). Another related measure of the organic material in a body of water is the *chemical oxygen demand (COD)*. This determination uses a strong oxidizing agent, such as acidic potassium dichromate, to oxidize the organic matter to CO₂; the amount of organic matter present is proportional to the amount of dichromate consumed. COD is often used as a rapid measure of water quality and of its potential BOD.

Figure 19.17 Effect of the input of organic-rich wastewaters into aquatic systems. (a) In a river, bacterial numbers increase and O₂ levels decrease with a spike of organic matter. The rise in algae and cyanobacteria is a response to inorganic nutrients, especially PO₄³⁻. (b) Photo of a eutrophic (nutrient-rich) lake, Lake Mendota, Madison, Wisconsin (USA), showing algae, cyanobacteria, and aquatic plants that bloom in response to nutrients from agricultural runoff. (See also Figure 19.1.)

We thus see that in freshwaters the oxygen and carbon cycles are linked, with the levels of organic carbon and oxygen being inversely related. Although oxygenic photosynthesis produces O₂, the corresponding production of organic matter leads to O₂ deficiencies. Anoxic aquatic environments, which are typically rich in organic material, are the end result of respiratory processes that remove dissolved oxygen from the ecosystem, leaving the remaining organic material to be mineralized by organisms employing the anaerobic energy metabolisms we discussed in Chapter 13. It is also important to recognize the importance of storms, floods, and droughts in determining delivery, transport, and cycling of organic matter and inorganic nutrients in freshwater systems, including streams, rivers, lakes, and reservoirs. These less predictable changes also affect microbial productivity, diversity, distribution, and interactions in freshwater systems.

A Phylogenetic Snapshot of Freshwater Prokaryotic Diversity

The importance of prokaryotes in lakes, streams, and rivers to the production, regeneration, and mobilization of nutrients is well recognized. However, only more recently have molecular methods been used to identify the participating microbial populations, their interactions, and seasonal patterns. As we saw for studies of soil diversity (Section 19.6), 16S ribosomal RNA gene sequencing is used as a culture-independent method to identify and quantify

microbial phylotypes (🔗 Section 18.5). Since most molecular studies of freshwater systems have focused on lakes, the emerging picture of lake community structure is examined here.

Figure 19.18 shows the major prokaryotic groups that inhabit lake surface samples (the epilimnion). Five major bacterial groups, or phyla, are routinely observed in the following approximate order of decreasing representation: *Proteobacteria*, *Actinobacteria*, *Bacteroidetes*, *Cyanobacteria*, and *Verrucomicrobia*. Archaea affiliated with *Euryarchaeota*, *Crenarchaeota*, and *Thaumarchaeota* are also present. This phylum-level composition shares features in common with the ocean, where *Proteobacteria* and *Bacteroidetes* also comprise the greater part of diversity (see Figure 19.27). However, unlike the high diversity of *Betaproteobacteria* in lakes, in the oceans *Gammaproteobacteria* and *Alphaproteobacteria* are the more diverse subgroups of the *Proteobacteria* (see Figure 19.27).

A functional interpretation of lake prokaryotic community structure is constrained by the limited availability of cultured representatives. Freshwater *Thaumarchaeota* affiliate with known ammonia-oxidizing species, but the metabolism of freshwater *Euryarchaeota* is not yet known. *Actinobacteria* are chemоорganotrophic bacteria that in lakes may be responsible for the breakdown of nucleic acid and proteins. In addition, metagenomic analyses (☞ Section 18.7) have shown that at least some *Actinobacteria* contain genes related to those that encode bacteriorhodopsin, a membrane-integrated protein that converts light energy into ATP (Section 19.11 and ☞ Section 16.1) in extremely halophilic *Archaea* (the *Actinobacteria* analog is called *actinorhodopsin*). Hence some *Actinobacteria* may be able to harvest light as an energy source.

Bacteroidetes are well represented in lake ecosystems. These organisms are known for their significant metabolic diversity and are likely to be important in lakes in the degradation of various biopolymers and humic materials. The abundant *Betaproteobacteria* tend to be fast-growing species that can respond quickly to pulses of organic nutrients, whereas the *Alphaproteobacteria* are

more competitive under conditions of low availability of organic nutrients; this likely accounts for their greater abundance in the oligotrophic open ocean (see Figure 19.27).

Taken as a whole, high prokaryotic diversity in freshwater lakes (Figure 19.18) reflects the dynamic character of these habitats. Lakes typically receive seasonally variable inputs of endogenous and exogenous nutrients, a pattern that sustains a phylogenetically and metabolically complex prokaryotic community.

19.9 The Marine Environment: Phototrophs and Oxygen Relationships

With the exception of oxygen, nutrient levels in the open ocean (the *pelagic zone*) are often very low compared with many freshwater environments. This is especially true of key inorganic nutrients for phototrophic organisms, such as nitrogen, phosphorus, and iron. In addition, water temperatures in the oceans are cooler and more constant seasonally than those of most freshwater lakes. The activity of marine phototrophs is limited by these factors, and thus total microbial cell numbers are typically about 10-fold lower in the oceans than in freshwater environments ($\sim 10^6/\text{ml}$ versus $10^7/\text{ml}$, respectively). These are average numbers, and studies of marine prokaryotic diversity are just beginning to reveal recurrent temporal patterns of diversity and abundance.

The Bermuda Atlantic Time-Series Study (BATS) has a history of continuous biogeochemical monitoring of ocean waters since the mid-1950s, and is now incorporating molecular analyses of microbial population structure. BATS has revealed three seasonal microbial communities in ocean waters: (1) the community corresponding to the spring surface water bloom (featuring small eukaryotic algae, marine actinobacteria, and two groups of *Alphaproteobacteria*); (2) the summertime community in the upper water column associated with water column stratification (featuring *Pelagibacter*, *Puniceispirillum*, and two groups of *Gammaproteobacteria*); and (3) the deeper, more stable community (featuring *Nitrosopumilus*, representatives of the SAR11 group with which the genus *Pelagibacter* affiliates, a group of *Deltaproteobacteria*, and species of two additional groups related to the *Chloroflexi* and *Fibrobacter*). Thus, a complex and poorly understood interplay of seasonal changes in physicochemical and biotic conditions controls the structure of this oceanic microbial community in recurring annual cycles.

Many different prokaryotes and eukaryotes inhabit ocean waters, but most are very small cells, a typical characteristic of organisms living in nutrient-poor environments. Smallness is an adaptive feature for nutrient-limited microorganisms in that it requires less energy for cellular maintenance. The trade-off is

that a greater number of transport enzymes relative to cell volume are needed for organisms to acquire nutrients from very dilute (oligotrophic) than from nutrient-rich (eutrophic) aquatic environments. For example, ammonia-oxidizing *Archaea* (*Nitrosopumilus*, [Section 16.6](#)) are the dominant chemolithotrophs in pelagic waters and have very high-affinity transport systems for acquiring the ammonia they need as an electron donor in energy metabolism.

(b) NASA Terra satellite image taken on May 24, 2010, of the Gulf of Mexico near New Orleans, Louisiana. A large plume of oil was released at about 1500 m depth, some of which reached the surface where sunlight reflects off of the oil slick (arrows).

In pelagic waters there is a lower return of nutrients from the bottom waters than in freshwater lakes, and thus lower average primary productivity. However, because the oceans are so large, the collective carbon dioxide sequestration and oxygen production from oxygenic photosynthesis in the oceans are major factors in Earth's carbon balance. Salinity is more or less constant in the pelagic zone but is more variable in coastal areas. Terrestrial inputs, retention of nutrients, and upwelling of nutrient-rich waters combine to support higher populations of phototrophic microorganisms in near-shore waters than in pelagic waters ([Figure 19.19](#)); the more productive near-shore waters in turn support higher densities of chemoorganotrophic bacteria and aquatic animals, such as fish and shellfish.

In shallow marine waters such as marine bays and inlets, nutrient inputs can actually lead to the waters becoming intermittently anoxic from the removal of O_2 by respiration and the production of H_2S by sulfate-reducing bacteria. An extensive region (6000–7000 square miles) of oxygen depletion in the Gulf of Mexico is associated with high loads of nitrogen and phosphorus carried in by the Mississippi River from agricultural runoff in the Mississippi Valley. This region, called the *Gulf of Mexico Dead Zone*, contributes to the loss and impairment of fish and benthic sea life that sustain major seafood industries in this region. The Gulf of Mexico experiences other ecological problems as well, as we examine now.

The Deepwater Horizon Catastrophe

In addition to the chronic degradation of the Gulf of Mexico ecology through agricultural runoff, increased offshore oil drilling also poses significant environmental risk. A major catastrophe for the Gulf of Mexico was the April 2010 explosion and sinking of the Deepwater Horizon offshore drilling platform; failure to control well pressure resulted in the rupture of the wellhead at a depth of 1.5 km and the release of over 4 million barrels of oil before the well was capped three months later ([Figure 19.20](#)). This

largest marine oil spill ever was unique in that most of the oil was released as a plume at great depths in the water column. Typically, marine oil spills contaminate primarily the surface waters, resulting in rapid volatilization and loss to the atmosphere of low-molecular-weight oil components (such as naphthalene, ethylbenzene, toluene, and xylene). By contrast, the Deepwater Horizon spill released both low-molecular-weight components *and* natural gas (methane, ethane, propane) deep into the water column. These components comprised about 35% of the hydrocarbon plume that extended many miles into the Gulf from the surface to depths greater than 800 m (Figure 19.20b).

The microbial response to hydrocarbon contamination was tracked over several months using both culture-based and molecular methods, including 16S ribosomal RNA gene and metagenomic sequencing, and phylochip microarray analyses (☞ Sections 18.5–18.7). These methods showed that the initial microbial response to the spill (May and June 2010) was a bloom of hydrocarbon-degrading *Gammaproteobacteria* species related to genera in the *Oceanospirillales* group, and of the genera *Colwellia* and *Cycloclasticus*. Increased numbers of *Colwellia* and *Oceanospirillales* species were attributed to their use of gaseous hydrocarbons, since both grew rapidly when ethane or propane was added to enrichment cultures (☞ Section 18.1). *Colwellia* species also contributed to the degradation of a variety of other hydrocarbons, as indicated by their growth in crude oil enrichment cultures lacking natural gas and by stable isotope probing experiments (☞ Section 18.11) showing their incorporation of ^{13}C benzene. Although there remains considerable uncertainty about the fate of all the hydrocarbons released during the Deepwater Horizon spill, it appears that the early stimulation of a bloom of hydrocarbon-degrading bacteria by the more easily degraded, soluble, low-molecular-weight components helped reduce the environmental impact of this immense oil spill.

Oxygen Minimum Zones

Another feature of the marine water column is **oxygen minimum zones** (OMZs), regions of oxygen-depleted waters at intermediate depths, typically in waters between 100 and 1000 m, that extend over wide expanses of the open and coastal ocean. These oxygen-depleted regions arise when the respiratory demand for oxygen exceeds oxygen availability, and they are associated with nutrient-rich, highly productive regions. In this way they are similar to the depletion of oxygen caused by agricultural runoff in coastal zones, such as contributes to the Gulf of Mexico Dead Zone. However, OMZs predate human activity and originate naturally in regions of high surface production and little mixing with oxygen-rich water.

The oxygen saturation values of the largest of the OMZs in the eastern Pacific off the coast of Peru are less than 10% of that at the surface. Oxygen levels at certain depth intervals in the OMZs of the Bay of Bengal and Arabian Sea approach zero. Because of this, OMZs have been recognized as significant sinks for the loss of fixed nitrogen through denitrification (☞ Section 13.17) and anammox processes (☞ Section 13.10). In addition to contributing to a significant fraction of the 50% loss of fixed nitrogen from the oceans, these regions are also a source of nitrous oxide (N_2O), a potent greenhouse gas of which approximately one-third is emitted from the oceans.

Ongoing studies of OMZs have shown that these regions of oxygen depletion are expanding, and that their recent expansion is almost certainly associated with global warming. As the oceans absorb more heat, warming of the surface waters increases stratification of near-surface waters and reduces oxygen transfer through mixing to deeper regions. Expansion of the OMZs will favor anaerobic microbial processes at the expense of the aerobic processes that sustain critical oceanic food webs. These changes may further affect atmospheric chemistry by increasing the release of N_2O and will negatively impact marine food webs by reducing levels of fixed nitrogen. Ultimately, these changes are expected to impact commercial fisheries.

19.10 Major Marine Phototrophs

The oceans contain large numbers of phototrophic microorganisms, including both prokaryotic and eukaryotic oxygenic phototrophs as well as significant numbers of a special group of purple (anoxygenic) phototrophs. We consider these organisms here as a prelude to exploring the marine prokaryotic world in general in the next section.

Primary Productivity: *Prochlorococcus*

Much of the primary productivity in the open oceans, even at significant depths, comes from photosynthesis by prochlorophytes, tiny prokaryotic phototrophs that are phylogenetically related to cyanobacteria (☞ Section 14.3); **prochlorophytes** contain chlorophylls *a* and *b* but do not contain phycobilins. The organism *Prochlorococcus* is a particularly important primary producer in the marine environment (Figure 19.21). Because *Prochlorococcus* lacks phycobilins, the accessory pigments of the cyanobacteria (☞ Section 13.2), dense suspensions of *Prochlorococcus* cells are olive green (as are green algae) rather than the blue-green color of cyanobacteria (compare Figures 19.1c and 19.21).

Prochlorococcus accounts for up to half of the photosynthetic biomass and primary production in the tropical and subtropical regions of the world's oceans, reaching cell densities of $10^5/\text{ml}$. At least four strains of *Prochlorococcus* have been identified, and each inhabits its own depth range in pelagic waters. The different *Prochlorococcus* strains are considered distinct *ecotypes*, genetic variants of a species that differ physiologically and therefore occupy slightly different niches. The different *Prochlorococcus* ecotypes photosynthesize at different light intensities and use different inorganic and organic nitrogen and phosphorus sources. *Prochlorococcus* is thus distributed in both surface waters and deeper waters to depths of 200 m, and when an oxygen minimum zone (Section 19.9) is present, it extends into the upper regions of this zone. This is near the bottom of the photic zone where light

intensities are very low (see Figure 19.24). Genome sequences of a dozen or so *Prochlorococcus* ecotypes have been determined and comparisons have revealed that although each ecotype contains about 2000 genes, only about 1100 genes are shared by all ecotypes. Each ecotype contains approximately 200 unique genes, which presumably have adaptive significance for growth in its realized niche. This was illustrated in Chapter 18 where we compared the genome of a single cultured *Prochlorococcus* ecotype to metagenome sequences obtained from pelagic waters (☞ Section 18.7 and Figure 18.19).

Other Pelagic Oxygenic Phototrophs

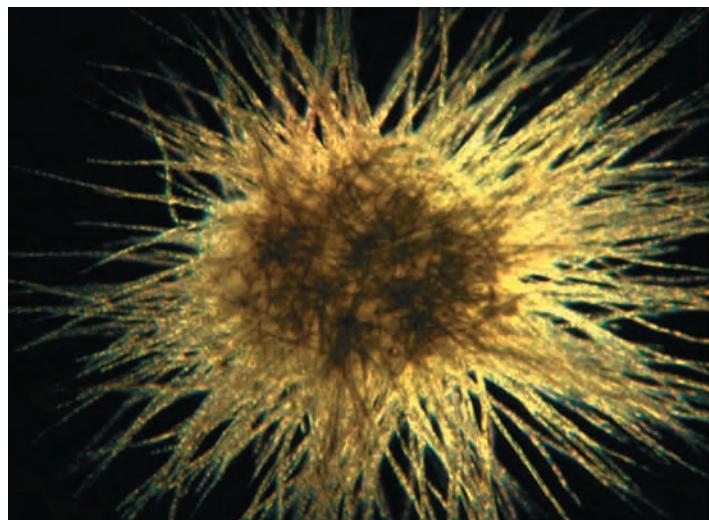

In tropical and subtropical oceans, the planktonic filamentous marine cyanobacterium *Trichodesmium* (Figure 19.22a) is a widespread and occasionally abundant phototroph. Cells of *Trichodesmium* form puffs (colonies) of filaments. Each puff can contain many hundreds of individual filaments, each filament composed of 20–200 cells. In the Caribbean Sea, colonies of *Trichodesmium* can approach 100/m³. *Trichodesmium* is a nitrogen-fixing cyanobacterium, and the production of fixed nitrogen by this organism is thought to be an important link in the marine nitrogen cycle. *Trichodesmium* contains phycobilins, absent from prochlorophytes, and thus differs from these organisms in its absorption properties (☞ Section 13.2).

Very small phototrophic eukaryotes also inhabit coastal and pelagic waters, and some of these are among the smallest eukaryotic cells known. Three common genera—*Bathycoccus*, *Micromonas*, and *Ostreococcus*—contain only one mitochondrion and one chloroplast per cell. These genera are now assigned to the *Prasinophyceae*, a family of green algae that diverged early from other lineages of green algae (☞ Section 17.16). Cells of *Ostreococcus* are cocci that measure only about

0.7 µm in diameter (Figure 19.22b), which is even smaller than a cell of *Escherichia coli*.

Although cells of *Ostreococcus* and *Prochlorococcus* are of roughly the same dimensions and they are both oxygenic phototrophs, their genomes are distinct. The genome of *Ostreococcus* is 12.6 Mbp (distributed over 20 chromosomes), which is more than seven times the size of the *Prochlorococcus* genome. Even though this is large relative to cyanobacteria, the *Ostreococcus* genome is very gene dense, containing about 8000 genes, and thought to be near the minimum genome size of a free-living photosynthetic eukaryote. As a reference, the genome of a common plant, Japanese rice (*Oryza sativa* subsp. *japonica*), is 420 Mbp and contains about 50,000 genes.

In many marine waters, other small eukaryotic cells are present at about 10⁴/ml. Although many of these are *Ostreococcus* or relatives, some are chemoorganotrophs and some are phototrophs unrelated

to *Ostreococcus* that incorporate small amounts of organic matter to supplement their primarily phototrophic lifestyle.

Aerobic Anoxygenic Phototrophs

Besides *oxygenic* phototrophs, *anoxygenic* phototrophs are also present in coastal and pelagic marine waters. Like purple *anoxygenic* phototrophs, these organisms contain bacteriochlorophyll *a* (Sections 13.1, 13.3, 14.4, and 14.5). However, unlike classical purple bacteria that carry out photosynthesis only under *anoxic* conditions, these *anoxygenic* phototrophs carry out photosynthetic light reactions only under *oxic* conditions.

Aerobic *anoxygenic* phototrophs include bacteria such as *Erythrobacter*, *Roseobacter*, and *Citromicrobium* (Figure 19.23), all genera of *Alphaproteobacteria*. Aerobic *anoxygenic* phototrophs synthesize ATP by photophosphorylation when oxygen is present (which is all of the time in *oxic* pelagic waters), but they are unable to grow autotrophically and thus rely on organic carbon for their carbon sources (a nutritional condition called *photoheterotrophy*). These organisms thus use the ATP produced by photophosphorylation to supplement their otherwise chemorganotrophic metabolism.

Surveys have shown that a great diversity of aerobic *anoxygenic* phototrophs exist in marine waters, especially near-shore waters. Oligotrophic and highly *oxic* freshwater lakes are also habitats for these interesting phototrophic bacteria. The physiology of aerobic *anoxygenic* phototrophs is thus ideal for their illuminated and highly *oxic* habitats.

19.11 Pelagic Bacteria, Archaea, and Viruses

Despite vanishingly low nutrient levels, significant numbers of prokaryotes live a planktonic existence in pelagic waters. These include species of both *Bacteria* and *Archaea*, and one organism in particular has garnered significant attention, a bacterium named *Pelagibacter*.

Distribution and Activity of Archaea and Bacteria in Pelagic Waters

The abundance of prokaryotic cells in the open oceans decreases with depth. In surface waters, cell numbers average about 10^6 /ml. Below 1000 m, however, total cell numbers fall to between 10^3 and 10^5 /ml. The distribution of *Bacteria* and *Archaea* with depth has been tracked in pelagic waters using fluorescence in situ hybridization (FISH) technology (Section 18.4).

Species of *Bacteria* tend to predominate in waters above 1000 m, although cells of *Bacteria* and *Archaea* are found in near-equal abundance in deeper waters (Figure 19.24). Deep-water *Archaea* are almost exclusively species of *Thaumarchaeota* (Section 16.6), and many or perhaps even most are ammonia-oxidizing chemolithotrophs (Sections 13.10 and 16.6); these organisms play an important role in coupling the marine carbon and nitrogen cycles (Chapter 20). Extrapolating from the data in Figure 19.24, it is

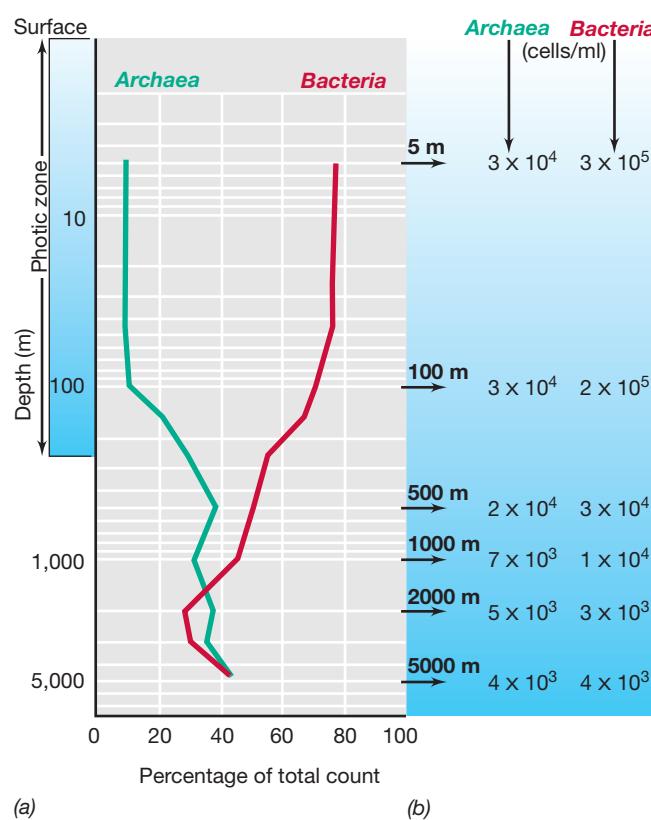

Figure 19.24 **Percentage of total prokaryotes belonging to Archaea and Bacteria in North Pacific Ocean water.** (a) Distribution of Archaea and Bacteria with depth. (b) Absolute numbers per milliliter of Archaea and Bacteria with depth in the open ocean.

estimated that 1.3×10^{28} and 3.1×10^{28} cells of *Archaea* and *Bacteria*, respectively, exist in the world's oceans. This means that the oceans contain the largest microbial biomass on Earth's surface.

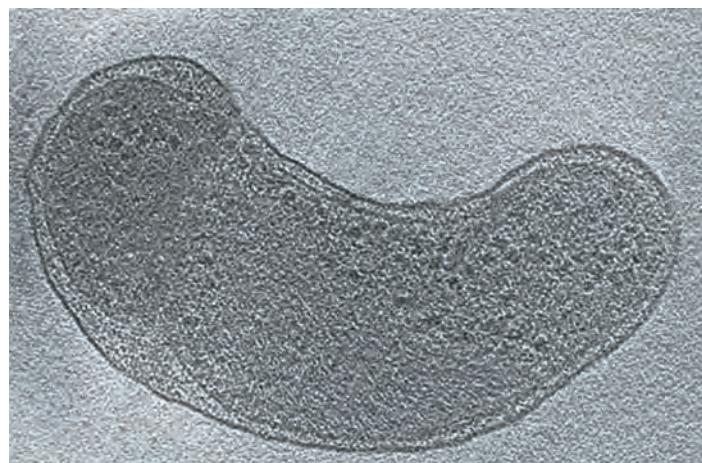

Pelagic *Bacteria* and *Archaea* are ecologically important because they consume dissolved organic carbon in the oceans, one of the largest pools of usable organic carbon on Earth. These small and free-living planktonic prokaryotes consume about half the total oceanic organic carbon produced from photosynthesis and are responsible for about half of all marine respiration and nutrient regeneration. Planktonic marine prokaryotes thus return organic matter to the marine food web that would otherwise be lost because of the inability of larger marine organisms to take up such diluted organic nutrients. This so-called "secondary production" is balanced by cell losses from bacterial grazing protists and from virus attack (see Figure 19.26), leading to a near-steady state in which bacterial abundance in the open ocean remains roughly constant over time. But importantly, secondary production both recycles nutrients and allows some of the dissolved organic carbon in seawater to reach larger organisms, including fish, because protists are passed up the food web by the feeding activities of larger organisms.

Pelagibacter

Very small planktonic chemoorganotrophic bacteria inhabit pelagic marine waters in numbers of 10^5 – 10^6 cells/ml. The most abundant of these are members of the SAR11 group within the *Alphaproteobacteria*, which includes the genus *Pelagibacter*. Environmental metagenomic studies (Sections 6.10 and 18.7) and cell counts done using FISH (Section 18.4) have revealed a great abundance of SAR11 group organisms in pelagic waters. The oceanic population of the SAR11 group is estimated to number 2.4×10^{28} cells, making it the most successful microbial group, as reflected by abundance, on the planet. *Pelagibacter* is an oligotroph, as are most pelagic prokaryotes. An oligotroph is an organism that grows best at very low concentrations of nutrients. *Pelagibacter* is a chemoorganotroph and grows in laboratory culture only up to the densities it is found in nature.

What makes *Pelagibacter* so successful in the open oceans? In part, their success is related to small size. Cells of *Pelagibacter* are small rods with a diameter of only 0.2–0.5 μm , near the limits of resolution of the light microscope (Figure 19.25), and a volume of 0.01 μm^3 . The resulting high surface-to-volume ratio (Section 2.6) facilitates nutrient transport, increasing substrate concentration and processing rates within the cell. Proteomic analyses (Section 6.8) have also revealed a high abundance of periplasmic substrate-binding proteins for soluble nutrients such as phosphate, amino acids, and sugars in *Pelagibacter*.

Another feature of *Pelagibacter* is its small genome, only 1.3 Mbp. This is the smallest known genome for a free-living bacterium (Chapter 6). Consistent with the proteome analysis, the genome encodes an unusually high number of ABC-type transport systems—transporters that have an extremely high affinity for their substrates (Section 2.9)—and other enzymes useful for an oligotrophic organism. The highly reduced genome is also highly "streamlined," having the shortest intergenic spacing (an average of only 3 base pairs) of any sequenced genome. Having a highly compact and efficient genome reduces the cost of replication.

Figure 19.25 *Pelagibacter*, the most abundant prokaryote in the ocean.

In addition to its small size and compact genome, *Pelagibacter* has genes that encode a form of the visual pigment rhodopsin that can convert light energy into ATP. In Section 16.1 we discussed the now well-studied molecule *bacteriorhodopsin*, a light-activated protein complex present in the extreme halophile *Halobacterium* (*Archaea*); *bacteriorhodopsin* functions in ATP synthesis as a simple light-driven proton pump (Figure 16.4). The form of rhodopsin in *Pelagibacter* and other pelagic prokaryotes is structurally similar to *bacteriorhodopsin* and has been called **proteorhodopsin** ("proteo" referring to *Proteobacteria*). Although *proteorhodopsin* was first discovered in species of *Proteobacteria*, it is actually fairly widely distributed in *Bacteria*, including many *Gamma-* and *Alphaproteobacteria*, *Bacteroidetes*, and *Actinobacteria*, and has also been found in nonhalophilic species of *Archaea*, such as species of the marine *Euryarchaeota*. The different variants of *proteorhodopsins* in marine microorganisms have absorption properties that reflect changing spectral properties of light at increasing depths in the water column, with near-surface variants absorbing green light and those at greater depths absorbing blue light.

Studies of various cultured *proteorhodopsin*-containing marine bacteria have now conclusively shown these organisms survive starvation better in the light than in the dark. That is, energy-starved cells use light-mediated ATP production to compensate for energy unavailable from carbon respiration due to the low levels of organic carbon present. Remarkably, *proteorhodopsins* have been estimated to exist in 80% of marine bacteria in some waters. *Proteorhodopsin* is thus a widespread strategy to supplement the energy metabolism of marine prokaryotes such that they need not rely solely on scarce organic carbon for their energy needs.

Marine Viruses

In the oceans, viruses are more abundant than cellular microorganisms, often numbering over 10^7 virions/ml in typical seawater (Section 8.11). In coastal waters, where bacterial cell numbers are higher than in the oceans, viral numbers are also higher, as many as 10^8 virions/ml. Most of these viruses are

The tiny green dots are viruses while the larger, brighter dots are prokaryotes about 0.5 μm in diameter. Viruses are typically 10 times more abundant than prokaryotes in seawater. Inset transmission electron micrographs show various marine bacterial viruses (scale bars, 100 nm in all images).

bacteriophages, which infect species of *Bacteria*, and archaeal viruses, which infect species of *Archaea*. The number of virions in seawater is about 10-fold greater than average prokaryotic cell numbers, suggesting that viruses are actively infecting their hosts, replicating, and being released into seawater (Figure 19.26). Only a small fraction of released viruses (an average of one per burst) successfully infects a new host, and most are inactivated or destroyed by sunlight and hydrolytic enzymes. In these ways, the entire viral population is replaced in periods of only a few days or weeks. We considered bacterial and archaeal viral diversity in Chapter 9.

Along with feeding by protists, marine virus infections probably help to maintain prokaryotic numbers at the levels that are observed, but viruses may also have other important ecosystem functions. These include facilitating genetic exchange between prokaryotic cells and allowing for lysogeny, the state in which a virus genome integrates within the cellular genome; lysogeny can confer new genetic properties on the cell (Sections 8.8 and 10.7). For example, the discovery that some of the viruses that infect *Prochlorococcus*, the most abundant oxygenic phototroph in the oceans (Figure 19.21 and Section 19.10), contain genes that encode proteins for photosynthesis indicates that even key metabolic properties may be encoded by viruses. Although the genetic diversity of marine viruses is just now being recognized, it is thought that the diversity of marine viral genomes could surpass even that of all prokaryotic cells, making the oceans a hotbed of genetic diversity.

A Phylogenetic Snapshot of Marine Prokaryotic Diversity

Several studies have attempted to characterize the diversity of planktonic marine prokaryotes by analysis of 16S ribosomal RNA genes obtained from seawater. The existence of abundant alpha-proteobacterial populations to which *Pelagibacter* is affiliated was first revealed by such 16S rRNA sequence analysis. Mesophilic *Archaea* related to *Nitrosopumilus maritimus* (Section 16.6) were discovered using similar methods.

Major bacterial groups now recognized as abundant in the open ocean include Alpha- and Gammaproteobacteria, cyanobacteria, *Bacteroidetes*, and to a lesser extent, Betaproteobacteria and Actinobacteria; Firmicutes are only minor components (Figure 19.27). As for soil, a large proportion of unclassified and minor bacterial groups are also present in seawater. A major group of marine Gammaproteobacteria is the yet to be cultured “SAR86 group,” which accounts for approximately 10% of the total prokaryotic community in the ocean surface layer. Representing the *Archaea* in pelagic waters is a rather restricted diversity of *Euryarchaeota*,

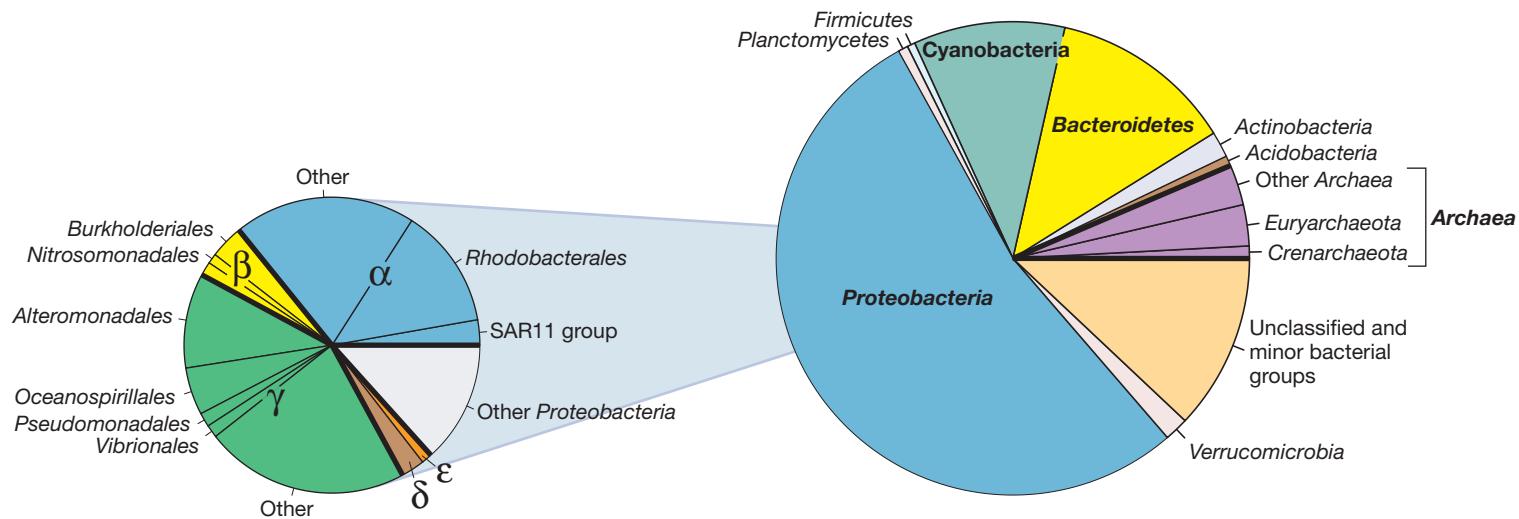

Figure 19.27 Ocean prokaryotic diversity. The results are pooled analyses of 25,975 16S ribosomal RNA sequences from several studies of pelagic ocean waters. Many of these groups are covered in Chapters 14 and 15 (*Bacteria*) or 16 (*Archaea*). For *Proteobacteria*, major subgroups are indicated. Compare the prokaryotic diversity of seawater with that of freshwater shown in Figure 19.18.

Crenarchaeota, and *Thaumarchaeota*, most of which have not yet been brought into laboratory culture.

With the exception of the cyanobacteria, most marine *Bacteria* are thought to be chemoorganotrophs adapted to extremely low nutrient availability, some augmenting energy conservation through proteorhodopsin or aerobic anoxygenic phototrophy (Section 19.10). The discovery of the chemolithotroph *Nitrosopumilus* suggested the possibility that many marine *Archaea* specialize in ammonia oxidation, although heterotrophic species likely exist as well. “Dilution culture” methods employing very dilute culture media have been successful in bringing some pelagic prokaryotes into culture (☞ Section 18.2). It appears that most of these organisms have evolved to grow only at very low nutrient concentrations, so it is either difficult or impossible to culture them to higher cell densities. Cell densities of marine oligotrophs in laboratory cultures are similar to those in their natural environments (10^5 – 10^6 /ml), which renders many of the common tools for measuring cell growth (turbidity, microscopic counts) useless on samples that are not first concentrated. Nevertheless, there have been notable successes with dilution culturing of marine bacteria and the aforementioned *Pelagibacter* is a good example (☞ Chapter 18 Explore the Microbial World, “Culturing the Uncultured”).

19.12 The Deep Sea and Deep-Sea Sediments

Light penetrates no farther than about 300 m in pelagic waters; as has been mentioned, this illuminated region is called the *photic zone* (Figure 19.24). Beneath the photic zone, down to a depth of about 1000 m, there is still considerable biological activity. However, water at depths greater than 1000 m is, by comparison, much less biologically active and is known as the *deep sea*. Greater than 75% of all ocean water is deep-sea water, lying primarily at depths between 1000 and 6000 m. The deepest waters in the oceans lie below 10,000 m. However, because holes this deep are very rare, the waters in them make up only a very small proportion of all pelagic waters.

Conditions in the Deep Sea

Organisms that inhabit the deep sea face three major environmental extremes: (1) low temperature, (2) high pressure, and (3) low nutrient levels. In addition, deep-sea waters are completely dark such that photosynthesis is impossible. Thus, microorganisms that inhabit the deep sea must be chemotrophic and able to grow under high pressure and oligotrophic conditions in the cold.

Below depths of about 100 m, ocean water temperatures stay constant at 2–3°C. We discussed the responses of microorganisms to changes in temperature in Sections 5.11 and 5.12. As would be

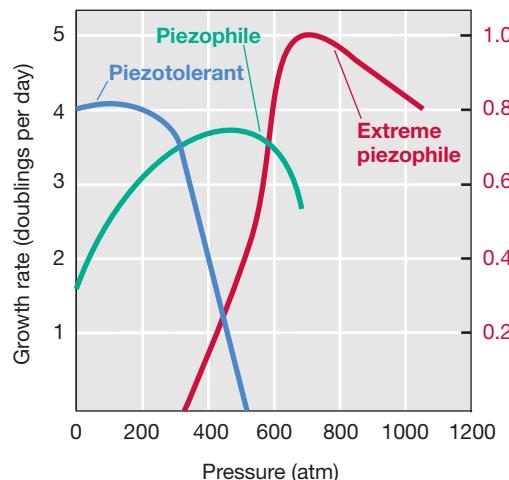

Figure 19.28 Growth of piezotolerant, piezophilic, and extremely piezophilic bacteria. The extreme piezophile (*Moritella*) was isolated from the Mariana Trench, off the Philippines, Pacific Ocean (Figure 19.30). Compare the slower growth rate of the extreme piezophile (right ordinate) with the growth rate of the piezotolerant and piezophilic bacteria (left ordinate), and note the inability of the extreme piezophile to grow at low pressures.

expected, bacteria isolated from marine waters below 100 m are psychrophilic (cold-loving) or at least psychrotolerant. Deep-sea microorganisms must also be able to withstand the enormous hydrostatic pressures associated with great depths. Pressure increases by 1 atm for every 10 m of depth in a water column. Thus, an organism growing at a depth of 5000 m must be able to withstand pressures of 500 atm. We will see that microorganisms are remarkably tolerant of high hydrostatic pressures; many species can withstand pressures of 500 atm, and some species can withstand far more than this.

Piezotolerant and Piezophilic Bacteria and Archaea

Different physiological responses to pressure are observed in different deep-sea microorganisms. Some organisms simply tolerate high hydrostatic pressure, but do not grow optimally under such pressure; these organisms are **piezotolerant** (Figure 19.28). By contrast, others actually *grow best* under elevated hydrostatic pressure; these are called **piezophiles**. Organisms isolated from surface waters down to about 3000 m are typically piezotolerant. In piezotolerant organisms, higher metabolic rates are observed at 1 atm than at 300 atm, although growth rates at the two pressures may be similar (Figure 19.28). However, piezotolerant isolates typically do not grow at pressures greater than about 500 atm.

By contrast, cultures derived from samples taken at greater depths, 4000–6000 m, are typically piezophilic, growing optimally at pressures of around 300–400 atm. However, although piezophiles grow best under high pressure, they can still grow at 1 atm (Figure 19.28). In even deeper waters (for example, 10,000 m), **extreme piezophiles** are present. These organisms require very high pressure for growth (Figure 19.29). For example, the extreme piezophile *Moritella*, isolated from the Mariana Trench (Pacific Ocean, >10,000-m depth) (Figure 19.30), grows optimally at a pressure of 700–800 atm and grows nearly as well at 1035 atm, the pressure it experiences in its natural habitat.

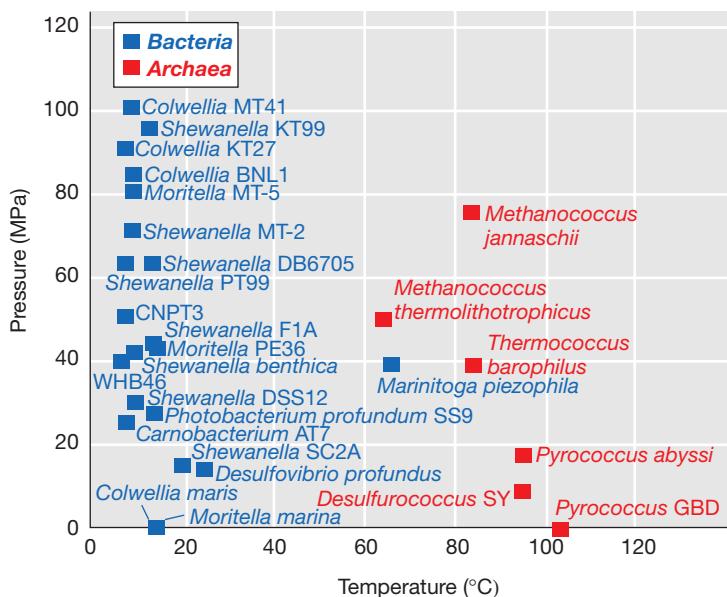

Figure 19.29 Pressure and temperature optima for cultured bacterial and archaeal piezophiles. Pressure is in pascals (Pa), the SI units for pressure. One megapascal (MPa) corresponds to approximately 10 atm. Note that different species of the same genus can have vastly different pressure optima. Data assembled by Doug Bartlett.

Molecular Effects of High Pressure

High pressure affects cellular physiology and biochemistry in many ways. In general, pressure decreases the ability of the sub-units of multi-subunit proteins to interact. Thus, large protein complexes in extreme piezophiles must interact in such a way as to minimize pressure-related effects. Protein synthesis, DNA synthesis, and nutrient transport are sensitive to high pressure. Piezophilic bacteria grown under high pressure have a higher proportion of unsaturated fatty acids in their cytoplasmic membranes than when grown at 1 atm. Unsaturated fatty acids allow membranes to remain functional and keep from gelling at high pressures or at low temperatures. The rather slow growth rates of extreme piezophiles such as *Moritella* compared with other marine bacteria (Figure 19.28) are likely due to the combined

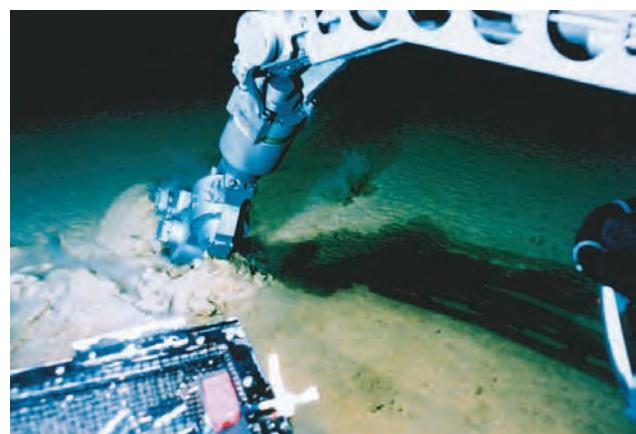

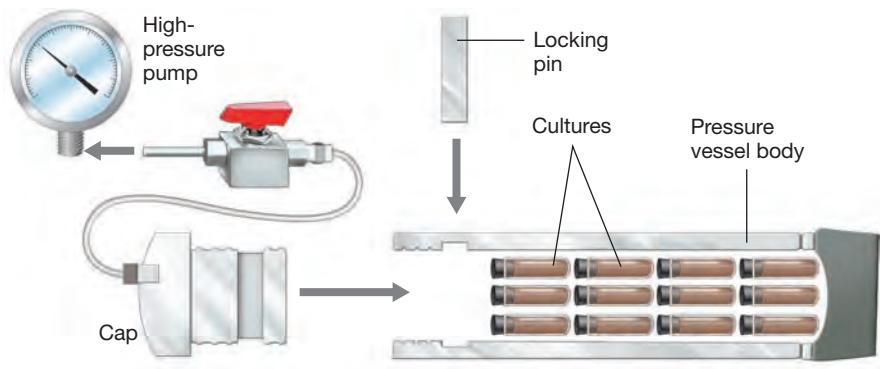

Figure 19.30 Sampling the deep sea. The unmanned submersible *Kaiko* collecting a sediment sample on the seafloor of the Mariana Trench at a depth of 10,897 m. The tubes of sediment are used for enrichment and isolation of piezophilic bacteria. Hideto Takami

effects of pressure and low temperature; low temperature slows down the reaction rates of enzymes, directly affecting cell growth (☞ Sections 5.11 and 5.12).

Studies of gene expression and adaptive features contributing to growth at high pressure have required special pressurized incubation devices (Figure 19.31). These studies have shown that when a gram-negative piezophile is grown under high pressure, a specific outer membrane protein called OmpH (outer membrane protein H) is present that is absent from cells grown at 1 atm. OmpH is a type of porin. Porins are proteins that form channels through which molecules diffuse into the periplasm (☞ Section 2.11). Presumably, the porin made by cells grown at 1 atm cannot function properly at high pressure and thus a different porin must be synthesized. Interestingly, pressure controls transcription of *ompH*, the gene encoding OmpH. In this piezophile a pressure-sensitive membrane protein complex is present that monitors pressure and triggers transcription of *ompH* only when conditions of high pressure warrant it. Transcriptomic analyses (☞ Section 6.7) indicate that even relatively modest changes

in hydrostatic pressure alter the expression of a large number of genes in piezophiles, so it is likely that many other pressure-monitoring proteins exist in these organisms.

Deep-Sea Sediments

Another vast and mostly unexplored microbial ecosystem exists deep below the seafloor. Deep drilling expeditions to explore the depths below the ocean seafloor have revealed both archaeal and bacterial populations as deep as 1600 m (Figure 19.32). Most studies thus far have focused on relatively organic-rich deep-subsurface sediments at continental margins. Here, cell numbers typically decrease from about 10^9 cells/g of surface sediment to about 10^6 cells/g at depths as great as 1000 m below the seafloor. The decrease in cell numbers with depth is correlated with the amount of organic carbon entering the sediment system, primarily through past particle transport from surface water production.

The better-studied continental margins and shelf sediments are not representative of most of the ocean floor, about 90% of which is at greater than 2000 m deep in marine waters of low productivity and therefore of significantly lower carbon content. Cell numbers in these sediments are several orders of magnitude lower than in organic-rich sediments, from about 10^6 cells/gram at the surface to fewer than 10^3 cells/gram at depths of a few hundred meters. Because of lower microbial activity, oxygen (O_2) penetrates much deeper into these sediments, meters as opposed to a few centimeters in organic-rich sediments.

The sub-seafloor ecosystems are estimated to contain about 4 petagrams (1 petagram is 10^{15} g) of microbial cellular carbon, approximately 0.6% of Earth's total living biomass. Sequencing

of 16S ribosomal RNA genes selectively amplified by PCR (Section 18.5) using DNA extracted from drilling cores, as well as more limited metagenomic surveys, has identified relatively few sequences related to the classical sulfate-reducing bacteria (Section 14.9) or methanogenic and methane-oxidizing Archaea (Sections 13.20, 13.24, and 16.2) common in surface sediments. Most of the Archaea in the subsurface, identified only by their 16S rRNA sequences, affiliate with novel phylum-level clades of Archaea having no presently cultured representatives. In turn, distinct lineages of novel Archaea preferentially inhabit the organic-rich coastal margin and the organic-poor sediments comprising most of the ocean floor, possibly reflecting varying electron donor and electron acceptor availability in these two types of sediment.

A Phylogenetic Snapshot of Marine Sediment Prokaryotic Diversity

Marine sediment communities have been explored only to a limited extent, given the great difficulty and expense of obtaining uncontaminated drilling cores from great depth (Figure 19.32). Analyses of available 16S ribosomal RNA gene sequences obtained from deep coring samples show these communities to be distinct from open-ocean and soil communities. Most notably, Archaea of unknown affiliation make up a large fraction of the diversity (Figure 19.33). By contrast, in shallow marine sediments *Proteobacteria* dominate, as they do in all of the other habitats explored by culture-independent techniques (Figures 19.14, 19.18, and 19.27, and see Figure 19.38). Within marine sediment *Proteobacteria*, phylotypes associated with sulfate-reducing bacteria such as the *Desulfobacterales* are quite

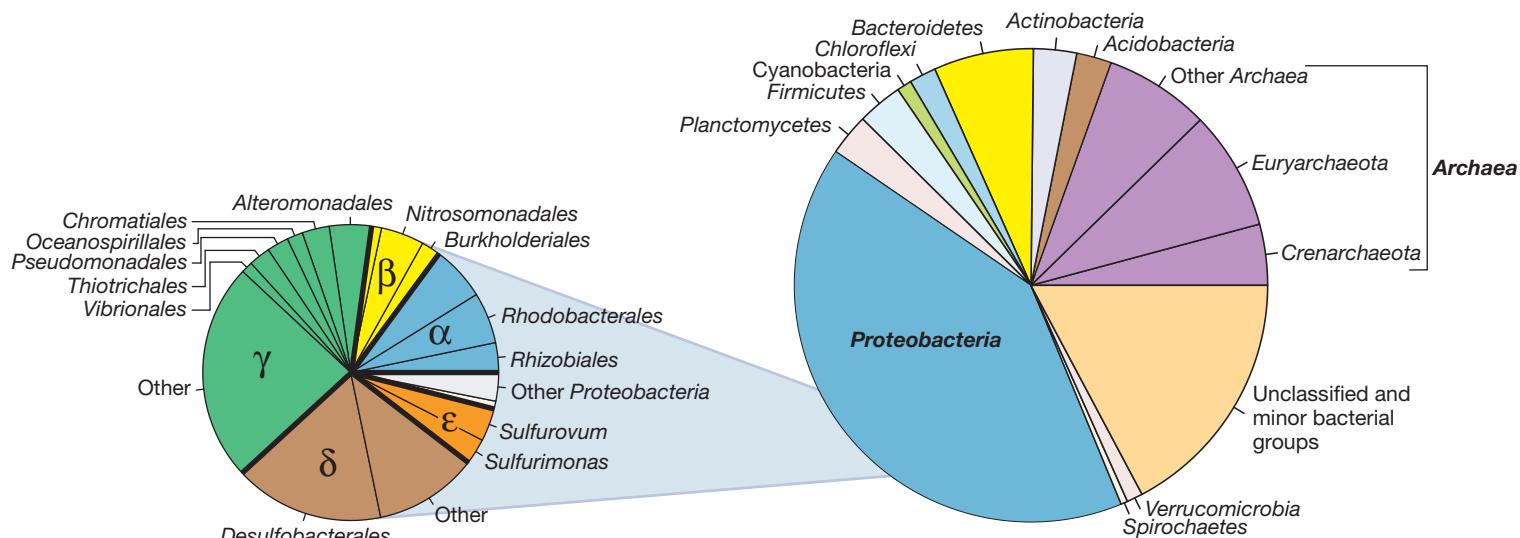

Figure 19.33 Marine sediment prokaryotic diversity. The results are pooled analyses of 13,360 16S ribosomal RNA gene sequences from several studies of shallow and deep marine sediments. Many of the groups indicated are covered in Chapters 14 and 15 (Bacteria) or 16 (Archaea). For *Proteobacteria*, major subgroups are indicated. common (Figure 19.33); sulfate reduction is the major form of anaerobic respiration in marine sediments (Sections 13.18 and 14.9). *Bacteroidetes* and the unclassified/minor groups are also well represented in shallow marine sediments.

Although major players in marine waters, cyanobacteria make up just a tiny proportion of the total cell population in the permanently dark and anoxic sediments and probably represent cells that have reached the sediments after attaching to a particle or dead animal that eventually sank. How organisms in deep marine sediments survive in the nutrient-depleted depths far below the seafloor is unclear, but it will not be surprising if it turns out they employ many of the strategies we have seen in pelagic prokaryotes, including small cell size and small, compact genomes.

19.13 Hydrothermal Vents

Although we have thus far described the deep sea as a remote, low-temperature, high-pressure environment suitable only for slow-growing piezotolerant and piezophilic microorganisms, there are some amazing exceptions. Thriving animal and microbial communities are found clustered in and around thermal springs in deep-sea waters throughout the world. These hot springs are located at depths from less than 1000 m to greater

than 4000 m from the ocean surface in regions of the seafloor where volcanic magma and hot rock have caused the floor to rift apart at crustal spreading centers (Figure 19.34), or where iron and magnesium minerals associated with ancient rocks react with seawater and generate heat. Seawater seeping into these dynamic cracking regions of the crust reacts with hot rock, resulting in hot springs saturated with inorganic chemicals and dissolved gases. Collectively, these types of underwater hot springs are called **hydrothermal vents**. We discuss several remarkable symbiotic associations between hydrothermal vent-associated animals and microorganisms in Chapter 22. Here we consider the vent environment as a habitat for free-living microorganisms.

Types of Vents

Volcanic hydrothermal systems are typically either warm (~5 to >50°C), diffuse vents or very hot vents that emit hydrothermal fluids at 270 to >400°C. The gently flowing, warm, diffuse fluids are emitted from cracks in the seafloor and the exterior walls of hydrothermal chimneys. The fluids originate from the mixing of cold seawater with hot hydrothermal fluids in subsurface regions of the sediments. Hot vents, called *black smokers*, form upright sulfide edifices called *chimneys* that can be less than 1 m to over 30 m in height. Chimneys form when acidic hydrothermal fluids rich in dissolved metals and magmatic gases are suddenly mixed with cold, oxygenated seawater. The rapid mixing causes fine-grained metal sulfide minerals such as pyrite and sphalerite to precipitate out, forming dark, buoyant plumes that rise above the seafloor (Figure 19.35).

A quite different type of hydrothermal vent environment is the “Lost City” formation located in the mid-Atlantic Ocean. Lost City

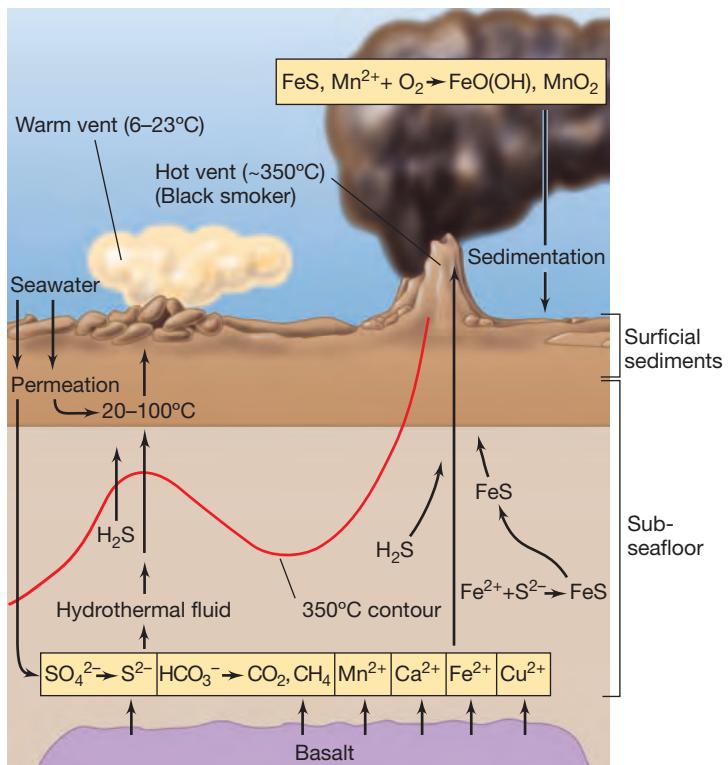

Figure 19.34 Hydrothermal vents. Schematic showing geological formations and major inorganic chemicals and minerals that are emitted from warm vents and black smokers. In warm vents, the hot hydrothermal fluid is cooled by cold 2–3°C seawater permeating the sediments. In black smokers, hot hydrothermal fluid near 350°C reaches the seafloor directly. Surficial is a geological term pertaining to Earth's surface.

is formed from the exposure of minerals associated with ocean crust 1–2 million years old that was once deep beneath the seafloor. Geological faults in these slow-spreading systems exposed magnesium and iron-rich rocks called *peridotites* at the seafloor. Chemical reactions of seawater and newly exposed peridotite are highly exothermic, generating heat and also driving the pH up to as high as pH 11. Extremely high levels of H₂, CH₄, and other low-molecular-weight hydrocarbons are also present in the hot (200°C) hydrothermal fluids. In contrast to the acidic volcanic black smoker systems (Figure 19.34), which are relatively transient, mixing of these alkaline fluids with seawater results in the formation of calcium carbonate (limestone) chimneys that can reach up to 60 m in height and be active for 100,000 years or more (Figure 19.36).

Prokaryotes in Hydrothermal Vents

Bacteria displaying chemolithotrophic metabolisms dominate hydrothermal vent microbial ecosystems. Sulfidic vents support sulfur bacteria, whereas vents that emit other inorganic electron donors support nitrifying, hydrogen-oxidizing, iron- and manganese-oxidizing, or methylotrophic bacteria, the latter presumably growing on the CH₄ and carbon monoxide (CO) emitted from the vents. Table 19.2 summarizes the inorganic electron donors and electron acceptors that are thought to play a role in chemolithotrophic metabolisms at hydrothermal vents. All of these metabolisms were discussed in Chapter 13.

Although prokaryotes cannot survive in the superheated hydrothermal fluids of black smokers, thermophilic and hyperthermophilic organisms do thrive in the gradients that form as the superheated water mixes with cold seawater. For example, the walls of smoker chimneys are teeming with hyperthermophiles such as *Methanopyrus*, a species of *Archaea* that oxidizes H₂ and makes CH₄ (Section 16.4). Phylogenetic FISH staining (Section 18.4) has detected cells of both *Bacteria* and *Archaea* in smoker chimney walls (Figure 19.37). The most thermophilic of all known sulfur-reducing prokaryotes, species of *Pyrolobus* and *Pyrodictium* (Chapter 16), were isolated from black smoker chimney walls. In contrast to the significant microbial diversity in volcanic vent chimney walls, the carbonate

chimney walls of the Lost City vents are comprised primarily of methanogens of the genus *Methanosarcina*. These organisms are presumably nourished by the H₂-rich fluids that permeate the porous chimney walls.

When smokers plug up from mineral debris, hyperthermophiles presumably drift away to colonize active smokers and somehow become integrated into the growing chimney wall. Surprisingly, although they require very high temperatures for growth, hyperthermophiles are remarkably tolerant of cold temperatures and oxygen. Thus, transport of cells from one vent site to another in cold oxic seawater apparently is not a problem.

Many of these groups are covered in Chapters 14 and 15 (*Bacteria*) or 16 (*Archaea*). For *Proteobacteria*, major subgroups are indicated. Note the high proportion of *Archaea* and of *Epsilonproteobacteria*. The physiology of many of these organisms is summarized in Table 19.2. Data assembled and analyzed by Nicolas Pinel.

A Phylogenetic Snapshot of Hydrothermal Vent Prokaryotic Diversity

Using the powerful tools developed for microbial community sampling (☞ Section 18.5), studies of prokaryotic diversity near volcanic hydrothermal vents have revealed an enormous diversity of *Bacteria*. These 16S rRNA gene sequence surveys include both warm and hot vents. Hydrothermal vent microbial communities are dominated by *Proteobacteria*, in particular *Epsilonproteobacteria* (☞ Section 15.5; **Figure 19.38**). *Alpha*-, *Delta*-, and *Gammaproteobacteria* are also abundant, whereas *Betaproteobacteria* are much less so. Many *Epsilon*- and *Gammaproteobacteria* oxidize sulfide and sulfur as electron donors with either O₂ or nitrate (NO₃⁻) as electron acceptors.

As shown in the blowup diagram of *Proteobacteria* in Figure 19.38, vent *Epsilonproteobacteria* phylotypes most closely match those of chemolithotrophic sulfur bacteria such as *Sulfurimonas*, *Arcobacter*, *Sulfurovum*, and *Sulfurospirillum*. These bacteria oxidize reduced sulfur compounds as electron donors (☞ Sections 13.8 and 14.11), and such a physiology is consistent with their presence near vent fluids charged with sulfur and sulfide. In addition, most *Deltaproteobacteria* specialize in

anaerobic metabolisms using oxidized sulfur compounds as electron acceptors.

In contrast to *Bacteria*, the diversity of volcanic hydrothermal vent *Archaea* is quite limited. Estimates of the number of unique phylotypes indicate that the diversity of *Bacteria* near hydrothermal vents is about 10 times that of *Archaea*. However, *Archaea* are prevalent in samples recovered from the walls of hot vent chimneys (Figure 19.37). Most of the *Archaea* detected near hydrothermal vents are either methanogens (☞ Section 16.2) or species of marine *Crenarchaeota* and *Euryarchaeota* (☞ Figure 16.1). With the exception of the ammonia-oxidizing thaumarchaeote *Nitrosopumilus* (☞ Section 16.6), organisms in these groups remain uncultured and their physiologies poorly understood.

MINIQUIZ

- Which phylum of *Bacteria* and which subgroups of this phylum dominate hydrothermal vent ecosystems, and why?

BIG IDEAS

19.1 • Ecosystems consist of organisms, their environments, and all of the interactions among the organisms and environments. The organisms are members of populations and communities and are adapted to habitats. Species richness and abundance are aspects of species diversity in a community and an ecosystem.

19.2 • Microbial communities consist of guilds of metabolically similar organisms. Microorganisms play major roles in energy transformations and biogeochemical processes that result in the recycling of elements essential to living systems.

19.3 • The niche for a microorganism consists of the specific assortment of biotic and abiotic factors within a microenvironment in which that microorganism can be competitive. Microorganisms in nature often live a feast-or-famine existence such that only the best-adapted species reach high population density in a given niche. Cooperation among microorganisms is also important in many microbial interrelationships.

19.4 • When surfaces are available, bacteria grow in attached masses of cells called biofilms. Biofilm formation involves both intra- as well as intercellular communication and confers several protective advantages on cells. Biofilms can have

significant medical and economic impacts on humans when unwanted biofilms develop on inert as well as living surfaces.

19.5 • Microbial mats are extremely thick biofilms consisting of microbial cells and trapped particulate materials. Microbial mats are widespread in hypersaline or thermal waters where grazing animals are prevented from feeding on the mat cells.

19.6 • Soils are complex microbial habitats with numerous microenvironments and niches. Microorganisms are present in the soil primarily attached to soil particles. The most important factors influencing microbial activity in soil are the availability of water and nutrients. However, in very arid soils microorganisms play important roles in stabilizing soil structure.

19.7 • The deep subsurface is a significant microbial habitat, most likely sustaining chemolithotrophic populations that can live on a diet of a few minerals, CO₂, SO₄²⁻, N₂, and H₂. Hydrogen is thought to be continually produced by interaction of water with iron minerals or by the radiolysis of water.

19.8 • In freshwater aquatic ecosystems, phototrophic microorganisms are the main primary producers.

Most of the organic matter produced is consumed by bacteria, which can lead to depletion of oxygen in the environment. The BOD of a body of water indicates its relative content of organic matter that can be biologically oxidized.

19.9 • Pelagic marine waters are more nutrient deficient than most freshwaters, yet substantial numbers of prokaryotes inhabit the oceans. However, in some highly productive and expansive oceanic regions, oxygen can be drawn down to low levels at depths between 100 and 1000 m called oxygen minimum zones.

19.10 • The major microbial oxygenic phototrophs in the open oceans include the prokaryote *Prochlorococcus* and eukaryote *Ostreococcus*; both of these phototrophs are small microorganisms. Marine anoxygenic phototrophs include *Roseobacter* and its relatives, the aerobic phototrophic purple bacteria.

19.11 • Species of *Bacteria* tend to predominate in marine surface waters, whereas in deeper waters *Archaea* comprise a larger fraction of the microbial community. Many pelagic *Bacteria* use light to make ATP by rhodopsin-driven proton pumps. Viruses outnumber prokaryotes by several orders of magnitude in marine waters.

19.12 • The deep sea is a cold, dark habitat where hydrostatic pressure is high and nutrient levels are low. Piezophiles grow best under pressure but do not require pressure, whereas extreme piezophiles require high pressure, typically several hundred atmospheres, for growth.

19.13 • Hydrothermal vents are deep-sea hot springs where either volcanic activity or unusual chemistry generates fluids containing large amounts of inorganic electron donors that can be used by chemolithotrophic bacteria.

Microbial Power Lines

An exciting new area of microbial research surrounds how insoluble electron acceptors such as iron and manganese oxides are reduced in anoxic habitats. Although it is widely believed that electrically conductive structures exist on the bacterial cell surface that deliver electrons to the insoluble electron acceptor, molecular details have remained elusive. However, a recent discovery made with a soluble electron acceptor system may have shed light on this mystery.

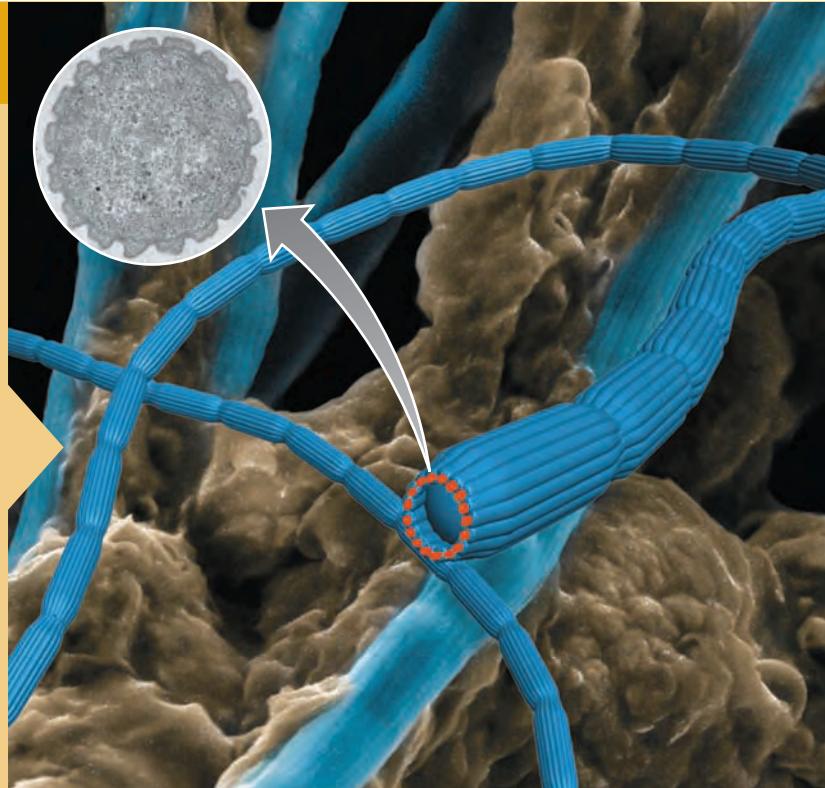

A morphologically distinctive filamentous bacterium related to sulfate-reducing bacteria was found to oxidize hydrogen sulfide (H_2S) in marine sediments using oxygen (O_2) as the electron acceptor.¹ However, the sulfide and oxygen were separated from each other by *more than a centimeter*, leading to the obvious question of how the donor and acceptor reactions were coupled.

Microscopic and microsensor analyses revealed that the filamentous bacteria extended vertically as single filaments connecting the oxic surface and the anoxic sulfide-rich zone. The capacity of the filaments to couple electron transfer over long distances was established by using a very thin wire to slice between the oxic and anoxic zones; this severed the filaments and stopped sulfide oxidation.

This remarkable system of electron transfer was associated with cable-like structures that formed a ring around each filament and extended the entire length of each filament (photos). These are thought to function as “living electrical cables,” coupling the transfer of electrons derived from sulfide oxidized at one end of the filament to the reduction of oxygen at the other end.

The mechanism of this remarkable metabolic feat, and its relationship to systems used by bacteria that reduce metal oxides, remains to be determined. However, it is clear that bacterially mediated electron transfers can occur over rather long distances in order to couple donor and acceptor events.

- I Carbon, Nitrogen, and Sulfur Cycles 632
- II Other Nutrient Cycles 639
- III Humans and Nutrient Cycling 645

In the previous chapter we examined a variety of microbial habitats in order to set the stage for the consideration of some major microbial activities in this chapter. Here we explore the concept of

nutrient cycles and the impact humans are having on those cycles. In particular we focus on the biogeochemical activities of microorganisms and see how these activities interrelate.

I • Carbon, Nitrogen, and Sulfur Cycles

The key nutrients for life are cycled by both microorganisms and macroorganisms, but for any given nutrient, it is microbial activities that dominate. Understanding how microbial nutrient cycles work is important because the cycles and their many feedback loops are essential for plant agriculture and the overall health of sustainable plant life.

We begin our coverage of nutrient cycles with the carbon cycle. Major areas of interest here are the magnitude of carbon reservoirs on Earth, the rates of carbon cycling within and between reservoirs, and the coupling of the carbon cycle to other nutrient cycles. We emphasize the gases *carbon dioxide* (CO_2) and *methane* (CH_4) as major components of the carbon cycle and of human impacts on the global ecosystem.

20.1 The Carbon Cycle

On a global basis, carbon (C) cycles as CO_2 through all of Earth's major carbon reservoirs: the atmosphere, the land, the oceans, freshwaters, sediments and rocks, and biomass (Figure 20.1). As we have already seen for freshwater environments, the carbon and oxygen cycles are intimately linked (see Section 19.8). All nutrient cycles link in some way to the carbon cycle, but the nitrogen (N) cycle links particularly strongly because, other than water (H_2O), C and N make up the bulk of living organisms (see Section 3.1 and see Figure 20.4).

Carbon Reservoirs

By far the largest C reservoir on Earth is the sediments and rocks of Earth's crust (Figure 20.1), but the rate at which sediments and rocks decompose and carbon is removed as CO_2 is so slow that flux out of this reservoir is insignificant on a human time scale. A large amount of C is found in land plants. This is the organic C of forests, grasslands, and agricultural crops—the major sites of phototrophic CO_2 fixation. However, more C is present in dead organic material, called **humus**, than in living organisms. Humus is a complex mixture of organic materials that have resisted rapid decomposition and is derived primarily from dead plants and microorganisms. Some humic substances are quite recalcitrant, with a decomposition time of several decades, but certain other humic components decompose much more rapidly.

The most rapid means of transfer of C is via the atmosphere. Carbon dioxide is removed from the atmosphere primarily by photosynthesis of land plants and marine microorganisms and is returned to the atmosphere by respiration of animals and chemotrophic microorganisms (Figure 20.1). The single most important contribution of CO_2 to the atmosphere is by microbial decomposition of dead organic material. However, since the Industrial Revolution, human activities have increased atmospheric CO_2 levels by nearly 40%, primarily from the combustion of fossil fuels. This rise in CO_2 , a major *greenhouse gas*, has triggered a period of steadily increasing global temperatures called

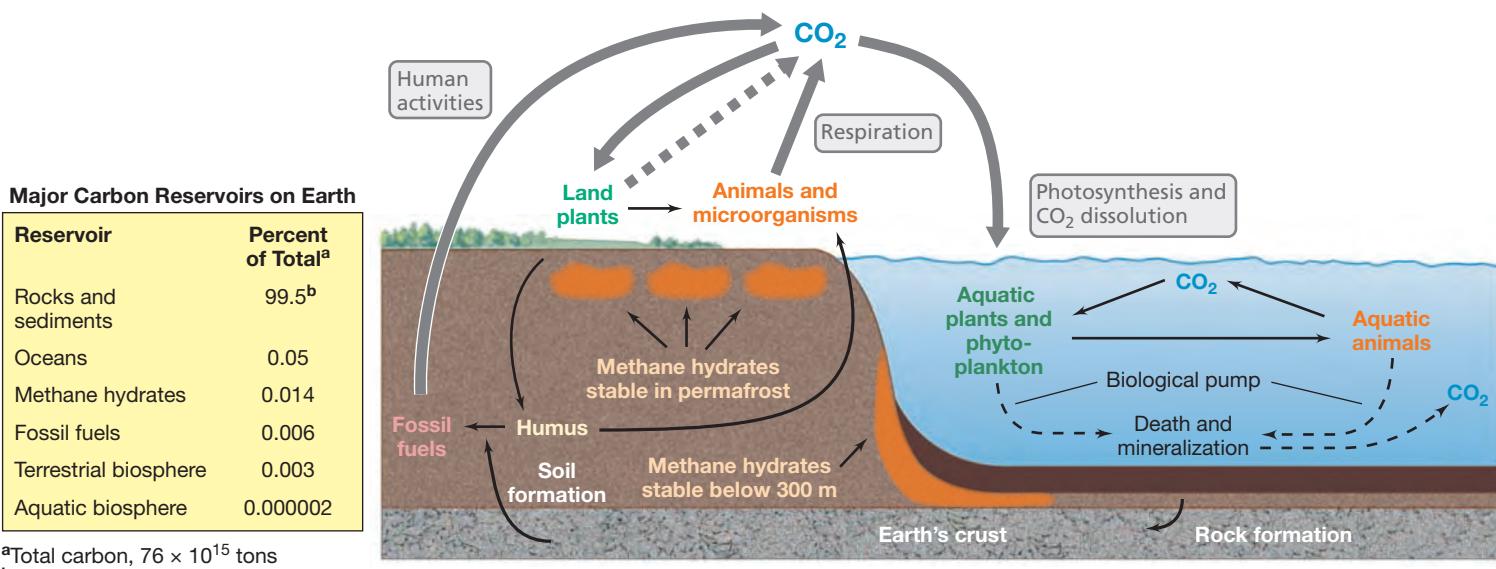

Figure 20.1 The carbon cycle. The carbon and oxygen cycles are closely connected, as oxygenic photosynthesis both removes CO_2 and produces O_2 , and respiration both produces CO_2 and removes O_2 . As the accompanying table shows, by far the greatest reservoir of carbon on Earth is in rocks and sediments, and most of this is in inorganic form as carbonates.

global warming (see Figure 20.18). Although the consequences of global warming on microbial nutrient cycling are currently unpredictable, everything we know about the biology of microorganisms tells us that microbial activities in nature will change in response to higher temperatures. Whether these responses will be favorable or unfavorable to higher organisms including people is today a major area of active research (Section 20.8).

Photosynthesis and Decomposition

New organic compounds are biologically synthesized on Earth only by CO₂ fixation by phototrophs and chemolithotrophs. Most organic compounds originate in photosynthesis and thus phototrophic organisms are the foundation of the carbon cycle (Figure 20.1). However, phototrophic organisms are abundant in nature only in habitats where light is available. The deep sea, deep terrestrial subsurface, and other permanently dark habitats are devoid of indigenous phototrophs. There are two groups of oxygenic phototrophic organisms: *plants* and *microorganisms*. Plants are the dominant phototrophic organisms of terrestrial environments, whereas phototrophic microorganisms dominate in aquatic environments.

The redox cycle for C (Figure 20.2) begins with photosynthetic CO₂ fixation, driven by the energy of light:

CH₂O represents organic matter at the oxidation–reduction level of cell material. Phototrophic organisms also carry out respiration,

both in the light and the dark. The overall equation for respiration is the reverse of oxygenic photosynthesis:

For organic compounds to accumulate, the rate of photosynthesis must exceed the rate of respiration. In this way, autotrophic organisms build biomass from CO₂, and then this biomass in one way or another supplies the C heterotrophic organisms need. Anoxygenic phototrophs and chemolithotrophs also produce excess organic compounds, but in most environments the contributions of these organisms to the accumulation of organic matter are minor compared to the inputs of oxygenic phototrophs. This is because the reductant used by oxygenic phototrophs, H₂O, is in virtually unlimited supply.

Organic compounds are degraded biologically to CH₄ and CO₂ (Figure 20.2). Carbon dioxide, most of which is of microbial origin, is produced by aerobic and anaerobic respirations (► Section 13.16). Methane is produced in anoxic environments by *methanogens* from the reduction of CO₂ with hydrogen (H₂) or from the splitting of acetate into CH₄ and CO₂. However, any naturally occurring organic compound can eventually be converted to CH₄ from the cooperative activities of methanogens and various fermentative bacteria, as we will see in the next section. Methane produced in anoxic habitats is insoluble and diffuses to oxic environments, where it is either released to the atmosphere or oxidized to CO₂ by *methanotrophs* (Figure 20.2). Hence, most of the C in organic compounds eventually returns to CO₂, and the links in the carbon cycle are closed.

Methane Hydrates

Although present in the atmosphere at levels lower than even CO₂, CH₄ is a potent greenhouse gas that is over 20 times more effective in trapping heat than is CO₂. Some CH₄ enters the atmosphere from methanogenic production, but not all biologically produced CH₄ is immediately consumed or released to the atmosphere. Huge amounts of CH₄ derived primarily from microbial activities are trapped underground or under marine sediments as *methane hydrates*, molecules of frozen CH₄. Methane hydrates form when sufficient CH₄ is present in environments of high pressure and low temperature such as beneath the permafrost in the Arctic and in marine sediments (Figure 20.1). These deposits can be up to several hundred meters thick and are estimated to contain 700–10,000 petagrams (1 petagram = 10¹⁵ g) of CH₄. This exceeds other known CH₄ reserves on Earth by several orders of magnitude.

Methane hydrates are highly dynamic, absorbing and releasing CH₄ in response to changes in pressure, temperature (Figure 20.3), and fluid movement. Methane hydrates also fuel deep-water ecosystems, called *cold seeps*. Here, the slow release of CH₄ from seafloor hydrates nourishes not only anaerobic methane-oxidizing *Archaea* (► Section 13.24), but also animal communities that contain aerobic methane-oxidizing endosymbionts that oxidize CH₄ and release organic matter to the animals (► Section 22.12). Anaerobic oxidation of CH₄ is coupled to the reduction of sulfate (SO₄²⁻), nitrate (NO₃⁻), and oxides of iron and manganese [e.g., FeO(OH)], and climate scientists now fear that global warming could catalyze a catastrophic release of CH₄ from methane hydrates, an event that would rapidly affect Earth's climate.

Figure 20.3 Burning methane hydrate. Frozen methane ice retrieved from marine sediments is ignited.

In fact, the sudden release of large amounts of CH_4 from methane hydrates may have triggered the Permian–Triassic extinctions some 250 million years ago. These extinctions, the worst in Earth’s history, wiped out virtually all marine animals and over 70% of all terrestrial plant and animal species. In addition to the release of methane hydrates, as permafrost melts, its huge reserve of organic matter could trigger the formation of additional methane (see *Archaea* and Global Warming, page 517).

Carbon Balances and Coupled Cycles

Although it is convenient to consider carbon cycling as a series of reactions separate from those in other nutrient cycles, awareness of how the various nutrient cycles feed back upon one another and are interconnected is extremely important. In reality, all nutrient cycles are *coupled cycles*; major changes in one cycle affect the functioning of others. But certain cycles, such as the carbon and nitrogen cycles (Figure 20.4), are very closely coupled and experience severe human impacts with untoward consequences for health of the planet (see Section 20.8). The rate of primary productivity (CO_2 fixation) is controlled by several factors, in particular by the magnitude of photosynthetic biomass and by available N, often a limiting nutrient. Thus, large-scale reductions in biomass, for instance by widespread deforestation, reduce rates of primary productivity and increase levels of CO_2 . High levels of organic C stimulate nitrogen fixation ($\text{N}_2 \rightarrow \text{NH}_3$) and this in turn adds more fixed N to the pool for primary producers; low levels of organic C have just the opposite effect (Figure 20.4). High levels of ammonia (NH_3) stimulate primary production and nitrification, but inhibit nitrogen fixation. High levels of nitrate (NO_3^-), an excellent N source for plants and aquatic phototrophs, stimulate primary production but also increase the rate of denitrification; the latter removes fixed forms of N from the environment and feeds back in a negative way on primary production (Figure 20.4).

This simple example illustrates how nutrient cycles are anything but isolated entities; they are coupled systems that maintain a delicate balance of inputs and outputs. Thus, one could expect these cycles to respond to large inputs in specific links (for example,

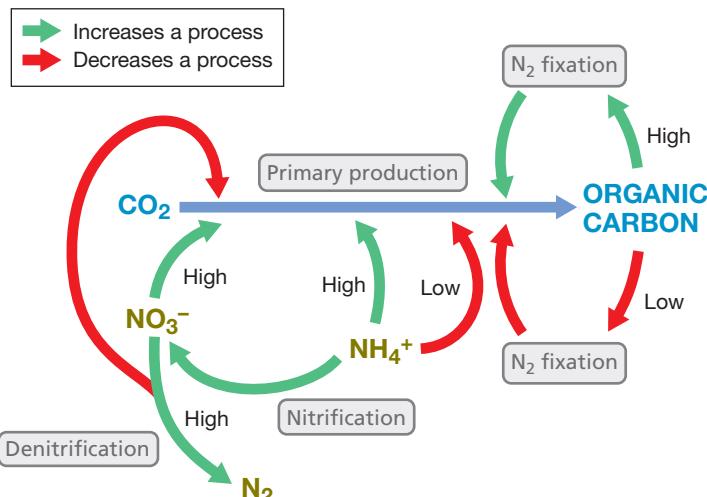

Figure 20.4 Coupled cycles. All nutrient cycles are interconnected, but the carbon and nitrogen cycles are intimately coupled. In the carbon cycle, CO_2 supplies the C for carbon compounds. The N cycle, shown in more detail in Figure 20.7, supplies N for many of the compounds.

through inputs of CO_2 or nitrogen fertilizers) in ways that are not always beneficial to the biosphere (Section 20.8). This is particularly true of the C and N cycles because next to H_2O , C and N are the most abundant elements in living organisms and their cycles interact with each other in such major ways.

20.2 Syntrophy and Methanogenesis

Most organic compounds are oxidized in nature by *aerobic* microbial processes. However, because oxygen (O_2) is a poorly soluble gas and is actively consumed when available, much organic carbon still ends up in anoxic environments. Methanogenesis, the biological production of CH_4 , is a major process in anoxic habitats and is catalyzed by a large group of *Archaea*, the *methanogens*, which are strict anaerobes. We discussed the biochemistry of methanogenesis in Section 13.20 and other aspects of methanogens in Section 16.2.

Most methanogens can use CO_2 as a terminal electron acceptor in anaerobic respiration, reducing it to CH_4 with H_2 as electron donor. Only a very few other substrates, chiefly acetate, are directly converted to CH_4 by methanogens. To convert most organic compounds to CH_4 , methanogens must team up with partner organisms called *syntrophs* that function to supply them with precursors for methanogenesis.

Anoxic Decomposition and Syntrophy

In Section 13.15 we discussed the biochemistry of *syntrophy*, a process in which two or more organisms cooperate in the anaerobic degradation of organic compounds. Here we consider the

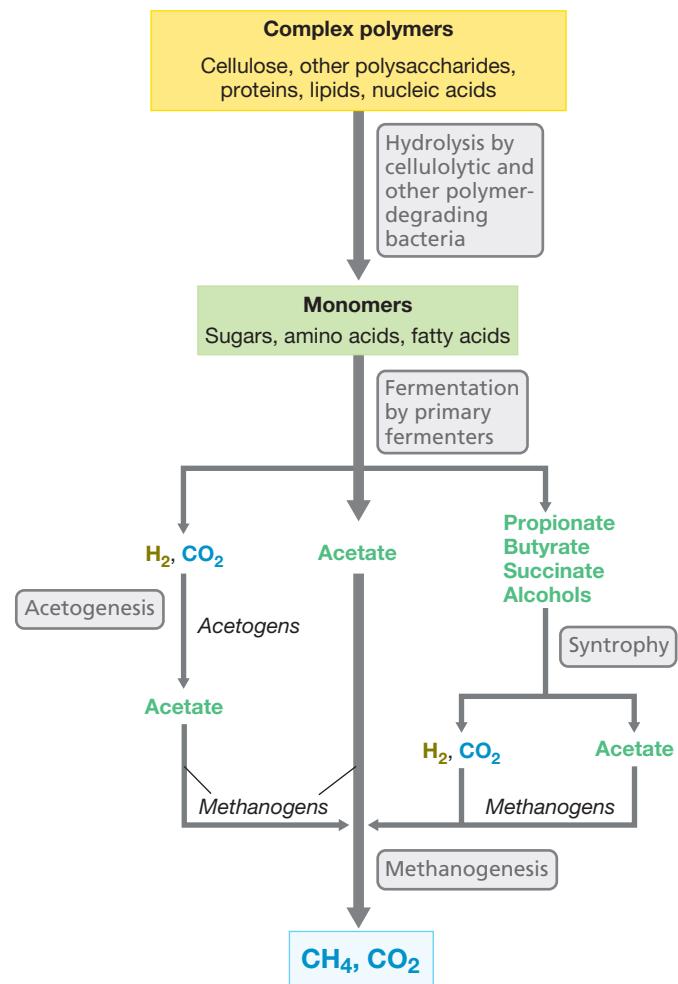

Figure 20.5 Anoxic decomposition. In anoxic decomposition various groups of fermentative anaerobes cooperate in the conversion of complex organic materials to CH₄ and CO₂. This pattern holds for environments in which sulfate-reducing bacteria play only a minor role; for example, in freshwater lake sediments, sewage sludge bioreactors, or the rumen.

interactions of syntrophic bacteria with their partner organisms and their significance for the carbon cycle. Our focus will be anoxic freshwater sediments and anoxic wastewater treatment, both of which are major sources of CH₄.

Polysaccharides, proteins, lipids, and nucleic acids from dead organisms find their way into anoxic habitats, where they are catabolized. The monomers released by hydrolysis of these polymers become major electron donors for energy metabolism. For the breakdown of a typical polysaccharide such as cellulose, the process begins with *cellulolytic* bacteria (Figure 20.5). These organisms hydrolyze cellulose into glucose, which is catabolized by fermentative organisms to short-chain fatty acids (acetate, propionate, and butyrate), alcohols such as ethanol and butanol, and the gases H₂ and CO₂. Hydrogen (H₂) and acetate are consumed by methanogens directly, but the bulk of the carbon remains in the form of fatty acids and alcohols; these cannot be directly catabolized by methanogens and require the activities of syntrophic bacteria (Section 13.15; Figure 20.5).

Syntrophic bacteria are *secondary* fermenters because they ferment the products of the primary fermenters, yielding H₂, CO₂, and acetate as products. For example, *Syntrophomonas wolfei* oxidizes C₄ to C₈ fatty acids, yielding acetate, CO₂ (if the fatty acid was C₅ or C₇), and H₂ (Table 20.1 and Figure 20.5). Other species of *Syntrophomonas* use fatty acids up to C₁₈ in length, including some unsaturated fatty acids. *Syntrophobacter wolinii* specializes in propionate (C₃) fermentation, generating acetate, CO₂, and H₂, and *Syntrophus gentianae* degrades aromatic compounds such as benzoate to acetate, H₂, and CO₂ (Table 20.1). Despite rather extensive metabolic diversity, syntrophs are unable to carry out any of these reactions in pure culture. Instead, they depend on a H₂-consuming partner organism because of the unusual bioenergetics linked to the syntrophic process.

As described in Section 13.15, H₂ consumption by a partner organism is absolutely essential for growth of syntrophic bacteria (in the absence of other electron acceptors), and the association of H₂ producer and H₂ consumer can be very intimate. In fact, it

is thought that H₂ transfer in some syntrophic associations may be through *direct conduction*, where electrons are transferred between species using electrically conductive wirelike structures (see Explore the Microbial World later in this chapter). But no matter how the transfer occurs, it is the transfer of H₂ itself that makes the syntrophic association work. How is this so?

When the reactions listed in Table 20.1 for the fermentation of butyrate, propionate, ethanol, or benzoate are written with all reactants at standard conditions (sugars, 1 M; gases, 1 atm, 25°C), the reactions yield free-energy changes (ΔG° , [Section 3.4](#)) that are positive in arithmetic sign; that is, the reactions *require* rather than *release* energy. But the consumption of H₂ dramatically affects the energetics, making the reaction favorable and allowing energy to be conserved. This can be seen in Table 20.1, where the ΔG values (free-energy change measured under actual conditions in the habitat) are negative in arithmetic sign if H₂ concentrations are kept near zero by a H₂-consuming partner organism. This allows the syntrophic bacterium to conserve a small amount of energy that is used to produce ATP.

The final products of the syntrophic partnership are CO₂ and CH₄ (Figure 20.5), and any naturally occurring organic compound that enters a methanogenic habitat will eventually be converted to these products. This includes even complex aromatic and aliphatic hydrocarbons. Additional organisms other than those shown in Figure 20.5 may participate in such degradations, but eventually fatty acids and alcohols will be generated and they will be converted to methanogenic substrates by syntrophs. Acetate produced by syntrophs (as well as by the activities of acetogenic bacteria, [Section 13.19](#)) is a direct methanogenic substrate and is converted to CO₂ and CH₄ by various methanogens.

Methanogenic Symbionts and Acetogens in Termites

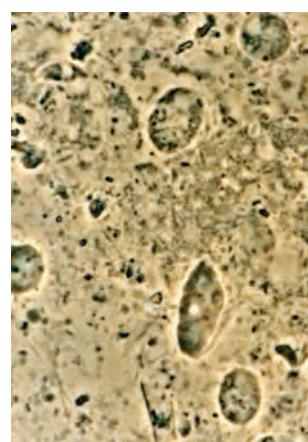

A variety of anaerobic protists that thrive under strictly anoxic conditions, including ciliates and flagellates, play a major role in the carbon cycle. Methanogenic *Archaea* live within some of these protist cells as H₂-consuming endosymbionts. For example, methanogens are present *within* cells of trichomonal protists inhabiting the termite hindgut (Figure 20.6) where methanogenesis and acetogenesis are major metabolic processes. Methanogenic symbionts of protists are species of the genera *Methanobacterium* or *Methanobrevibacter* ([Section 16.2](#)).

In the termite hindgut, endosymbiotic methanogens along with acetogenic bacteria are thought to benefit their protist hosts by consuming H₂ generated from glucose fermentation by cellulolytic protists. The acetogens are not endosymbionts but instead reside in the termite hindgut itself, consuming H₂ from primary fermenters and reducing CO₂ to make acetate. Unlike methanogens, acetogens can ferment glucose directly to acetate. Acetogens can also ferment methoxylated aromatic compounds to acetate. This is especially important in the termite hindgut because termites live on wood, which contains lignin, a complex polymer of methoxylated aromatic compounds. The acetate produced by acetogens in the termite hindgut is consumed by the insect as its primary energy source. Microbial symbioses in the termite hindgut are discussed in more detail in Section 22.10.

20.3 The Nitrogen Cycle

Nitrogen is an essential element for life ([Section 3.1](#)) and exists in a number of oxidation states. We have discussed four major microbial N transformations thus far: nitrification, denitrification, anammox, and nitrogen fixation (Chapter 13). These and other key N transformations are summarized in the redox cycle shown in Figure 20.7.

Nitrogen Fixation and Denitrification

Nitrogen gas (N₂) is the most stable form of N and is a major reservoir for N on Earth. However, only a relatively small number of prokaryotes are able to use N₂ as a cellular N source by the process of *nitrogen fixation* (N₂ + 8H⁺ → 2NH₃ + H₂) ([Section 3.17](#)). The N recycled on Earth is mostly already “fixed N”; that is, N in

combination with other elements, such as in ammonia (NH_3) or nitrate (NO_3^-). In many environments, however, the short supply of fixed N puts a premium on biological nitrogen fixation, and in these habitats, nitrogen-fixing bacteria flourish.

We discussed the role of NO_3^- as an alternative electron acceptor in anaerobic respiration in Section 13.17. Under most conditions, the end product of NO_3^- reduction is N_2 , nitric oxide (NO), or nitrous oxide (N_2O). The reduction of NO_3^- to these gaseous N compounds, called **denitrification** (Figure 20.7), is the main means by which N_2 and N_2O are formed biologically. On the one hand, denitrification is a detrimental process. For example, if agricultural fields fertilized with NO_3^- fertilizer become waterlogged following heavy rains, anoxic conditions can develop and denitrification can be extensive; this removes fixed N from the soil. On the other hand, denitrification can aid in wastewater treatment (Sections 21.6 and 21.7). By converting NO_3^- to volatile forms of N, denitrification minimizes fixed N and thus algal growth when the treated sewage is discharged into lakes and streams.

The production of N_2O and NO by denitrification can have other environmental consequences. Nitrous oxide can be photochemically oxidized to NO in the atmosphere. Nitric oxide reacts with ozone (O_3) in the upper atmosphere to form nitrite (NO_2^-), and this returns to Earth as nitric acid (HNO_3). In addition, N_2O is a very potent greenhouse gas. Although N_2O molecules persist on average only about 100 years because of their reactivity, on a per weight basis, the contribution of N_2O to warming is about 300 times that of CO_2 . Thus, denitrification contributes to global warming; to O_3 destruction, which increases passage of ultraviolet radiation to the surface of Earth; and to acid rain, which increases acidity of soils. Increases in soil acidity can change microbial community

structure and function and, ultimately, soil fertility, impacting both plant diversity and agricultural yields of crop plants.

Ammonification and Ammonia Fluxes

Ammonia is released during the decomposition of organic N compounds such as amino acids and nucleotides, a process called **ammonification** (Figure 20.7). Another process contributing to the generation of NH_3 is the respiratory reduction of NO_3^- to NH_3 , called **dissimilative reduction of nitrate to ammonia** (DRNA, Figure 20.7). DRNA dominates NO_3^- and nitrite (NO_2^-) reduction in reductant-rich anoxic environments, such as highly organic marine sediments and the human gastrointestinal tract. It is thought that nitrate-reducing bacteria exploit this pathway primarily when NO_3^- is limiting because DRNA consumes eight electrons compared with the four and five electrons consumed when NO_3^- is reduced to N_2O or N_2 , respectively.

At neutral pH, NH_3 exists as ammonium (NH_4^+). Much of the NH_4^+ released by aerobic decomposition in soils is rapidly recycled and converted to amino acids in plants and microorganisms. However, because NH_3 is volatile, some of it can be lost from alkaline soils by vaporization, and there are major losses of NH_3 to the atmosphere in areas with dense animal populations (for example, cattle feedlots). On a global basis, however, NH_3 constitutes only about 15% of the N released to the atmosphere, the rest being primarily N_2 or N_2O from denitrification.

Nitrification and Anammox

Nitrification, the oxidation of NH_3 to NO_3^- , is a major process in well-drained oxic soils at neutral pH, and is carried out by the nitrifying prokaryotes (Figure 20.7). Whereas denitrification *consumes* NO_3^- ,

nitrification produces NO_3^- . If materials high in NH_3 , such as manure or sewage, are added to soils, the rate of nitrification increases.

Nitrification is a two-step process in which some species oxidize NH_3 to NO_2^- and then other species oxidize NO_2^- to NO_3^- . Many species of both *Bacteria* and *Archaea* can oxidize NH_3 (➡ Sections 13.10, 14.13, 16.6), whereas thus far, only species of *Bacteria* are known that oxidize NO_2^- . Archaeal nitrifiers generally greatly outnumber their bacterial counterparts in marine and terrestrial systems and likely control rates of NH_3 oxidation in nature.

Although NO_3^- is readily assimilated by plants, it is very soluble, and therefore rapidly leached or denitrified from waterlogged soils; consequently, nitrification is not beneficial for plant agriculture. Ammonium, on the other hand, is positively charged and strongly adsorbed to negatively charged soils. Anhydrous NH_3 is therefore used extensively as an agricultural fertilizer, but to prevent its conversion to NO_3^- , chemicals are added to the NH_3 to inhibit nitrification. One common inhibitor is a pyridine compound called *nitrapyrin* (2-chloro-6-trichloromethylpyridine). Nitrapyrin specifically inhibits the first step in nitrification, the oxidation of NH_3 to NO_2^- . However, this effectively inhibits both steps in nitrification because the second step, $\text{NO}_2^- \rightarrow \text{NO}_3^-$, depends on the first (➡ Section 13.10). The addition of nitrapyrin to anhydrous NH_3 has greatly increased the efficiency of crop fertilization and has helped prevent pollution of waterways by NO_3^- leached from nitrified soils.

Ammonia can be oxidized under anoxic conditions by the bacterium *Brocadia* in the process called *anammox*. In this reaction, NH_3 is oxidized anaerobically with NO_2^- as the electron acceptor, forming N_2 as the final product (Figure 20.7), which is released to the atmosphere. Although a major process in sewage and in anoxic marine basins and sediments, anammox is not significant in well-drained (oxic) soils. The microbiology and biochemistry of anammox was discussed in Section 13.10.

20.4 The Sulfur Cycle

Microbial transformations of sulfur (S) are even more complex than those of N because of the large number of oxidation states of S and the fact that several transformations of S also occur spontaneously (abiotically). Chemolithotrophic S oxidation and sulfate (SO_4^{2-}) reduction were covered in Sections 13.8, 13.18, 14.9, and 14.11. The redox cycle for microbial S transformations is shown in Figure 20.8.

Although a number of oxidation states of S are possible, only three are significant in nature, -2 (sulfhydryl, $\text{R}-\text{SH}$, and sulfide, HS^-), 0 (elemental sulfur, S^0), and +6 (sulfate, SO_4^{2-}). The bulk of Earth's S is in sediments and rocks in the form of sulfate minerals, primarily gypsum (CaSO_4) and sulfide minerals (pyrite, FeS_2), but the oceans constitute the most significant reservoir of SO_4^{2-} in the biosphere. A significant amount of S, in particular sulfur dioxide (SO_2 , a gas), enters the S cycle from human activities, primarily the burning of fossil fuels.

Hydrogen Sulfide and Sulfate Reduction

A major volatile S gas is hydrogen sulfide (H_2S). Hydrogen sulfide is produced from bacterial sulfate reduction ($\text{SO}_4^{2-} + 4\text{H}_2$

$\text{H}_2\text{S} + 2\text{H}_2\text{O} + 2\text{OH}^-$) (Figure 20.8) or is emitted from sulfide springs and volcanoes. Although H_2S is volatile, different forms

exist depending on pH: H_2S predominates below pH 7 and the nonvolatile HS^- and S^{2-} predominate above pH 7. Collectively, H_2S , HS^- , and S^{2-} are referred to as “sulfide.”

Sulfate-reducing bacteria are a large and highly diverse group (Sections 13.18 and 14.9) and are widespread in nature. However, in anoxic habitats such as freshwater sediments and many soils, sulfate reduction is limited by SO_4^{2-} availability. Moreover, because organic electron donors (or H_2 , which is a product of the fermentation of organic compounds) are needed to support sulfate reduction, it only occurs where significant amounts of organic material are present.

In marine sediments, the rate of sulfate reduction is typically carbon-limited and can be greatly increased by an influx of organic matter. This is important because the disposal of sewage or garbage in the oceans or coastal regions can trigger sulfate reduction. Hydrogen sulfide is toxic to many plants and animals and therefore its formation is potentially detrimental (sulfide is toxic because it combines with the iron of cytochromes and blocks respiration). Sulfide is commonly detoxified in nature by combination with iron, forming the insoluble minerals FeS (pyrrhotite) and FeS_2 (pyrite). The black color of sulfidic sediments or sulfate-reducing bacterial cultures is due to these metal sulfide minerals (Figure 14.23g).

Sulfide and Elemental Sulfur Oxidation–Reduction

Under oxic conditions, sulfide rapidly oxidizes spontaneously at neutral pH. Sulfur-oxidizing chemolithotrophic bacteria, most of which are aerobes (Sections 13.8 and 14.11), can catalyze the oxidation of sulfide. However, because of the rather rapid spontaneous reaction, microbial sulfide oxidation is significant only in areas where H_2S emerging from anoxic environments meets air. Where light is available, there can be anoxic oxidation of sulfide, catalyzed by the phototrophic purple and green sulfur bacteria (Sections 13.3, 14.4, and 14.6).

Elemental sulfur is chemically stable but is readily oxidized by sulfur-oxidizing chemolithotrophic bacteria such as *Thiobacillus* and *Acidithiobacillus*. Because S^0 is insoluble, the bacteria that oxidize it must attach to the S^0 crystals to obtain their substrate (Figure 13.21). The oxidation of S^0 forms sulfuric acid (H_2SO_4), and thus S^0 oxidation characteristically lowers the pH in the environment, sometimes drastically. For this reason, S^0 is sometimes added to alkaline soils as an inexpensive and natural way to lower the pH, relying on the ubiquitous sulfur chemolithotrophs to carry out the acidification process.

Elemental sulfur can be reduced as well as oxidized. The reduction of S^0 to sulfide (a form of anaerobic respiration) is a major ecological process of some *Bacteria* and hyperthermophilic *Archaea* (Section 14.10 and Chapter 16). Although sulfate-reducing bacteria can also reduce S^0 , in sulfidic habitats most S^0 is reduced by the physiologically specialized sulfur reducers, organisms that are incapable of SO_4^{2-} reduction (Section 14.10). The habitats of the sulfur reducers are generally those of the sulfate reducers, so from an ecological standpoint, the two groups form a metabolic guild unified by their formation of H_2S .

Organic Sulfur Compounds

In addition to *inorganic* forms of S, several *organic* S compounds are also cycled in nature. Many of these foul-smelling compounds are highly volatile and can thus enter the atmosphere. The most abundant organic S compound in nature is *dimethyl sulfide* ($\text{CH}_3-\text{S}-\text{CH}_3$); it is produced primarily in marine environments as a degradation product of dimethylsulfoniopropionate, a major osmoregulatory solute in marine algae (Section 5.15). This compound can be used as a carbon source and electron donor by microorganisms and is catabolized to $\text{CH}_3-\text{S}-\text{CH}_3$ and acrylate ($\text{CH}_2=\text{CHCOO}^-$). The latter, a derivative of the fatty acid propionate, is used to support growth.

Dimethyl sulfide released to the atmosphere undergoes photochemical oxidation to methanesulfonate (CH_3SO_3^-), SO_2 , and SO_4^{2-} . By contrast, $\text{CH}_3-\text{S}-\text{CH}_3$ produced in anoxic habitats can be microbially transformed in at least three ways: (1) by methanogenesis (yielding CH_4 and H_2S), (2) as an electron donor for photosynthetic CO_2 fixation in phototrophic purple bacteria (yielding dimethyl sulfoxide, DMSO), and (3) as an electron donor in energy metabolism in certain chemoorganotrophs and chemolithotrophs (also yielding DMSO). DMSO can be an electron acceptor for anaerobic respiration (Section 13.21), producing $\text{CH}_3-\text{S}-\text{CH}_3$. Many other organic S compounds affect the global sulfur cycle, including methanethiol (CH_3SH), dimethyl disulfide ($\text{H}_3\text{C}-\text{S}-\text{S}-\text{CH}_3$), and carbon disulfide (CS_2), but on a global basis, $\text{CH}_3-\text{S}-\text{CH}_3$ is the most significant.

II • Other Nutrient Cycles

In this unit we explore the interactions of microorganisms with metals—in particular iron and manganese—and with some nonmetals whose microbial transformations are of major global significance.

20.5 The Iron and Manganese Cycles

Iron (Fe) is one of the most abundant elements in Earth’s crust. On the surface of Earth, Fe exists naturally in two oxidation states, ferrous [Fe^{2+} , also Fe(II)] and ferric [Fe^{3+} , also Fe(III)]. A third oxidation state,

Fe^0 , is abundant in Earth’s core and is also a major product of human activities from the smelting of iron ores to form cast iron.

In nature, iron cycles primarily between the Fe^{2+} and Fe^{3+} forms, and these redox transitions are one-electron oxidations and reductions. Ferric iron is reduced both chemically and as a form of anaerobic respiration, and Fe^{2+} is oxidized both chemically and as a form of chemolithotrophic metabolism (Figure 20.9). Manganese (Mn), although present at 5- to 10-fold lesser abundance than Fe

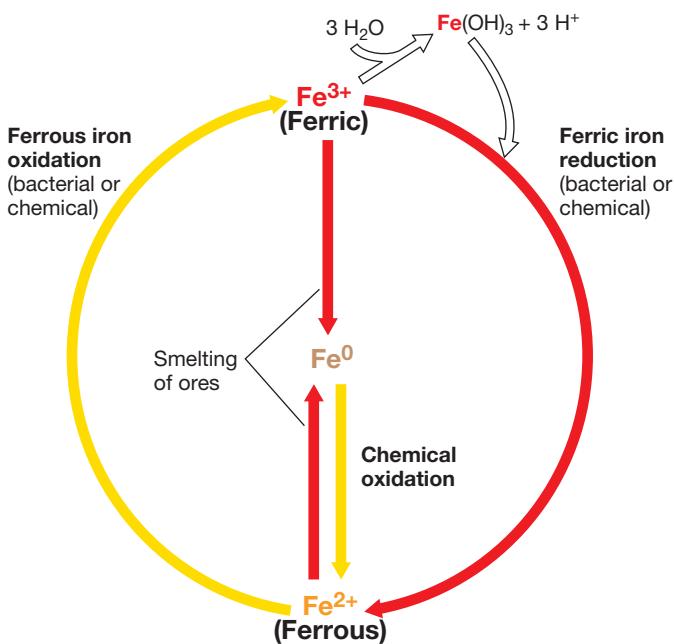

Figure 20.9 Redox cycle for iron. The major forms of iron in nature are Fe^{2+} and Fe^{3+} . Fe^0 is primarily a product of smelting of iron ores. Oxidations are shown by yellow arrows and reductions by red arrows. Fe^{3+} forms various minerals such as ferric hydroxide, Fe(OH)_3 .

in the near surface environment, is another redox-active metal of microbiological significance, existing primarily in two oxidation states (Mn^{2+} and Mn^{4+} , see Figure 20.10).

A key feature of the iron and manganese cycles is the different solubilities of these metals in their oxidized versus reduced forms. Reduced iron (Fe^{2+}) and manganese (Mn^{2+}) are soluble. In contrast, oxidized minerals of iron such as iron oxide-hydroxides [e.g., Fe(OH)_3 , FeOOH , and Fe_2O_3] and manganese oxide (MnO_2) are insoluble and tend to settle out in aquatic environments. As a consequence, these strong oxidants can comprise several percent by weight of marine and freshwater sediments, making them among the most abundant of potential electron acceptors in many anoxic systems (see Figure 20.10).

Bacterial Reduction of Iron and Manganese Oxides

Some *Bacteria* and *Archaea* can use Fe^{3+} as an electron acceptor in anaerobic respiration (Section 13.21). These organisms also commonly have the capacity to use Mn^{4+} as an electron acceptor, and some have the capacity to reduce oxidized uranium (Section 21.3).

Ferric iron and manganese oxide reduction is common in waterlogged soils, bogs, and anoxic lake sediments (Figure 20.10). When soluble reduced iron and manganese reach oxic regions, for example, through diffusion from anoxic regions of sediments, they are oxidized chemically [e.g., $\text{Fe}^{2+} + \frac{1}{4}\text{O}_2 + 2\frac{1}{2}\text{H}_2\text{O} \rightarrow \text{Fe(OH)}_3 + 2\text{H}^+$] or microbiologically (Figure 20.9). The chemical oxidation of Fe^{2+} is very rapid at near-neutral pH. Although the spontaneous oxidation of Mn^{2+} is very slow at neutral pH, the rate of oxidation can be increased up to five orders of magnitude by a variety of manganese-oxidizing bacteria and even fungi. The oxidized metal

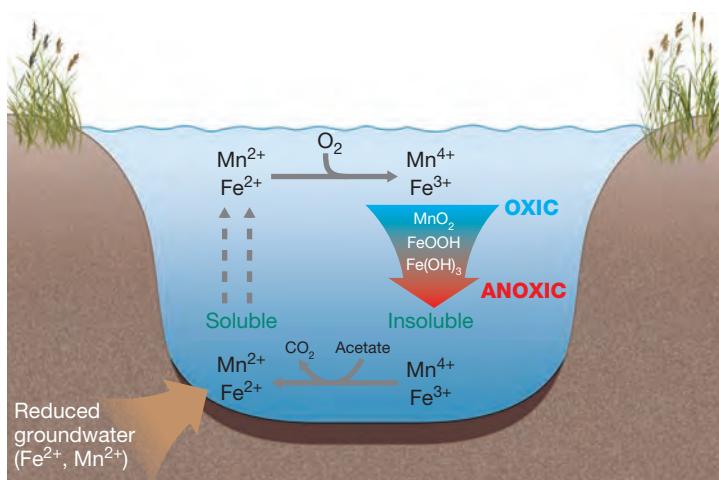

Figure 20.10 Iron and manganese redox cycling in a typical freshwater system. Iron and manganese oxides in sediments are used as electron acceptors by metal-reducing bacteria. The resulting reduced forms are soluble and diffuse into the oxic regions of the sediment or water column, where they are oxidized microbially or chemically. Precipitation of the insoluble oxidized metals then returns the metals to the sediments, completing the redox cycle.

oxides and hydroxides then precipitate, returning the oxidized metals to the sediments where they can again serve as electron acceptors, completing the cycle.

Oxidized iron (Fe^{3+}) and manganese (Mn^{4+}) are chemically very reactive. Phosphate is trapped as insoluble ferric phosphate precipitates. Chemical oxidation of refractory organic compounds by Mn^{4+} oxide may yield more available sources of carbon for microbial growth. Other metals [e.g., copper (Cu), cadmium (Cd), cobalt (Co), lead (Pb), arsenic (As)] form insoluble complexes with the iron and manganese oxides. When these oxides are subsequently reduced, the bound phosphate and metals are also liberated along with the soluble forms of these metals.

In recent years it has been recognized that the surfaces and appendages of cells of bacteria that interact with iron and manganese oxides, such as *Geobacter*, are electrically conductive,

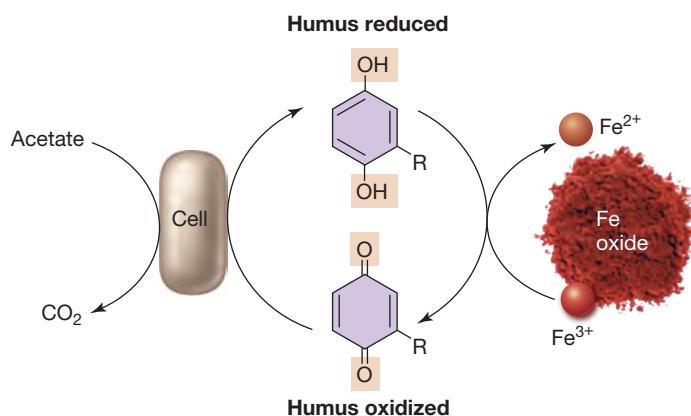

Figure 20.11 Role of humic substances in humus as an electron shuttle in microbial metal reduction. Quinone-like functional groups in humus are reduced by acetate-oxidizing bacteria. The reduced humus then donates electrons to metal oxides, releasing reduced soluble iron (Fe^{2+}) and oxidized humus. The cycle continues as oxidized humus is again reduced by the bacteria.

Regardless of the electron acceptor they use, when bacteria respire, they carry out oxidations and reductions that generate electricity. They do this when they oxidize an organic or inorganic electron donor and separate electrons from protons during electron transport. The electrons eventually reduce some electron acceptor and the protons generate the proton motive force.

In any form of respiration, electron disposal is necessary for energy conservation. When the electron acceptor is oxygen (O_2), nitrate (NO_3^-), or many of the other soluble substances used by bacteria as electron acceptors (Sections 13.16–13.21), the final product diffuses away from the cell. Many bacteria reduce ferric iron (Fe^{3+}) as an electron acceptor under anoxic conditions, including the bacterium *Geobacter sulfurreducens* (Figure 1). However, in contrast to soluble electron acceptors, Fe^{3+} is typically present in nature as an insoluble mineral, such as an iron oxide (Figure 20.11), and thus the reduction of Fe^{3+} occurs outside the cell. Under such conditions, the ferric iron functions as an electrical anode, and the bacterial cell facilitates transfer of electrons from the electron donor to the anode.¹

Research has shown that *Geobacter* forms direct electrical connections with insoluble materials that can either accept or donate electrons. Electron transfer involves cytochromes localized along the length of pili that are generally 10–20 micrometers long (Figure 14.35c). These electrically conductive structures function as electrical nanowires, much as copper wire does in a household electrical circuit. Being conductive structures, nanowires can form direct electrical connections with insoluble materials that either accept or donate electrons, or alternatively, nanowires can form connections between cells. In this way, electrons obtained by *Geobacter* from

the oxidation of organic electron donors or from H_2 can be shuttled to a suitable electron acceptor. Although the cytochromes are required for the ultimate transfer of electrons, for example, to the reduction of the iron oxide electron acceptor, studies of the process suggest that the organic material comprising the pili is itself electrically conductive.

Surprisingly, bacterial electron shuttling can occur over rather large spatial distances, much larger than the cell itself. In studies of hydrogen sulfide (H_2S) oxidation in anoxic marine sediments (sulfide is the product of sulfate-reducing bacteria), the oxidation of H_2S deep in the sediments released electrons that reduced O_2 at the sediment water interface, some 20 cm away (see “Microbial Power Lines” on page 631).² The electrical conductors in the sediment are filamentous bacteria affiliated with the *Desulfobulbaceae* family of sulfate-reducing bacteria (Section 14.9). Although phylogenetically affiliated with *sulfate reducers*, the filamentous bacteria actually function as *sulfide oxidizers*, using O_2 as the terminal electron acceptor.

The surface of the filamentous bacterial cells has ridges running along its entire length. Microscopically these ridges appear much like cables, each microbial filament surrounded by 15–17 structures 400–700 nm in width that run continuously along the length of the filament. These structures are implicated in electron transfer from the sulfide oxidized at one end of the filament to the reduction of O_2 near the sediment surface at the other end of the filament. Although reminiscent of *Geobacter* nanowires, the mechanism for electron transfer over such large distances is unknown.

In nature, electrical communication between bacterial cells may be a major way by which electrons generated from microbial metabolism in anoxic habitats are shuttled to oxic

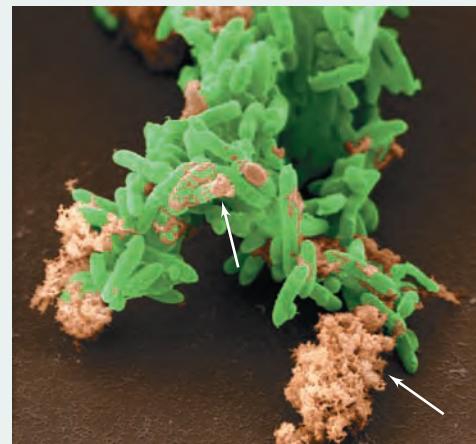

Figure 1 Cells of *Geobacter* attached to ferric iron precipitates (arrows) reduce Fe^{3+} to Fe^{2+} .

regions. Moreover, research on the microbiology of the process indicates that this microbial electricity could be harnessed in the form of microbial “fuel cells” that could oxidize toxic and waste carbon compounds in anoxic environments, with the resulting electrons coupled to power generation. In such a scheme, bacteria would be exploited to function as catalysts for diverting electrons from electron donors directly to artificial anodes, with the resulting electrical current being siphoned off to supply a portion of human power needs.

functioning as “nanowires” to move electrons around in microbial habitats. This movement of electrons is a form of electricity, and the process may eventually have commercial applications for power generation (see Explore the Microbial World, “Microbially Wired”). Humic substances (Section 20.1) can also facilitate microbial metal reduction. Since some constituents of humics can alternate between oxidized and reduced forms, they can function to shuttle electrons from the bacterium to the reduction of the iron or manganese oxides (Figure 20.11).

Microbial Oxidation of Reduced Iron and Manganese

At neutral pH, ferrous iron (Fe^{2+}) is rapidly oxidized abiotically in oxic environments. In contrast, at acidic pH ($pH < 4$) Fe^{2+} is not oxidized spontaneously. Thus, much of the research on microbial oxidation of iron is focused on acidic, iron-rich habitats, where acidophilic chemolithotrophs such as *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* oxidize Fe^{2+} to Fe^{3+} (Figure 20.12).

The oxidation of Fe^{2+} to Fe^{3+} yields a single electron; consequently very little energy can be conserved (Sections 13.9

Ricardo Amils

The mat consists of acidophilic green algae (eukaryotes) and various iron-oxidizing chemolithotrophic prokaryotes. and 14.15) and so these bacteria must oxidize large amounts of Fe^{2+} in order to grow. In such environments, even a relatively small population of cells can precipitate a large amount of iron minerals. Although O_2 is the most environmentally significant electron acceptor, Fe^{2+} oxidation can also be coupled to NO_3^- reduction by some organisms (Sections 13.9 and 14.15) and functions as an electron donor in photosynthesis for some anoxygenic phototrophs (Sections 13.9, 14.2, and 14.5). Even though the oxidation of Mn^{2+} to Mn^{4+} is also potentially energetically favorable for growth, and many microorganisms catalyze Mn^{2+} oxidation, as yet no organism has been conclusively shown to derive energy from the oxidation of reduced manganese.

Since the abiotic oxidation of reduced iron is rapid at near-neutral pH, iron-oxidizing bacteria that inhabit nonacidic environments are restricted to a very narrow redox region in which ferrous iron-rich water impinges on oxygenated water (Figure 20.10). These microoxic habitats include freshwater and coastal sediments, slow-moving streams, ferrous iron-rich waters from springs, and hydrothermal vents (Figure 20.13). For example, when ferrous iron-rich groundwaters are exposed to air, Fe^{2+} is oxidized at the interface of these two zones by iron-oxidizing bacteria such as *Gallionella* and *Leptothrix* (Figure 20.13b, c, d; Sections 13.9 and 14.15). Thus, their physiology dictates that they maintain a position within a narrow environment of low levels of O_2 and high levels of reduced metals. How these organisms secure and maintain a position within such a narrow range of abiotic conditions is not well understood, but the sheath and stalk structures typically found in iron oxidizers may assist their proper positioning (Figure 20.13b, d, f; Figures 14.36 and 14.60).

As we have seen, organisms that reduce insoluble metal oxides can use extracellular conductors for electron transfer, such as electrically conductive pili or cell-surface-associated cytochromes. However, a similar problem exists for organisms that oxidize metals: Insoluble metal oxides are the product of metal oxidation, and the organism

must ensure that these insoluble oxides are deposited external to the cell. Thus, organisms that oxidize Fe^{2+} or Mn^{2+} use surface-associated electron transfer proteins to ensure that metals are oxidized *outside* the cytoplasm. Cytochromes participate in both iron reduction and iron oxidation, and genomes of metal-oxidizing *Gallionella* and *Sideroxydans* species contain genes encoding surface-associated cytochromes (e.g., MtrA) that resemble those encoding proteins known to reduce metal oxides in *Shewanella*, suggesting that mechanistically similar electron transfer pathways are likely used for both the reduction and oxidation of extracellular metals.

Although possibly sharing similar electron transfer mechanisms, metal-oxidizing bacteria are confronted with another problem—their metabolism could soon encase the cell in an iron oxide shell. To prevent this, metal oxidizers produce extracellular organic material that captures metal oxides and deposits it some distance away from the cell. Some metal oxidizers, such as *Gallionella*, produce extended organic stalks that become encrusted with metal oxides away from the cell (Figure 20.13d; see also Figure 14.36). An alternative strategy is used by *Leptothrix* species. These bacteria produce an organic sheath surrounding the cells that becomes encrusted with metal oxides (Figure 20.13b and Figure 14.60). In this case the cells can move out of the sheath, leaving the metal oxide crust behind.

Although not all metal oxidizers produce such morphologically conspicuous structures, it is thought that most if not all metal oxidizers are forced to produce some form of extracellular organic material in order to sequester the insoluble product of their energy metabolism. In addition, the incorporation of this organic matter into the metal oxides likely alters the physical and chemical properties of the minerals themselves.

20.6 The Phosphorus, Calcium, and Silica Cycles

Many other chemical elements undergo microbial cycling and we focus on three key ones here—phosphorus (P), calcium (Ca), and silica (Si). The cycling of these elements is important in aquatic environments, particularly in the oceans, which are major reservoirs of Ca and Si. In the oceans, huge amounts of Ca and Si are incorporated into the exoskeletons of certain microorganisms. However, unlike the C, N, and S cycles, in the P, Ca, and Si cycles there are no redox changes or gaseous forms that can escape and alter Earth's atmospheric chemistry. Nevertheless, as we will see, keeping these cycles in balance—especially that of Ca—is important for maintaining sustainable life on Earth.

Phosphorus

Phosphorus exists in nature primarily as organic and inorganic phosphates. Phosphorus reservoirs include phosphate-containing

minerals in rocks, dissolved phosphates in freshwaters and marine waters, and the nucleic acids and phospholipids of living organisms. Although P has multiple oxidation states, most environmental phosphates are at the +5 oxidation state (for example, inorganic phosphate, HPO_4^{2-}). In nature P cycles through living organisms (as cellular P), waters and soils (as inorganic and organic P), and Earth's crust (as inorganic P). P is typically the limiting nutrient for photosynthesis in freshwaters, which receive it from the weathering of rocks.

In the oceans, a fraction of dissolved P is organic, in the form of phosphate esters and *phosphonates*. Phosphonates are organophosphate compounds that contain a direct bond between the P and C atoms. Phosphonates are produced by certain microorganisms and comprise about a quarter of the organic P pool in nature; however, for many organisms phosphonates are a less available source of P than is HPO_4^{2-} because of the enzymes required to degrade phosphonates. Organisms lacking these enzymes can be phosphorus-limited even when

sufficient P is present as phosphonates. Moreover, the degradation of methylphosphonate ($\text{CH}_3\text{O}_3\text{P}$) by some marine microorganisms—a process that liberates CH_4 —may explain the previously puzzling observation that relatively high levels of CH_4 are present in the oxygenated surface waters of the ocean (methanogenic *Archaea* are strict anaerobes; [Section 16.2](#)).

Calcium

The major global reservoirs of Ca are calcareous rocks and the oceans. In the oceans, where dissolved Ca exists as Ca^{2+} , calcium cycling is a highly dynamic process although the concentration of Ca^{2+} in seawater remains constant at about 10 mM. Several marine eukaryotic phototrophic microorganisms take up Ca^{2+} to form their calcareous exoskeletons; these include in particular the *coccolithophores* and *foraminifera* ([Figure 20.14](#); [Section 17.7](#)). The calcium-cycling activities of these planktonic phototrophs are also tightly coupled with inorganic components of the carbon cycle.

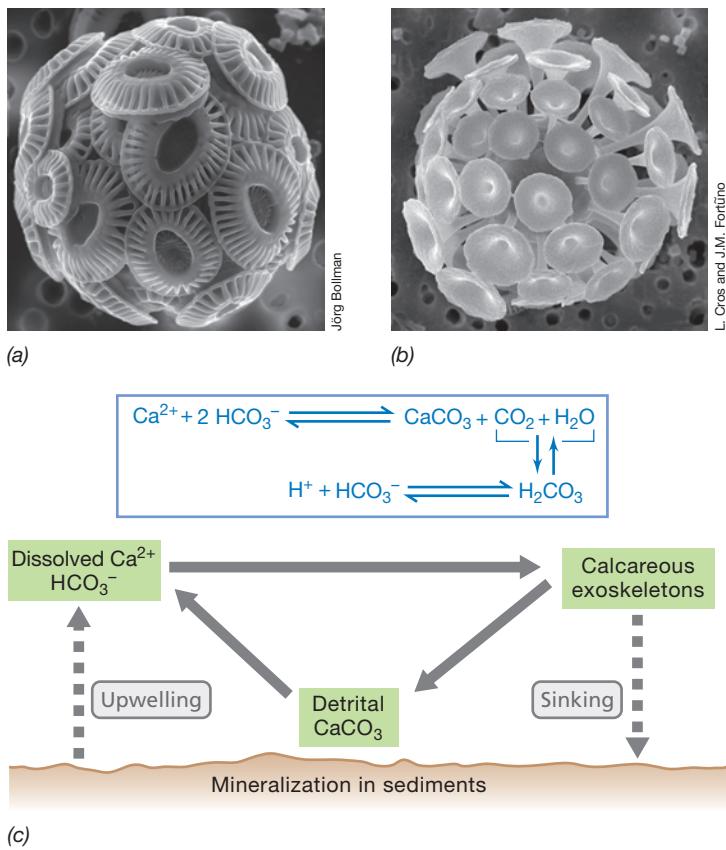

Figure 20.14 The marine calcium (Ca) cycle. Scanning electron micrographs of cells of the calcareous phytoplankton (a) *Emiliania huxleyi* and (b) *Discosphaera tubifera*. The exoskeletons of these coccolithophores are made of calcium carbonate (CaCO₃). A cell of *Emiliania* is about 8 µm wide and a cell of *Discosphaera* is about 12 µm wide. (c) The marine calcium cycle; dynamic pools of Ca²⁺ are shaded in green. Detrital CaCO₃ is that in fecal pellets and other organic matter from dead organisms. Note how H₂CO₃ formation decreases ocean pH when it dissolves to form H⁺ and HCO₃⁻.

The precipitation of calcium carbonate (CaCO₃) to form the shells of calcareous phytoplankton controls both CO₂ flux into ocean surface water and inorganic C transport into deep ocean water and the sediments. Moreover, the formation of CaCO₃ both depletes surface dissolved bicarbonate (HCO₃⁻) and increases the level of dissolved CO₂ (Figure 20.14c). The latter reduces the influx of atmospheric CO₂ into surface ocean waters and this helps maintain the slightly alkaline pH of the oceans. When these calcareous organisms die and sink toward the sediments, inorganic and organic C and Ca²⁺ are transported to the deep ocean from which they are only slowly released over long periods.

The formation of CaCO₃ exoskeletons brings into play a delicate balance between Ca²⁺ and C and is a process sensitive to changes in atmospheric CO₂ levels. This is because increased levels of atmospheric CO₂ increase the formation of carbonic acid (H₂CO₃), and as this dissociates to form HCO₃⁻ and H⁺, CaCO₃ dissolves and seawater pH decreases (Figure 20.14c). The more acidic oceans that will result from rising atmospheric CO₂ are predicted to reduce the rate of formation of calcareous shells, which will likely have effects on other microbial nutrient cycles and plant and animal communities (Section 20.8).

Silica

The marine Si cycle is controlled primarily by unicellular eukaryotes (diatoms, silicoflagellates, and radiolarians) that build ornate external cell skeletons called *frustules* (Figure 20.15a) (Sections 17.6 and 17.7). These structures are not constructed of CaCO₃ as in the coccolithophores, but of opal (SiO₂), whose formation begins with the uptake by the cell of dissolved silicic acid (Figure 20.15b).

Diatoms are rapidly growing phototrophic eukaryotes and often dominate blooms of phytoplankton in coastal and open ocean waters. However, unlike other major phytoplankton groups, diatoms require Si and can become silica-limited when blooms develop. Also, because of their large size, diatom cells tend to sink faster than other organic particles, and in this way, they contribute significantly to the return of Si and C to deeper ocean waters. The transport of organic material produced through primary production in near-surface waters to deeper ocean waters, primarily by sinking particles, is called the *biological pump* and is an important aspect of the carbon cycle in terms of carbon burial and mineralization in marine environments (Figure 20.1).

In addition to the major nutrient requirements of any phototrophic organism (CO₂, N, P, Fe), diatoms require sufficient dissolved Si, and in nature this originates primarily from Si released from the skeletons of dead diatoms (Figure 20.15b). Although Si is released fairly rapidly following cell death, during periods of high

diatom production in relatively shallow waters, a significant fraction of dissolved Si can be buried in sediments and remain there for millions of years. This has consequences for continued diatom growth and their phototrophic consumption of dissolved CO₂ from ocean waters. The flux of CO₂ into and out of ocean water affects its pH (Figure 20.14c), and through this link, the Si and C cycles are coupled in similar fashion to what we have seen with the Ca and C cycles.

III • Humans and Nutrient Cycling

Humans have a profound impact on microbial nutrient cycles by adding and removing components of the cycles in large amounts. Here we consider human inputs of three major species: mercury (Hg), CO₂ and other atmospheric gases, and various fixed N compounds. These compounds either cause toxicity problems (Hg) or affect our planet in globally significant ways (gases and N compounds). We begin with the very toxic metal Hg, which is transformed by bacteria in many different ways.

20.7 Mercury Transformations

Mercury is not a biological nutrient but microbial transformations of various mercuric compounds help to detoxify some of its most toxic forms. Mercury is a widely used industrial product, especially in the electronics industry. Mercury is also an active ingredient in many pesticides, a pollutant from the chemical and mining industries and from the combustion of fossil fuels and municipal wastes, and a common contaminant of aquatic ecosystems and wetlands. Because of its propensity to concentrate in living tissues, Hg is of considerable environmental importance. The major form of Hg in the atmosphere is elemental mercury (Hg⁰), which is volatile and is oxidized to mercuric ion (Hg²⁺) photochemically. Most Hg thus enters aquatic environments as Hg²⁺ (Figure 20.16).

Microbial Redox Cycle for Mercury

Mercuric ion readily adsorbs to particulate matter and can be metabolized from there by microorganisms. Microbial activity

methylates Hg, yielding *methylmercury* (CH₃Hg⁺) (Figure 20.16). Methylmercury is extremely toxic to animals because it can be readily absorbed through the skin and is a potent neurotoxin. But in addition, CH₃Hg⁺ is soluble and can be concentrated in the food chain, primarily in fish, or can be further methylated by microorganisms to yield the volatile compound *dimethylmercury* (CH₃—Hg—CH₃). Both methyl- and dimethylmercury accumulate in animals, especially in muscle tissues. Methylmercury is about 100 times more toxic than Hg⁰ or Hg²⁺, and its accumulation in the aquatic food chain seems to be particularly acute in freshwater lakes and marine coastal waters where enhanced levels of CH₃Hg⁺ have been detected in fish caught for human consumption. Mercuric compounds can cause liver and kidney damage in humans and other animals.

Several other microbial Hg transformations occur, including reactions catalyzed by sulfate-reducing bacteria (H₂S + Hg²⁺ → HgS) and methanogens (CH₃Hg⁺ → CH₄ + Hg⁰) (Figure 20.16). The solubility of mercuric sulfide (HgS) is very low, so in sulfidic sediments, most Hg exists as HgS. But upon aeration, HgS can be oxidized to Hg²⁺ and SO₄²⁻ by metal-oxidizing bacteria (Section 20.5), and the Hg²⁺ is eventually converted to CH₃Hg⁺. Note, however, that it is not the Hg in HgS that is oxidized here, but instead the *sulfide*, probably by organisms related to *Acidithiobacillus* (➡ Section 14.11).

Mercury Resistance

At sufficiently high concentrations, Hg²⁺ and CH₃Hg⁺ can be toxic to microorganisms as well as to macroorganisms. However, several gram-positive and gram-negative bacteria convert toxic forms of Hg to nontoxic or less toxic forms. These mercury-resistant bacteria employ the enzyme *organomercury lyase* to degrade the highly toxic CH₃Hg⁺ to Hg²⁺ and methane (CH₄), and the NADPH (or NADH)-linked enzyme *mercuric reductase* to reduce Hg²⁺ to Hg⁰, which is volatile and thus mobile (Figure 20.17).

In many mercury-resistant bacteria, genes encoding Hg resistance reside on plasmids or transposons (➡ Sections 4.3 and 10.11). These *mer* genes are arranged in an operon under control of the regulatory protein MerR, which can function as either a repressor or an activator of transcription (➡ Sections 7.3 and 7.4), depending on Hg availability. In the absence of Hg²⁺, MerR functions as a *repressor* and binds to the operator region of the *mer* operon, thus preventing transcription of the structural genes, *merTPABD*. However, when Hg²⁺ is present, it forms a complex with MerR, which then binds to the *mer* operon and functions as an *activator* of transcription of *mer* structural genes (Figure 20.17).

The protein MerP is a periplasmic mercuric ion-binding protein. MerP binds Hg²⁺ and transfers it to the membrane transport protein MerT, which interacts with mercuric reductase (MerA) to

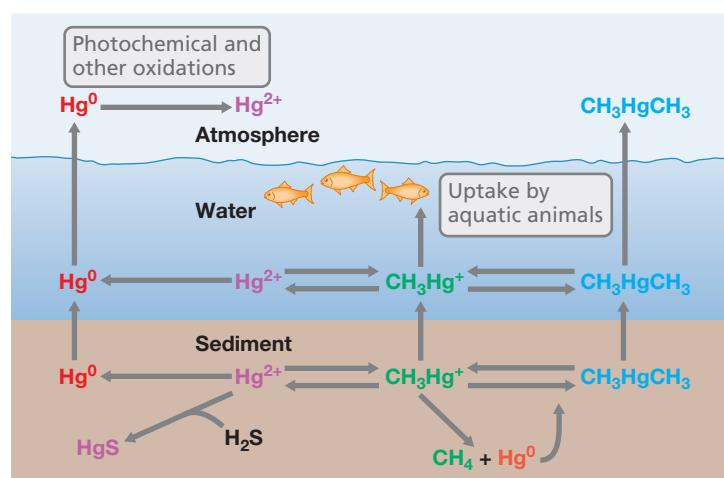

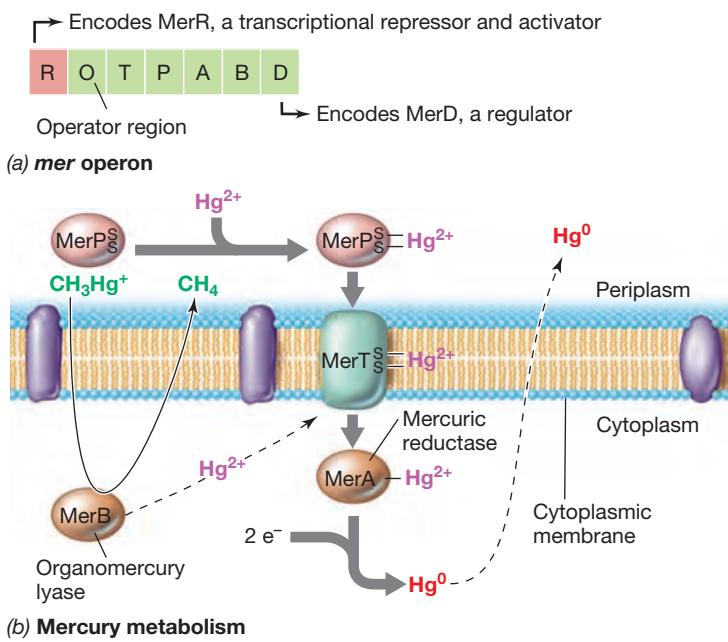

Figure 20.16 Biogeochemical cycling of mercury. The major reservoirs of mercury are water and sediments. Mercury in water can be concentrated in animal tissues; it can be precipitated as HgS from sediments. The forms of mercury commonly found in aquatic environments are each shown in a different color.

reduce Hg^{2+} to Hg^0 (Figure 20.17b). Thus, Hg^{2+} is not released into the cytoplasm and the final result is the release of Hg^0 from the cell. Mercuric ion produced from the activity of MerB is trapped by MerT and reduced by MerA, again releasing Hg^0 (Figure 20.17b). In this way, Hg^{2+} and CH_3Hg^+ are converted to the relatively nontoxic Hg^0 .

20.8 Human Impacts on the Carbon and Nitrogen Cycles

Human activities are having major impacts on the carbon and nitrogen cycles, and these impacts have significance for the health of our planet in general. The period of marked human influence on these nutrient cycles began with the Industrial Revolution and is informally termed the *Anthropocene*, a new geological epoch. Although the greatest human impacts have been on the release of CO_2 through the burning of fossil fuels (oil, gas, and coal) and from extensive and ongoing deforestation, human activity has also profoundly affected the nitrogen cycle. We discussed earlier the close coupling of the carbon and nitrogen cycles (Section 20.1), and here we consider some of the projected biogeochemical consequences of human alteration of these two critical nutrient cycles.

CO_2 and Global Warming

Atmospheric CO_2 levels have increased approximately 40% since the beginning of the Industrial Revolution in the 1800s, and are now higher than at any time in the last 800,000 years. Carbon dioxide

is one of several *trace gases* (primarily water vapor, CO_2 , CH_4 , and N_2O) which comprise less than 0.5% of the atmosphere but contribute significantly to terrestrial and atmospheric warming due to the *greenhouse effect*, the ability of these gases to trap the infrared radiation emitted by the Earth. The increase in atmospheric CO_2 concentration, measured across a global network of sampling stations (Figure 20.18), is currently about 2 parts per million per year. This increase would be much more rapid were it not for the high solubility of CO_2 in water, which produces carbonic acid; much anthropogenic CO_2 thus dissolves in the oceans (Figures 20.1 and 20.14).

The surface waters of the oceans have taken up an estimated 500 billion tons of CO_2 from the atmosphere out of a total of 1300 billion tons of total anthropogenic emissions, thus modulating the greenhouse effect. The increase in average Earth air temperature (estimated to have increased 0.75°C in the twentieth century and projected to increase by anywhere from 1.1 to 6.4°C in the twenty-first century) would also have been more rapid without the buffering influence of the oceans. Since three orders of magnitude more energy is required to raise the temperature of a cubic meter of water than a cubic meter of air, over 80% of the heat retained on Earth due to the greenhouse effect has actually entered the ocean.

Although there is considerable uncertainty about the consequences of ocean warming and CO_2 consumption on Earth's biological systems, there is agreement on how these changes will affect biogeochemistry. Warmer ocean surface waters are more buoyant (because of their lower density) than are deeper waters. Thus, as occurs seasonally in lakes (Section 19.8), the oceans will become more stratified with future global warming. Stratification tends to slow the transfer of nutrients from deeper waters that are needed to nourish phytoplankton production at the base of the food web in surface waters. This in turn reduces ocean productivity and export of a portion of that production to the deeper ocean through sedimentation

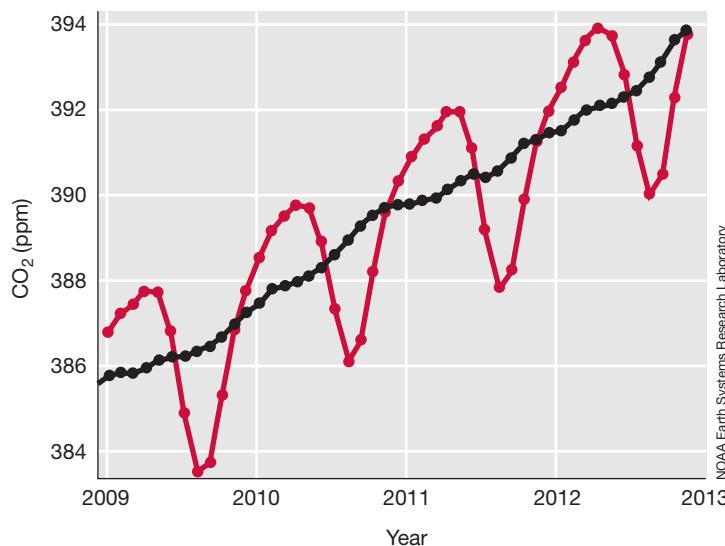

Figure 20.18 Global average of monthly mean carbon dioxide (CO_2) concentrations in air above marine surface sites. These data are continuously collected by the Global Monitoring Division of NOAA/Earth System Research Laboratory. The red curve shows variations in monthly mean values associated with annual fluctuations of temperature and precipitation affecting photosynthesis and respiration on land. The black curve shows the average monthly increase in CO_2 after correcting for seasonal cycle influence.

(the biological pump, Figure 20.1). The biological pump is important to the long-term removal of carbon from the atmosphere. Melting of polar sea ice by global warming might, however, mitigate this effect somewhat by opening up new waters for phytoplankton production.

Ocean warming is also contributing to the expansion of oxygen minimum zones (OMZs), regions of naturally occurring low O₂ concentration in subsurface waters between 100 and 1000 m in depth (☞ Section 19.9). OMZs are a consequence of both the reduced solubility of O₂ in warmer water and the increasing stratification associated with surface warming, which reduces mixing of surface and subsurface waters. Animals will be excluded from the expanding OMZs whereas anaerobic microbial processes, such as denitrification and anammox that directly influence the nitrogen cycle and production of the greenhouse gas N₂O, will be enhanced.

Acidification of the ocean resulting from the ongoing uptake of anthropogenic CO₂ has reduced ocean pH by 0.1 pH units since the beginning of the Industrial Revolution, and may further reduce the pH by 0.3–0.4 units by the year 2100. The ongoing reduction in carbonate (CO₃²⁻) concentration, a consequence of increasing acidification, is expected to be detrimental to marine calcifiers (organisms synthesizing CaCO₃ shells or skeletons, Figure 20.14). Since the concentration of Ca in seawater is relatively constant, continued reduction in CO₃²⁻ will ultimately reach a point where the dissolution of existing CaCO₃ is chemically favored, ultimately releasing more dissolved CO₂ (Figure 20.14), which reduces the capacity of the oceans to absorb more atmospheric CO₂.

Although the biological response to ocean acidification is unknown, it is likely that coral reef ecosystems, a major component of the marine biosphere (☞ Section 22.14), will cease to occur naturally on Earth if CO₂ emissions continue at their present rate (Figure 20.18). Calcification in foraminifera (☞ Section 17.7) will likely be impaired significantly by ocean acidification, as will calcification in coccolithophores (Figure 20.14). Over periods of a century or so, the invasion of anthropogenic CO₂ into the deep ocean will ultimately result in a significant reduction in the levels of CaCO₃ sequestered there, and this is predicted to disrupt the carbon cycle in major ways.

Anthropogenic Effects on the Nitrogen Cycle

Anthropogenic impacts on the nitrogen cycle are as profound as those on the carbon cycle (Figure 20.1). The yearly industrial production of nitrogenous fertilizers through the Haber–Bosch

process, which combines N₂ + H₂ to form NH₃ under high temperature and pressure, is now comparable to the amount of fixed nitrogen entering the biosphere through biological nitrogen fixation, a key link in the nitrogen cycle (Section 20.3). This includes nitrogen fixation by both microorganisms living alone and those which live in symbiotic associations with plants or algae. Most of the industrially produced N is applied to farmland, but a significant fraction runs off to the oceans and contributes to coastal eutrophication (☞ Section 19.9). Large amounts are also lost as gaseous nitrogen compounds (N₂, N₂O, and NO) from nitrification of NH₃ and denitrification of NO₃⁻ (Section 20.3).

Transport of N from industrial and agricultural centers through the atmosphere fertilizes both terrestrial and marine systems. Atmospheric deposition of fixed N₂ to the oceans is now about the same as that which enters through biological nitrogen fixation. The ecological consequences of this fertilization are a major unknown. On the one hand, if deposition suppresses microbial nitrogen fixation, this would to some degree mitigate the fertilization effect. On the other hand, a greater supply of both CO₂ and iron (caused by greater deposition of dust from areas of increasing desertification, ☞ Section 19.6) along with increased N depositions could enhance primary production, since iron is also often a limiting nutrient. Either way, major effects on the carbon cycle should be expected from human inputs in the nitrogen cycle.

Although changes in Earth's biosphere from human intervention in microbial nutrient cycles are a certainty, precisely what these changes will be is less clear. However, because major nutrient cycles are closely coupled (Section 20.1 and Figure 20.4), it is likely that any significant changes in the carbon and nitrogen cycles will have feedback effects on other cycles as well. Collectively, these events could upset the interrelationships of the nutrient cycles we have explored in this chapter and have significant (and likely negative) consequences for Earth's higher organisms.

BIG IDEAS

20.1 • The oxygen and carbon cycles are interconnected through the complementary activities of autotrophic and heterotrophic organisms. Microbial decomposition is the single largest source of CO₂ released to the atmosphere.

20.2 • Under anoxic conditions, organic matter is degraded to CH₄ and CO₂. Methane is formed primarily from the reduction of CO₂ by H₂ and from acetate, both supplied by syntrophic bacteria; these organisms depend on H₂ consumption as the basis of their energetics. On a global basis, biogenic CH₄ is a much larger source than abiogenic CH₄.

20.3 • The principal form of nitrogen on Earth is N₂, which can be used as a N source only by nitrogen-fixing bacteria. Ammonia produced by nitrogen fixation or by ammonification can be assimilated into organic matter or oxidized to NO₃⁻. Denitrification and anammox cause major losses of fixed nitrogen from the biosphere.

20.4 • Bacteria play major roles in both the oxidative and reductive sides of the sulfur cycle. Sulfur- and sulfide-oxidizing bacteria produce SO₄²⁻, whereas sulfate-reducing bacteria consume SO₄²⁻, producing H₂S. Because sulfide is toxic and

reacts with various metals, SO_4^{2-} reduction is an important biogeochemical process. Dimethyl sulfide is the major organic sulfur compound of ecological significance in nature.

20.5 • Iron and manganese exist naturally in two oxidation states, $\text{Fe}^{2+}/\text{Fe}^{3+}$ and $\text{Mn}^{2+}/\text{Mn}^{4+}$. Bacteria reduce the oxidized metals in anoxic environments and oxidize the reduced forms primarily in oxic environments. At neutral pH, bacteria compete with abiotic oxidation in the presence of O_2 . Ferrous iron oxidation is common in coal-mining regions, where it causes a type of pollution called acid mine drainage.

20.6 • P, Ca, and Si are elements cycled by microbial activities, primarily in aquatic environments. Calcium and silica play important roles in the biogeochemistry

of the oceans as components of the exoskeletons of coccolithophores and diatoms, respectively.

20.7 • A major toxic form of Hg in nature is CH_3Hg^+ , which can yield Hg^{2+} , which is reduced by bacteria to Hg^0 . Genes conferring resistance to the toxicity of Hg, such as those that encode enzymes that can detoxify or pump out the metal, often reside on plasmids or transposons.

20.8 • Anthropogenic inputs of CO_2 and reactive nitrogen are impacting major nutrient cycles. Although some consequences are reasonably well understood, including expansion of OMZs and impaired growth of calcareous organisms, the long-term changes to the nutrient cycles that sustain Earth's biosphere are not well understood.

Your Subway System: What's in the Air?

Does the congregation of people in buildings and transportation systems influence the microflora of these “built environments”? A recent study of air quality in a metropolitan transit system posed this very question using culture-independent methods to characterize the diversity and abundance of the indoor airborne microflora for its possible impact on public health.¹

The New York City municipal subway system moved a total of 1.6 billion passengers in 2011 and was the site of the first intensive molecular survey of aerosol microbiology in heavily trafficked enclosed structures. Investigators placed air samplers designed to efficiently capture bacteria-sized particles at various locations in boarding areas of the subway system (photos). Following collection of the microflora from several cubic meters of air, DNA was extracted for phylogenetic analyses of ribosomal RNA genes as a metric of microbial diversity.

Surprisingly, phylogenetic analyses showed no evidence of pathogens. Instead, the microflora was mostly composed of organisms associated with outdoor air, along with a much smaller component of microorganisms typically found on humans. For example, about 5% of the subway air microflora were organisms found on human skin. Since the normal microflora of the human skin has been well characterized and shown to vary by body location, these investigators could also conclude that the skin-derived microorganisms in New York subway air came mainly from the feet, hands, arms, and heads of riders—the generally more exposed areas of the human body.

This survey is reassuring in its discovery that serious microbial pathogens are not floating around the subway air system. But the study also served as a prototype for how the microbial composition of the built environment can be monitored in a scientifically sound and objective way.

- III **Wastewater and Drinking Water Treatment 657**
- IV **Microbially Influenced Corrosion 664**

This chapter addresses the microbiology of built systems. These include the infrastructure for drinking water and wastewater distribution and treatment, gas and oil transmission, building materials, and environments modified for mineral extraction or for the cleanup of pollutants. Built systems create new microbial habitats, promoting both desired and undesired microbial activities. Examples of systems designed to select for desirable microbial activities include the construction of biological reactors for the treatment of wastewater and the stimulation of microbial activity in aquifers to clean up environmental pollutants.

A notable example of an unwanted activity is microbially influenced corrosion of the pipelines used for transmission of wastewater, drinking water, and oil. These are natural processes in which microorganisms simply exploit the resources provided to them in the built environment. Essential infrastructure costing several billion dollars is lost every year to microbially influenced corrosion. For example, the American Association of Civil Engineers estimates that in the next 30 years, about 30% of the drinking water distribution system in the United States will need to be replaced at an annual cost of \$11 billion.

I • Mineral Recovery and Acid Mine Drainage

The biogeochemical capacities of microorganisms seem almost limitless, and it is often said that microorganisms are “Earth’s greatest chemists.” The activities of these great little chemists have been exploited in many ways. Here we consider how microbial activities help extract valuable metals from low-grade ores.

21.1 Mining with Microorganisms

One of the most common forms of iron in nature is **pyrite** (FeS_2), which is often present in bituminous coals and in metal ores. Sulfide (HS^-) also forms insoluble minerals with many metals, and many ores mined as sources of these metals are sulfide ores. If the concentration of metal in the ore is low, it may be economically feasible to mine the ore only if the metals of interest are first

concentrated by **microbial leaching** (Figure 21.1). The promotion of acid production and dissolution of FeS_2 by acidophilic bacteria such as *Acidithiobacillus ferrooxidans* is used to leach the metal ores in large-scale mining operations. Leaching is especially useful for copper ores because copper sulfate (CuSO_4), formed during the oxidation of copper sulfide ores, is very water-soluble. Indeed, approximately a quarter of all copper mined worldwide is obtained by microbial leaching.

The Leaching Process

The susceptibility to oxidation varies among minerals, and those minerals that are most readily oxidized are most amenable to microbial leaching. Thus, iron and copper sulfide ores such as

The low-grade ore has been crushed and dumped in such a way that the surface area exposed is as high as possible. Pipes distribute the acidic leach water over the surface of the pile. The acidic water slowly percolates through the pile and exits at the bottom. (b) Effluent from a copper leaching dump. The acidic water is very rich in Cu^{2+} . (c) Recovery of copper as metallic copper (Cu^0) by passage of the Cu^{2+} -rich water over metallic iron in a long flume. (d) A small pile of metallic copper removed from the flume, ready for further purification.

pyrrhotite (FeS) and covellite (CuS) are readily leached, whereas lead and molybdenum ores are much less so. In microbial leaching, low-grade ore is dumped in a large pile called the *leach dump* and a dilute sulfuric acid solution at pH 2 is percolated down through the pile (Figure 21.1). The liquid emerging from the bottom of the pile (Figure 21.1b) is rich in dissolved metals and is transported to a precipitation plant (Figure 21.1c) where the desired metal is precipitated and purified (Figure 21.1d). The liquid is then pumped back to the top of the pile and the cycle repeated. As needed, acid is added to maintain an acidic pH.

We illustrate microbial leaching of copper with the common copper ore CuS , in which copper exists as Cu^{2+} . *A. ferrooxidans* oxidizes the sulfide in CuS to SO_4^{2-} , releasing Cu^{2+} as shown in Figure 21.2. However, this reaction can also occur spontaneously. Indeed, the key reaction in copper leaching is actually not the bacterial oxidation of sulfide in CuS but the spontaneous oxidation of sulfide by ferric iron (Fe^{3+}) generated from the bacterial oxidation of ferrous iron (Fe^{2+}) (Figure 21.2). In any copper ore, FeS_2 is also present, and its oxidation by bacteria leads to the formation of Fe^{3+} (Figure 21.2). The spontaneous reaction of CuS with Fe^{3+} proceeds in the absence of O_2 and forms Cu^{2+} plus Fe^{2+} ; importantly for efficiency of the leaching process, this reaction can take place deep in the leach dump where conditions are anoxic.

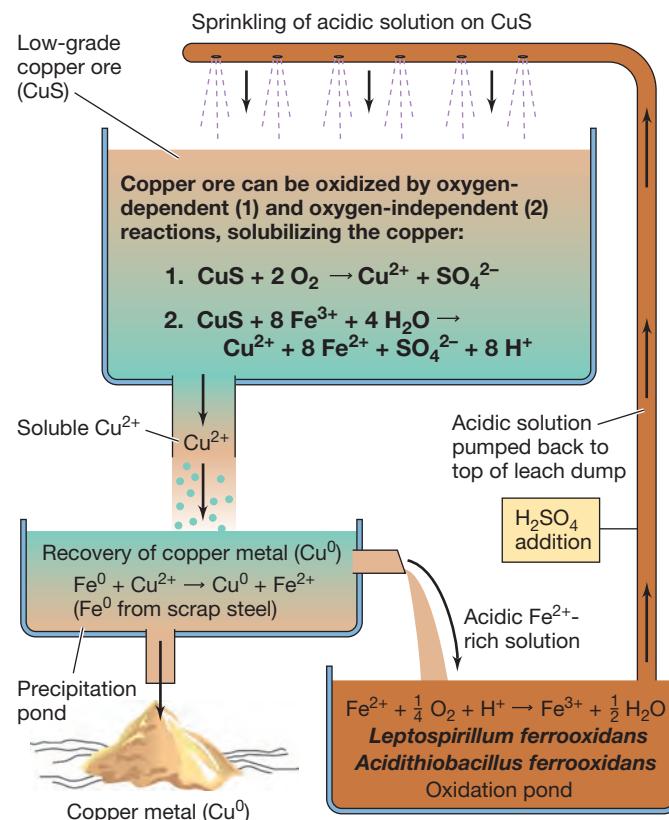

Figure 21.2 Arrangement of a leaching pile and reactions in the microbial leaching of copper sulfide minerals to yield metallic copper. Reaction 1 occurs both biologically and chemically. Reaction 2 is strictly chemical and is the most important reaction in copper-leaching processes. For reaction 2 to proceed, it is essential that the Fe^{2+} produced from the oxidation of sulfide in CuS to sulfate be oxidized back to Fe^{3+} by iron chemolithotrophs (see chemistry in the oxidation pond).

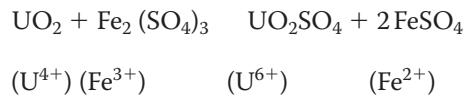

Metal Recovery

The precipitation plant is where the Cu^{2+} from the leaching solution is recovered (Figure 21.1c, d). Shredded scrap iron (a source of elemental iron, Fe^0) is added to the precipitation pond to recover copper from the leach liquid by the chemical reaction shown in the lower part of Figure 21.2. This results in a Fe^{2+} -rich liquid that is pumped to a shallow oxidation pond where iron-oxidizing chemolithotrophs oxidize the Fe^{2+} to Fe^{3+} . This now ferric iron-rich acidic liquid is pumped to the top of the pile and the Fe^{3+} is used to oxidize more CuS (Figure 21.1). The entire CuS leaching operation is thus driven by the oxidation of Fe^{2+} to Fe^{3+} by iron-oxidizing bacteria.

Temperatures rise in a leaching dump and this leads to shifts in the iron-oxidizing microbial community. *A. ferrooxidans* is a mesophile, and when heat generated by microbial activities raises temperatures above about 30°C inside a leach dump, this bacterium is outcompeted by mildly thermophilic iron-oxidizing chemolithotrophic *Bacteria* such as *Leptospirillum ferrooxidans* and *Sulfobacillus*. At even higher temperatures (60–80°C), hyperthermophilic *Archaea* such as *Sulfolobus* (Section 16.10) predominate in the leach dump.

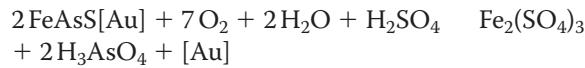

Other Microbial Leaching Processes: Uranium and Gold

Bacteria are also used in the leaching of uranium (U) and gold (Au) ores. In uranium leaching, *A. ferrooxidans* oxidizes U^{4+} to U^{6+} with O_2 as an electron acceptor. However, U leaching depends more on the abiotic oxidation of U^{4+} by Fe^{3+} with *A. ferrooxidans* contributing to the process mainly through the reoxidation of Fe^{2+} to Fe^{3+} , as in copper leaching (Figure 21.2). The reaction observed is as follows:

Unlike UO_2 , the uranyl sulfate (UO_2SO_4) formed is highly soluble and is concentrated by other processes.

Gold is typically present in nature in deposits associated with minerals containing arsenic (As) and FeS_2 . *A. ferrooxidans* and related bacteria can leach the arsenopyrite minerals, releasing the trapped Au:

The Au is then complexed with cyanide (CN^-) by traditional gold-mining methods. Unlike copper leaching, which is done in a huge dump (Figure 21.1a), gold leaching is done in small bioreactor tanks (Figure 21.3), where more than 95% of the trapped Au can be released. Moreover, the potentially toxic As and CN^- residues from the mining process are removed in the gold-leaching bioreactor. Arsenic is removed as a ferric precipitate, and CN^- is removed by its bacterial oxidation to CO_2 plus urea in later stages of the Au recovery process. Small-scale microbial-bioreactor leaching has thus become popular as an alternative to the environmentally devastating gold-mining techniques that leave a toxic trail of As and CN^- at the extraction site. Pilot processes are also being developed for bioreactor leaching of zinc, lead, and nickel ores.

Figure 21.3 Gold bioleaching. Gold leaching tanks in Ghana (Africa). Within the tanks, a mixture of *Acidithiobacillus ferrooxidans*, *Acidithiobacillus thiooxidans*, and *Leptospirillum ferrooxidans* solubilizes the pyrite/arsenic mineral containing trapped gold, which releases the gold.

21.2 Acid Mine Drainage

Although microbial leaching has tremendous value in mining operations, the same process has contributed to extensive environmental destruction where mining operations improperly handle or dispose of pyrite containing coal and mineral deposits. Bacterial and spontaneous oxidation of sulfide minerals is the major cause of **acid mine drainage**, an environmental problem worldwide caused by surface mining operations. As described for the oxidation of copper sulfides promoted in microbial mining (Section 21.1), the oxidation of FeS₂ is a combination of chemically and bacterially catalyzed reactions, and two electron acceptors participate in the process: O₂ and Fe³⁺. When FeS₂ is first exposed in a mining operation (Figure 21.4b), a slow chemical reaction with O₂ begins (Figure 21.4c). This reaction, called the *initiator reaction*, leads to the oxidation of HS⁻ to SO₄²⁻ and the development of acidic conditions as Fe²⁺ is released. *A. ferrooxidans* and *L. ferrooxidans* then oxidize Fe²⁺ to Fe³⁺, and the Fe³⁺ formed under these acidic conditions, being soluble, reacts spontaneously with more FeS₂ and oxidizes the HS⁻ to sulfuric acid (H₂SO₄), which immediately dissociates into SO₄²⁻ and H⁺:

Again, the bacteria oxidize Fe²⁺ to Fe³⁺, and this Fe³⁺ reacts with more FeS₂. Thus, there is a progressive, rapidly increasing rate at which FeS₂ is oxidized, called the *propagation cycle* (Figure 21.4c). Under natural conditions some of the Fe²⁺ generated by the bacteria leaches away and is subsequently carried by anoxic groundwater into surrounding streams. However, bacterial or spontaneous oxidation of Fe²⁺ then takes place in the aerated streams, and because O₂ is present, the insoluble Fe(OH)₃ is formed.

As we have seen (Figure 21.4c), the breakdown of FeS₂ ultimately leads to the formation of H₂SO₄ and Fe²⁺; in waters in which these products have formed, pH values can be lower than 1. Mixing of acidic mine waters into rivers (Figure 21.5) and lakes

seriously degrades water quality because both the acid and the dissolved metals (in addition to iron, there is aluminum, and heavy metals such as cadmium and lead) are toxic to aquatic organisms.

T. D. Brock

Figure 21.5 Acid mine drainage from a surface coal-mining operation. The yellowish-red color is due to the precipitated iron oxides in the drainage (see Figure 21.4c for the reactions in acid mine drainage).

The O₂ requirement for the oxidation of Fe²⁺ to Fe³⁺ explains how acid mine drainage develops. As long as the pyritic material is not mined, FeS₂ cannot be oxidized because O₂, water, and the bacteria cannot reach it. However, when a mineral or coal seam is exposed (Figure 21.4b), O₂ and water are introduced, making both spontaneous and bacterial oxidation of FeS₂ possible. The acid formed can then leach into surrounding aquatic systems (Figure 21.5).

Where acid mine drainage is extensive and Fe²⁺ levels high, a strongly acidophilic species of *Archaea*, *Ferroplasma*, is often present. This aerobic iron-oxidizing organism is capable of

growth at pH 0 and at temperatures up to 50°C. Cells of *Ferroplasma* lack a cell wall and are phylogenetically related to *Thermoplasma*, also a cell-wall-lacking and strongly acidophilic (but chemoorganotrophic) member of the *Archaea* (► Section 16.3).

II • Bioremediation

The term **bioremediation** refers to the microbial cleanup of oil, toxic chemicals, or other environmental pollutants, usually by stimulating the activities of indigenous microorganisms in some way. These pollutants include both natural materials, such as petroleum products, and **xenobiotic** chemicals, synthetic chemicals not produced by organisms in nature.

Although bioremediation of many toxic substances has been proposed, most successes have been in cleaning up spills of crude oil or the leakage of hydrocarbons from bulk storage tanks. More recently, the targeted destruction of chlorinated environmental pollutants, including commonly used solvents and pesticides, has become more amenable to bioremediation as a result of better understanding of associated microbiology. There has also been increasing success in the bioremediation of uranium-contaminated environments, many of which are the legacy of poorly regulated

past mining of uranium for nuclear fuel and weapons. We begin here with a consideration of this very toxic pollutant.

21.3 Bioremediation of Uranium-Contaminated Environments

Major classes of inorganic pollutants are metals and radionuclides that cannot be destroyed, but only altered in chemical form. Often the extent of environmental pollution is so great that physical removal of the contaminated material is impossible. Thus, *containment* is the only real option, and a common goal in the bioremediation of inorganic pollutants is to change their mobility, making them less likely to move with groundwater and so contaminate surrounding environments. Here we consider how the radioactive element uranium can be contained by the activities of bacteria.

Bioremediation of Uranium

Uranium contamination of groundwater has occurred at sites in the United States and elsewhere where uranium ores have been processed or stored (Figure 21.6), and the movement of radioactive materials offsite via groundwater is a threat to environmental and human health. Because the contamination is often widespread, making mechanical methods of recovery very expensive, microbiologists have joined forces with engineers to develop biological treatments that exploit the ability of some bacteria to reduce U⁶⁺ to U⁴⁺. Uranium as U⁶⁺ is soluble, whereas U⁴⁺ forms an immobile uranium mineral called *uraninite*, thus limiting the movement of U into groundwater and potential contact with humans and other animals.

Bacterial Transformations of Uranium

The major strategy for immobilizing uranium has been to use bacteria to change the oxidation state of U in major uranium contaminants to a form that will stabilize

Figure 21.6 Uranium bioremediation. An experimental plot at a United States Department of Energy uranium-contaminated site. Organic carbon (acetate) is being infused into the site (see inset photo) and travels in groundwater in the direction of the arrow shown in the main photo. Acetate is an electron donor for reduction of U⁶⁺ to U⁴⁺, which immobilizes the uranium.

the element. In this regard, *Bacteria*, including metal-reducing *Shewanella* and *Geobacter* species (Section 14.14) and sulfate-reducing *Desulfovibrio* species (Section 14.9), couple the oxidation of organic matter and H₂ to the reduction of U⁶⁺ to U⁴⁺.

Field studies in which organic electron donors have been injected into uranium-contaminated aquifers to stimulate U⁶⁺ reduction have shown that this approach can lower U levels to below the U.S. Environmental Protection Agency's drinking water standard of 0.126 µM. However, even though uraninite is stable under reducing conditions, if conditions become oxic, it reoxidizes. Thus, much ongoing uranium bioremediation research is focused on questions of whether microbially reduced uranium is stable if the composition of the microbial community changes or if oxidants, such as O₂, NO₃⁻, and Fe³⁺, are introduced via groundwater. This is obviously an important question because uraninite stability must be targeted for the long term in order to account for the long half-life of nuclear decay of uranium.

MINIQUIZ

- Which reaction, oxidation or reduction, is key to uranium bioremediation?
- Why is immobilization a good strategy for dealing with uranium pollution?

21.4 Bioremediation of Organic Pollutants: Hydrocarbons

Organic pollutants, unlike inorganic pollutants, can generally be completely degraded by microorganisms, eventually to CO₂. This is true of petroleum released in oil spills (Figure 21.7), which can be attacked by many different microorganisms. These organisms have been exposed to complex mixtures of hydrocarbons through natural oil seeps for millennia and thus have evolved the catabolic machinery necessary to degrade this naturally occurring pollutant. In contrast, xenobiotic pollutants tend to be more persistent and are degraded by more specialized groups of microorganisms. In this section we focus on hydrocarbons and in the next section on xenobiotics.

Petroleum and Hydrocarbon Bioremediation

Petroleum is a rich source of organic matter, and because of this, microorganisms readily attack hydrocarbons when petroleum is pumped to Earth's surface and comes into contact with air and moisture. Under some circumstances, such as in bulk petroleum storage tanks, microbial growth is undesirable. However, in oil spills, biodegradation is desirable and can be promoted by the addition of inorganic nutrients to balance the huge influx of organic carbon from the oil (Figure 21.7).

The biochemistry of hydrocarbon catabolism was covered in Sections 13.22–13.24. Both oxic and anoxic biodegradation is possible. We emphasized that under oxic conditions oxygenase enzymes play an important role in introducing oxygen atoms into the hydrocarbon. Our discussion here will focus on *aerobic* processes, because it is only when O₂ is present that oxygenase enzymes can function and hydrocarbon bioremediation can be effective in a relatively short time.

Diverse bacteria, fungi, and a few green algae can oxidize petroleum products aerobically. Small-scale oil pollution of aquatic and terrestrial ecosystems from human as well as natural activities is common. Oil-oxidizing microorganisms develop rapidly on oil films and slicks, and hydrocarbon oxidation is most extensive if the temperature is warm enough and supplies of inorganic nutrients (primarily N and P) are sufficient.

Because oil is insoluble in water and is less dense, it floats to the surface and forms slicks. There, hydrocarbon-degrading bacteria attach to the oil droplets (Figure 21.8) and eventually decompose the oil and disperse the slick. Certain oil-degrading bacteria are specialist species; for example, the bacterium *Alcanivorax borkumensis* grows only on hydrocarbons, fatty acids, or pyruvate. This organism produces surfactant chemicals that help break up the oil and solubilize it. Once solubilized, the oil can be incorporated more readily and catabolized as an electron donor and carbon source.

In large surface oil spills such as those shown in Figure 21.7, volatile hydrocarbons, both aliphatic and aromatic, evaporate quickly without bioremediation, leaving nonvolatile components for cleanup crews and microorganisms to tackle. Microorganisms

consume oil by oxidizing it to CO₂. When bioremediation activities are promoted by inorganic nutrient application, oil-oxidizing bacteria typically develop quickly after an oil spill (Figure 21.7b), and under ideal conditions, 80% or more of the nonvolatile oil components can be oxidized within one year. However, certain oil fractions, such as those containing branched-chain and polycyclic hydrocarbons, are not preferred microbial substrates and remain in the environment much longer. Spilled oil that finds its way into sediments is even more slowly degraded and can have a significant long-term impact on fisheries that depend on unpolluted waters for productive yields.

A notable exception to the more common surface spill of oil was the 2010 sinking of the Deepwater Horizon offshore drilling platform in the Gulf of Mexico, resulting in the rupture of the wellhead at a depth of 1.5 km and release of over 4 million barrels of oil into the deep ocean (Section 19.9 and Figure 19.20). About 35% of the resulting hydrocarbon plume was comprised of low-molecular-weight components and natural gas (methane, ethane, propane). The availability of these more easily degraded oil components is thought to have accelerated the natural degradation process by stimulating the development of a large bloom of bacteria having the capacity to oxidize both the easily degraded and more recalcitrant hydrocarbon components. It remains uncertain whether the industry decision to promote dispersal of the oil (which was intended to increase the oil's surface area and bioavailability) by injecting thousands of gallons of chemical dispersants directly into the plume actually accelerated microbial degradation. Regardless, although some legacy of this major oil spill remains, much of the oil did disappear from a combination of volatilization and microbial activities.

Degradation of Stored Hydrocarbons

Interfaces where oil and water meet often form on a large scale. Besides water that separates from crude petroleum during storage and transport, moisture can condense inside bulk fuel storage tanks (Figure 21.9) where there are leaks. This water eventually accumulates in a layer beneath the petroleum. Gasoline and crude oil storage tanks are thus potential habitats for hydrocarbon-oxidizing microorganisms. If sufficient sulfate (SO₄²⁻) is present in the oil, as it often is in crude oils, sulfate-reducing bacteria can grow in the tanks, consuming hydrocarbons under anoxic conditions (Sections 13.24 and 14.9). The sulfide (H₂S) produced is highly corrosive and causes pitting and subsequent leakage of

the tanks along with souring of the fuel. Aerobic degradation of stored fuel components is less of a problem because the storage tanks are sealed and the fuel itself contains little dissolved O₂.

21.5 Bioremediation of Organic Pollutants: Pesticides and Plastics

Unlike hydrocarbons, many chemicals that humans put into the environment have never been there before. These are the xenobiotics, and we consider their microbial degradation here.

Pesticide Catabolism

Xenobiotics include pesticides, polychlorinated biphenyls (PCBs), munitions, dyes, and chlorinated solvents, among many other chemicals. Some xenobiotics differ chemically in such major ways from anything organisms have experienced in nature that they biodegrade extremely slowly, if at all. Other xenobiotics are structurally related to one or more natural compounds and can sometimes be degraded slowly by enzymes that normally degrade the structurally related natural compounds. We focus here on pesticide bioremediation.

Over 1000 pesticides have been marketed worldwide for pest control purposes. Pesticides include *herbicides*, *insecticides*, and *fungicides*. Pesticides display a wide variety of chemistries, and include chlorinated, aromatic, and nitrogen- and phosphorus-containing compounds (Figure 21.10). Some of these substances can be used as carbon and energy sources by microorganisms, whereas others are utilized only poorly or not at all. Highly chlorinated compounds are typically the pesticides most resistant to microbial attack. However, related compounds may differ

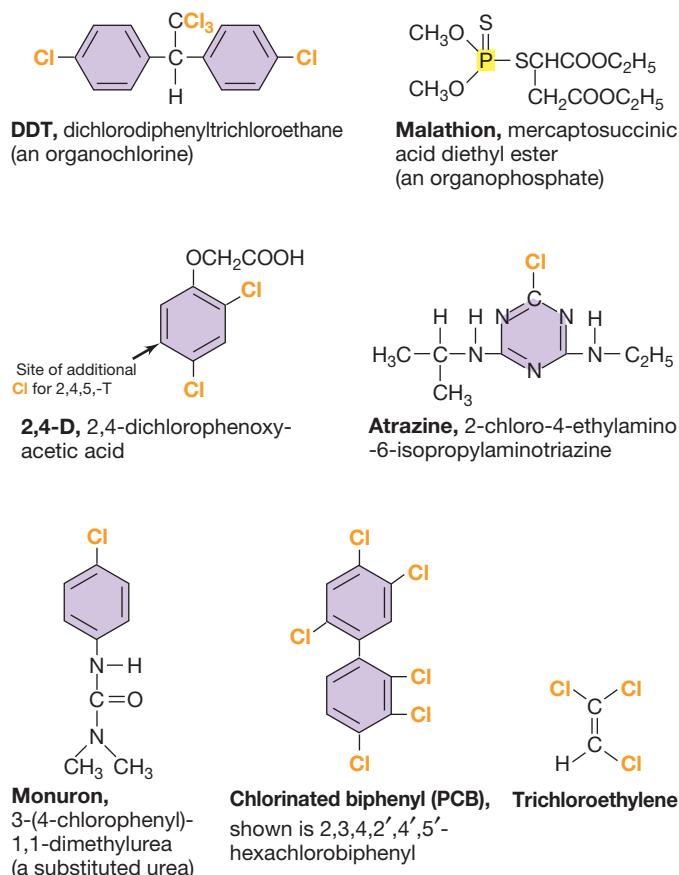

Figure 21.10 Examples of xenobiotic compounds. Although none of these compounds exist naturally, microorganisms exist that can break them down.

remarkably in their degradability. For example, chlorinated compounds such as DDT persist relatively unaltered for years in soils, whereas chlorinated compounds such as 2,4-D are significantly degraded in just a few weeks.

Environmental factors, such as temperature, pH, aeration, and organic content of the soil, influence the rate of pesticide decomposition, and some pesticides can disappear from soils nonbiologically by volatilization, leaching, or spontaneous chemical breakdown. In addition, some pesticides are degraded only when other organic material is present that can be used as the primary energy source, a phenomenon called *cometabolism*. In most cases, pesticides that are cometabolized are only partially degraded, generating new xenobiotic compounds that may be even more toxic or difficult to degrade than the original compound. Thus, from an environmental standpoint, cometabolism of a pesticide is not always good.

Dechlorination

Many xenobiotics are chlorinated compounds and their degradation proceeds through *dechlorination*. For example, the bacterium *Burkholderia* dechlorinates the pesticide 2,4,5-T aerobically, releasing chloride ion (Cl^-) in the process (Figure 21.11); this reaction is catalyzed by oxygenase enzymes (► Section 13.22). Following dechlorination, a dioxygenase enzyme breaks the aromatic ring to yield compounds that can enter the citric acid cycle and yield energy.

Although the aerobic breakdown of chlorinated xenobiotics is undoubtedly ecologically important, **reductive dechlorination** may be even more so because of the rapidity with which anoxic conditions develop in polluted microbial habitats. We previously described reductive dechlorination as a form of anaerobic respiration in which chlorinated organic compounds such as chlorobenzoate ($\text{C}_7\text{H}_4\text{O}_2\text{Cl}^-$) are terminal electron acceptors and when reduced, release chloride (Cl^-), a nontoxic substance (► Section 13.21).

Many compounds can be reductively dechlorinated including dichloro-, trichloro-, and tetrachloro- (perchloro-) ethylene, chloroform, dichloromethane, and polychlorinated biphenyls (Figure 21.10). In addition, several brominated and fluorinated organic compounds can be dehalogenated in analogous fashion. Many of these chlorinated or halogenated compounds are highly toxic and some have been linked to cancer (particularly trichloroethylene). Some of these compounds, such as PCBs, have been widely used as insulators in electrical transformers and enter anoxic environments from slow leakage of the transformer or from leaking storage containers. Eventually these compounds end up in groundwater or sediment, where they are among the most common contaminants detected in the United States. There is therefore great interest in reductive dechlorination as a bioremediation strategy for their removal from anoxic environments.

Plastics

Plastics are classic examples of xenobiotics, and the plastics industry worldwide produces over 40 million tons of plastic per year, almost half of which are discarded rather than recycled. Plastics are polymers of various chemistries (Figure 21.12a). Many plastics remain essentially unaltered for long periods in landfills, refuse dumps, and as litter in the environment. This problem has fueled the search for biodegradable alternatives called **microbial plastics** as replacements for some synthetic plastics.

Polyhydroxyalkanoates (PHAs) are a common bacterial storage polymer (► Section 2.14), and these readily biodegradable polymers have many of the desirable properties of xenobiotic plastics. PHAs can be biosynthesized in various chemical forms, each with its own unique physical properties (stiffness, shear and impact

strength, and the like). A PHA *copolymer* containing equal amounts of poly- β -hydroxybutyrate and poly- β -hydroxyvalerate (Figure 21.12b) has been marketed in Europe as a container for personal care products and has had the greatest success as a plastic substitute thus far (Figure 21.12c). However, because synthetic plastics are currently less expensive than microbial plastics, synthetic petroleum-based plastics make up virtually the entire plastics market today.

The bacterium *Ralstonia eutropha* has been used as a model organism for the commercial production of PHAs. This genetically manipulable and metabolically diverse bacterium produces PHAs in high yield, and specific copolymers can be obtained by simple nutritional modifications. Nevertheless, the microbial plastics industry is burdened by the reality that the best substrates for PHA biosyntheses are glucose and related organic compounds, substances obtained from corn or other crops. And even at today's prices for oil, plant products cannot compete with oil as feedstocks for the plastics industry.

III • Wastewater and Drinking Water Treatment

Water is the most important potential common source of infectious diseases and a potential source for chemically induced intoxications. This is because a single water source often serves large numbers of people, as, for example, in large cities. Everyone in these cities must use the available water, and contaminated water has the potential to spread disease to all exposed individuals. Similarly, appropriate treatment of wastewater is essential for maintaining environmental quality and for reducing the spread of disease.

The outbreak of cholera in Haiti following the 2010 earthquake is a reminder of the importance of well-maintained waste and drinking water treatment systems in securing public health. Here we examine systems built for the chemical and biological treatment of water and the transmission systems used for delivering treated water to consumers. We also examine the human health significance of the microbial ecology that develops within the pipes of municipal water distribution systems and premise plumbing.

21.6 Primary and Secondary Wastewater Treatment

Wastewater is domestic sewage or liquid industrial waste that cannot be discarded in untreated form into lakes or streams due to public health, economic, environmental, and aesthetic considerations. Wastewater treatment employs physical and chemical methods as well as industrial-scale

use of microorganisms. Wastewater enters a treatment plant and, following treatment, the **effluent water**—treated wastewater discharged from the wastewater treatment facility—is suitable for release into surface waters such as lakes and streams or to drinking water purification facilities (Figure 21.13).

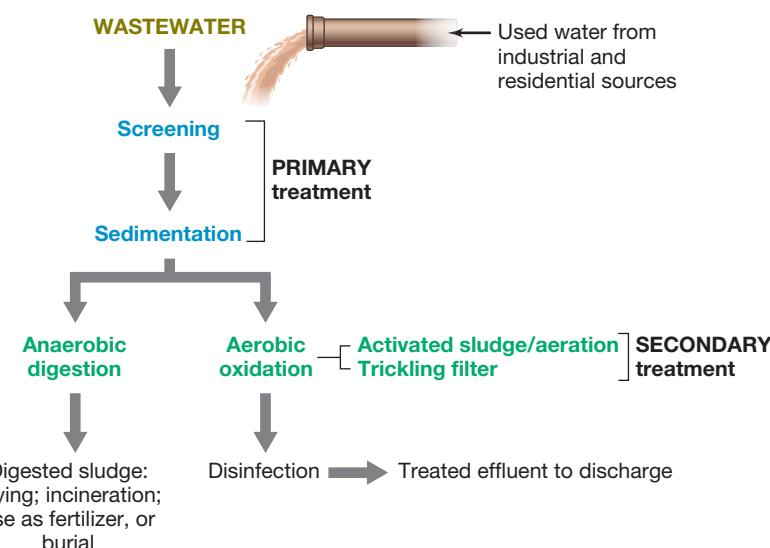

Figure 21.13 Wastewater treatment processes. Effective water treatment plants use the primary and secondary treatment methods shown here. Tertiary treatment may also be used to reduce biochemical oxygen demand (BOD) levels in effluent water to undetectable levels.

Wastewater and Sewage

Wastewater from domestic sewage or industrial sources cannot be discarded in untreated form into lakes or streams. **Sewage** is liquid effluent contaminated with human or animal fecal materials. Wastewater may also contain potentially harmful inorganic and organic compounds as well as pathogenic microorganisms. Wastewater treatment can use physical, chemical, and biological (microbiological) processes to remove or neutralize contaminants.

On average, each person in the United States uses 100–200 gallons of water every day for washing, cooking, drinking, and sanitation. Wastewater collected from these activities must be treated to remove contaminants before it can be released into surface waters. About 16,000 publicly owned treatment works (POTW) operate in the United States. Most POTWs are fairly small, treating 1 million gallons (3.8 million liters) or less of wastewater per day. Collectively, however, these plants treat about 32 billion gallons of wastewater daily. Wastewater plants are usually constructed to handle both domestic and industrial wastes. Domestic wastewater is made up of sewage, “gray water” (the water resulting from washing, bathing, and cooking), and wastewater from small-scale food processing in homes and restaurants.

Industrial wastewater includes liquid discharged from the petrochemical, pesticide, food and dairy, plastics, pharmaceutical, and metallurgical industries. Industrial wastewater may contain toxic substances; some manufacturing and processing plants are required by the U.S. Environmental Protection Agency (EPA) to pretreat toxic or heavily contaminated discharges before they enter POTWs. Pretreatment may involve mechanical processes in which large debris is removed. Some wastewaters are pretreated biologically or chemically to remove highly toxic substances such as cyanide; heavy metals such as arsenic, lead, and mercury; or organic materials such as acrylamide, atrazine (a herbicide), and benzene. These substances are converted to less toxic forms by treatment with chemicals or microorganisms capable of neutralizing, oxidizing, precipitating, or volatilizing these wastes. The pretreated wastewater can then be released to the POTW.

Wastewater Treatment and Biochemical Oxygen Demand

The goal of a wastewater treatment facility is to reduce organic and inorganic materials in wastewater to a level that no longer supports microbial growth and to eliminate other potentially toxic materials. The efficiency of treatment is expressed in terms of a reduction in the **biochemical oxygen demand (BOD)**, the relative amount of dissolved oxygen consumed by microorganisms to completely oxidize all organic and inorganic matter in a water sample (see Section 19.8). High levels of organic and inorganic materials in the wastewater result in a high BOD.

Typical values for domestic wastewater, including sewage, are approximately 200 BOD units. For industrial wastewater from sources such as dairy plants, the values can be as high as 1500 BOD units. An efficient wastewater treatment facility reduces BOD levels to less than 5 BOD units in the final treated water. Wastewater facilities are designed to treat both low-BOD sewage and high-BOD industrial wastes.

Treatment is a multistep operation employing a number of independent physical and biological processes (Figure 21.13). *Primary*, *secondary*, and sometimes additional treatments are employed to

reduce biological and chemical contamination in the wastewater, and each higher level of treatment employs more complex technologies.

Primary Wastewater Treatment

Primary wastewater treatment uses only physical separation methods to separate solid and particulate organic and inorganic materials from wastewater. Wastewater entering the treatment plant is passed through a series of grates and screens that remove large objects. The effluent is allowed to settle for a few hours. Solids settle to the bottom of the separation reservoir and the effluent is drawn off to be discharged or for further treatment (Figure 21.14).

Municipalities that provide only primary treatment discharge extremely polluted water with high BOD into adjacent waterways; high levels of soluble and suspended organic matter and other nutrients remain in water following primary treatment. These nutrients can trigger undesirable microbial growth, further reducing water quality. Most treatment plants employ secondary and even *tertiary* treatments to reduce the organic content of the wastewater before release to natural waterways. Secondary treatment processes use both aerobic and anaerobic microbial digestion to further reduce organic nutrients in wastewater.

Secondary Anaerobic Wastewater Treatment

Secondary anaerobic wastewater treatment involves a series of degradative and fermentative reactions carried out by various prokaryotes under anoxic conditions. Anaerobic treatment is typically used to treat wastewater containing large quantities of insoluble organic matter (and therefore having a very high BOD) such as fiber and cellulose waste from food and dairy plants. The anaerobic degradation process is carried out in large, enclosed tanks called *sludge digesters* or *bioreactors* (Figure 21.15). The process requires the collective activities of many different types of prokaryotes. The major reactions are summarized in Figure 21.15c.

First, anaerobes use polysaccharidases, proteases, and lipases to digest suspended solids and large macromolecules into soluble components. These soluble components are then fermented to yield a mixture of fatty acids, H₂, and CO₂; the fatty acids are

As the water level rises, the water spills through the grates to successively lower levels. Water at the lowest level, now virtually free of solids, enters the spillway (arrow) and is pumped to a secondary treatment facility.

further fermented by the cooperative actions of syntrophic bacteria (Section 13.15) to produce acetate, CO₂, and H₂. These products are then used as substrates by methanogenic Archaea (Section 16.2), fermenting acetate to produce methane (CH₄) and CO₂, the major products of anoxic sewage treatment (Figure 21.15c). The CH₄ is burned off or used as fuel to heat and power the wastewater treatment plant.

Secondary Aerobic Wastewater Treatment

Secondary aerobic wastewater treatment uses oxidative degradation reactions carried out by microorganisms under aerobic conditions to treat wastewater containing low levels of organic materials (Figure 21.16a, b). In general, wastewaters that originate from residential sources can be treated efficiently using only aerobic treatment. Several aerobic degradative processes can be used for wastewater treatment; *activated sludge* methods are the most common (Figure 21.16a, b). Here, wastewater is continuously mixed and aerated in large tanks. Slime-forming aerobic bacteria, including *Zoogloea ramigera* and others, grow and form aggregated masses called flocs (Figure 21.17). The biology of *Zoogloea* is discussed in Section 15.2. Protists, small animals, filamentous bacteria, and fungi attach to the flocs. Oxidation of organic matter occurs on the floc as it is agitated and exposed to air. The aerated effluent containing the flocs is pumped into a holding tank or clarifier where the flocs settle. Some of the floc material (called activated sludge) is then returned to the aerator as inoculum for new wastewater, and the rest is pumped to the anaerobic sludge digester (Figure 21.15) or is removed, dried, and burned, or is used for fertilizer.

Wastewater normally stays in an activated sludge tank for 5–10 hours, a time too short for complete oxidation of all organic matter. However, during this time much of the soluble organic matter is adsorbed to the floc and incorporated by the microbial cells. The BOD of the liquid effluent is considerably reduced (up to 95%) when compared to the incoming wastewater; most of the material with high BOD is now in the settled flocs. The flocs can then be transferred to the anoxic sludge digester for conversion to CO₂ and CH₄.

The *trickling filter* method is also commonly used for secondary aerobic treatment (Figure 21.16c). A trickling filter is a bed of

crushed rocks, about 2 m thick. Wastewater is sprayed on top of the rocks and slowly passes through the bed. The organic material in the wastewater adsorbs to the rocks, and microorganisms grow on the large, exposed rock surfaces. The complete mineralization of organic matter to CO₂, ammonia, nitrate, sulfate, and phosphate takes place in the extensive microbial biofilm that develops on the rocks.

Most treatment plants chlorinate the effluent after secondary treatment to further reduce the possibility of biological contamination. The treated effluent can then be discharged into streams or lakes. In the eastern United States, many wastewater treatment facilities use UV radiation to disinfect effluent water. Ozone (O₃), a strong oxidizing agent that is an effective bactericide and viricide, is also used for wastewater disinfection in some treatment plants in the United States.

21.7 Advanced Wastewater Treatment

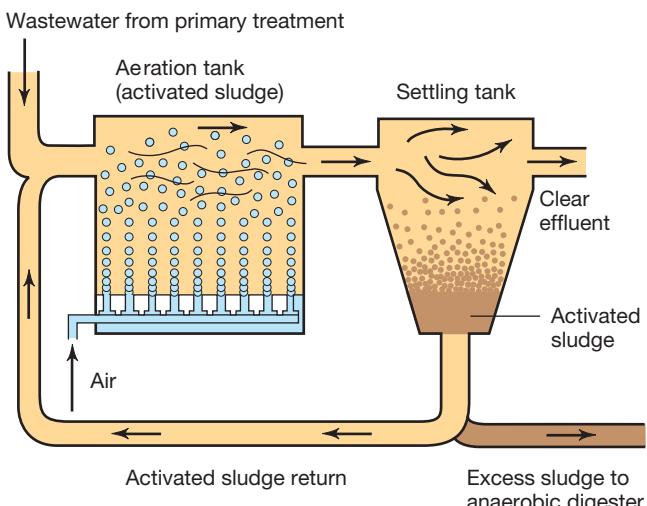

Advanced wastewater treatment is any process designed to produce an effluent of higher quality than normally achieved by secondary treatment. It includes tertiary treatment, physical-chemical treatment, or combined biological-physical treatment. **Tertiary wastewater treatment** is defined as any treatment process in which unit operations are added for the further processing of the secondary treatment effluent.

Typical goals of advanced treatment include additional removal of organic matter and suspended solids, removal of key inorganic nutrients required for microbial growth (including ammonia, nitrate, nitrite, phosphorus, or dissolved organic carbon), and

degradation of any potentially toxic materials. Advanced water treatment is the most complete method of treating sewage but has not been widely adopted due to the costs associated with such complete nutrient removal. Here we examine biological removal of phosphorus and trace contaminants, two areas of advanced treatment of increasing importance to wastewater treatment.

Biological Phosphorus Removal

Conventional secondary biological treatment removes only about 20% of phosphorus from wastewater, necessitating additional chemical or biological treatment. Chemical precipitation is the most commonly used process, removing up to 90% of the influent phosphorus. Removal is accomplished by the addition of either Fe or Al as chloride or sulfate salts, with Fe^{2+} or Fe^{3+} salts more commonly used. At near-neutral pH, the Fe^{3+} forms insoluble ferric phosphate (FePO_4) or ferric hydroxide-phosphate complexes. These then precipitate and are removed as sludge.

The chemical precipitation process results in up to 95% more sludge, contributing to additional disposal problems. As an alternative, tertiary treatment that encourages the growth of phosphorus-accumulating bacteria can also remove up to 90% of phosphorus, a process called *enhanced biological phosphorus removal (EBPR)*. Here the waste stream is processed by sequential passage through anaerobic and aerobic bioreactors (Figure 21.18). In the anaerobic reactor, *phosphorus-accumulating organisms (PAOs)* use energy available from stored polyphosphate to assimilate short-chain fatty acids, and produce intracellular polyhydroxyalkanoates (PHAs) (Figure 21.18a; [Section 2.14](#)); as this occurs, soluble orthophosphate (PO_4^{3-}) is released. During the following aerobic phase of treatment, the stored PHA is metabolized, providing energy and carbon for new cell growth. The energy is used to form intracellular polyphosphate,

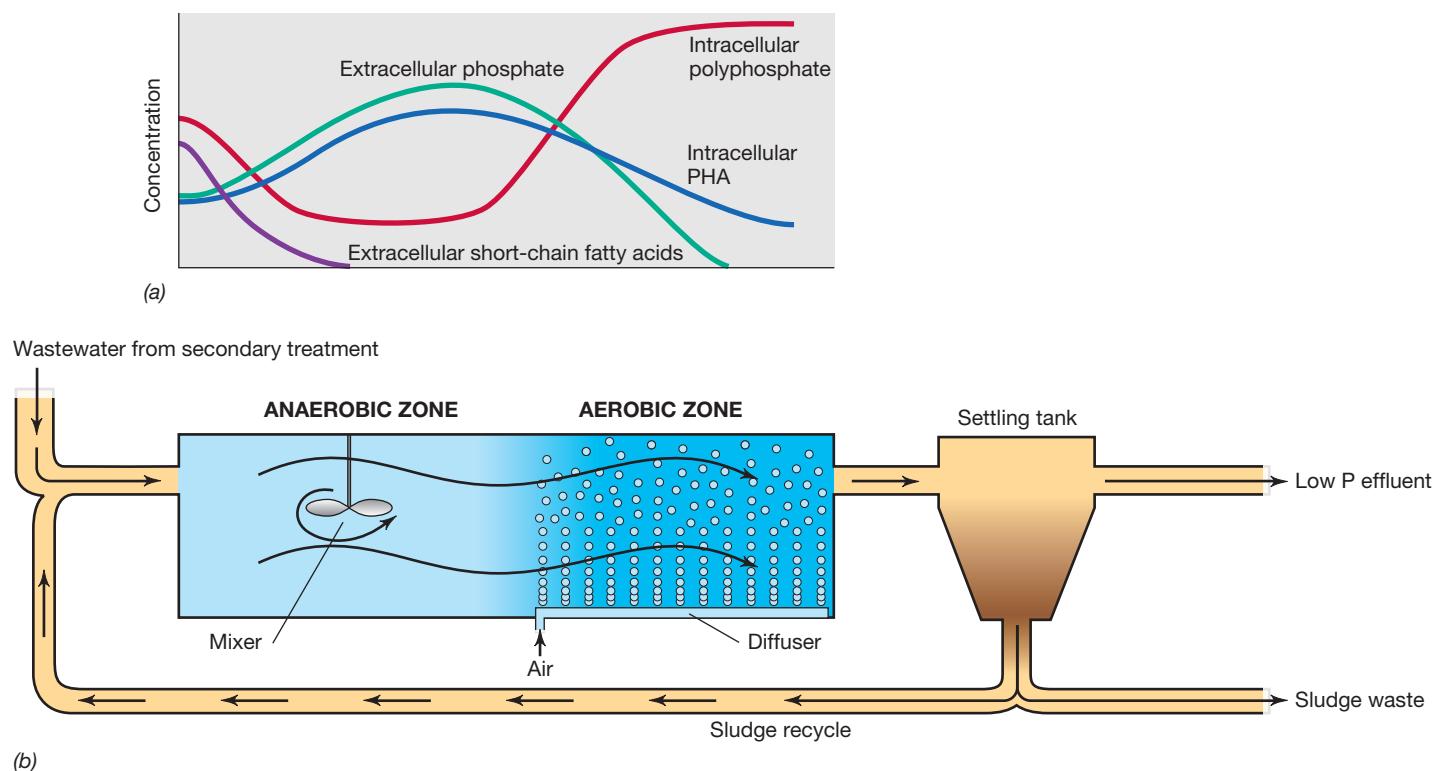

Figure 21.18 Enhanced biological phosphorus removal process. During passage through the reactor system the microbial community transitions from anaerobic to aerobic growth. In the anaerobic zone, short-chain fatty acids are taken up and internal stores of polyphosphate (polyP) are released as extracellular orthophosphate. In the aerobic zone, the extracellular phosphate is reassimilated as polyP and the intracellular stores of polyhydroxyalkanoates (PHAs) are metabolized. High-phosphorus sludge is harvested for disposal.

removing orthophosphate from solution (Figure 21.18a). The new biomass (sludge) with high polyphosphate content is then collected for phosphorus removal (Figure 21.18b).

The EBPR process sometimes fails due to the overgrowth of competing microbial populations, commonly microorganisms that accumulate glycogen as opposed to phosphorus, thus rendering the process less efficient. Hence, better control of the process will require improved understanding of the ecology and physiology of the PAOs. Recent progress in this area has been made with identification of one of the principal PAOs, *Accumulibacter phosphatis*. *A. phosphatis* is part of a clade of related phosphorus-accumulating *Betaproteobacteria* (Section 15.2) that have been identified in different EBPR systems. Although no pure cultures are yet available, laboratory reactor systems enriched in these organisms are now providing insight into operating conditions necessary for stable operation of the EBPR.

Contaminants of Emerging Concern

Until recently, studies of the environmental fate of chemicals have focused primarily on priority pollutants, including heavily used agricultural products and chemicals that demonstrate acute toxicity or carcinogenicity. However, it is now clear that new bioactive pollutants are entering the environment and will likely pose new challenges for microbial bioremediation. These pollutants include pharmaceuticals, active ingredients in personal care products, fragrances, household products, sunscreens, and many other unusual or xenobiotic molecules.

Unlike pesticides, these “new” pollutants are more or less continuously discharged to the environment primarily through release of treated or untreated sewage, and because of this, they do not need to persist to have environmental effects. For example, it is known that synthetic estrogen compounds, excreted in the urine of women taking birth control pills and eventually discharged from wastewater treatment plants, can activate estrogen response genes in aquatic animals such as fish and contribute to the feminization of males.

Wastewater treatment plants were originally designed to handle natural materials, primarily human and industrial wastes, but now there is a growing interest in carefully researching the design of future treatment facilities to stimulate bioremediation of these emerging contaminants. Because these contaminants are often present in very low concentrations and are often new classes of xenobiotic chemicals, they may not actually support microbial growth but be degraded only by cometabolism or by highly specialized species. We can therefore expect that the bioremediation of emerging contaminants will be an active area of microbiological research and public policy in coming years.

21.8 Drinking Water Purification and Stabilization

Wastewater treated by secondary methods can usually be discharged into rivers and streams. However, such water is not **potable** (safe for human consumption). The production of potable water requires further treatment to remove potential pathogens, eliminate taste and odor, reduce nuisance chemicals such as iron and manganese, and decrease **turbidity**, which is a measure of suspended solids. **Suspended solids** are small particles of solid pollutants that resist separation by ordinary physical means.

Intestinal infections due to waterborne pathogens are still common, even in developed countries (🔗 Section 31.1), and some estimates indicate that waterborne diseases impact the health of several million people each year in the United States alone. Water treatment practices, however, have significantly improved access to safe water, starting with public works projects coupled with the application and development of water microbiology in the early twentieth century.

A century ago, water purification in the United States was limited to *filtration* to reduce turbidity, and this resulted in high rates of waterborne disease. Although filtration significantly decreased the microbial load of water, many microorganisms still passed through the filters. However, around 1913, **chlorination** using Cl_2 came into use as a disinfectant for large water supplies. Chlorine gas was an effective and inexpensive general disinfectant for drinking water, and its use quickly reduced the incidence of waterborne disease (🔗 Section 28.5). Major improvements in public health in the United States were largely due to the adoption of water filtration and disinfection treatment procedures. Public works engineering and microbiology working hand in hand were thus the major contributors to the dramatic advances in public health in the United States and other developed countries in the twentieth century.

Physical and Chemical Purification

A typical city installation for drinking water treatment is shown in **Figure 21.19a**. Figure 21.19b shows the process that purifies **raw water**

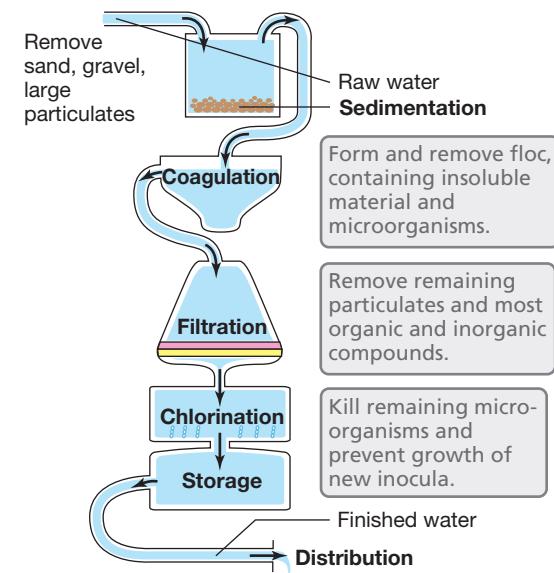

(a)

(also called **untreated water**) that flows through the treatment plant. Raw water is first pumped from the source, in this case a river, to a sedimentation basin where anionic polymers, alum (aluminum sulfate), and chlorine are added. **Sediment**, including soil, sand, mineral particles, and other large particles, settles out. The sediment-free water is then pumped to a **clarifier** or coagulation basin, which is a large holding tank where **coagulation** takes place. The alum and anionic polymers form large particles from the much smaller suspended solids. After mixing, the particles continue to interact, forming large, aggregated masses, a process called **flocculation**. The large, aggregated particles (floc) settle out by gravity, trapping microorganisms and adsorbing suspended organic matter and sediment.

After coagulation, flocculation, and sedimentation, the clarified water undergoes **filtration** through a series of filters designed to remove organic and inorganic solutes, as well as remaining suspended particles and microorganisms. The filters typically consist of thick layers of sand, activated charcoal, and ion exchangers. When combined with previous purification steps, the filtered water is free of particulate matter, most organic and inorganic chemicals, and nearly all microorganisms.

Disinfection

Clarified, filtered water must be disinfected before it is released to the supply system as pure, potable **finished water**. **Primary disinfection** is the introduction of sufficient disinfectant into clarified, filtered water to kill existing microorganisms and inhibit further microbial growth. Chlorination is the most common method of primary disinfection. In sufficient doses, chlorine kills most microorganisms within 30 minutes. A few pathogenic protists such as *Cryptosporidium*, however, are not easily killed by chlorine treatment (🔗 Sections 28.7 and 32.4). In addition to killing microorganisms, chlorine oxidizes and effectively neutralizes many organic compounds. Since most taste- and odor-producing chemicals are organic compounds, chlorination improves water taste and smell. Chlorine is added to water either from a concentrated solution of sodium hypochlorite or calcium hypochlorite, or as chlorine gas

(b)

from pressurized tanks. Chlorine gas is commonly used in large water treatment plants because it is most amenable to automatic control. When dissolved in water, chlorine gas is extremely volatile and dissipates within hours from treated water. To maintain adequate levels of chlorine for primary disinfection, many municipal water treatment plants introduce ammonia gas with the chlorine to form the more stable, nonvolatile chlorine-containing compound **chloramine**, HOCl + NH₃ → NH₂Cl + H₂O.

Chlorine is consumed when it reacts with organic materials. Therefore, sufficient quantities of chlorine must be added to finished water containing organic materials so that a small amount, called the *chlorine residual*, remains. The chlorine residual reacts to kill any remaining microorganisms. The water plant operator performs chlorine analyses on the treated water to determine the level of chlorine to be added for **secondary disinfection**, the maintenance of sufficient chlorine residual or other disinfectant residual in the water distribution system to inhibit microbial growth. A chlorine residual level of 0.2–0.6 mg/liter is suitable for most water supplies. After chlorine treatment, the now potable water is pumped to storage tanks from which it flows by gravity or pumps through a **distribution system** of storage tanks and supply lines to the consumer. Residual chlorine levels inhibit growth of bacteria in the finished water prior to reaching the consumer. It does not protect against catastrophic system failures such as a broken pipe in the distribution system.

Ultraviolet (UV) radiation is also used as an effective means of disinfection. As we discussed in Section 5.18, UV radiation is used to treat secondarily treated effluent from water treatment plants. In Europe, UV irradiation is commonly used for drinking water applications, and it is increasingly used in the United States. For disinfection, UV light is generated from mercury vapor lamps. Their major energy output is at 253.7 nm, a wavelength that is bacteriocidal and may also kill cysts and oocysts of protists such as *Giardia* and *Cryptosporidium*, important eukaryotic pathogens in water (☞ Section 32.4). Viruses, however, are more resistant.

UV radiation has several advantages over chemical disinfection procedures like chlorination. First, UV irradiation is a physical process that introduces no chemicals into the water. Second, UV radiation–generating equipment can be used in existing flow systems. Third, no disinfection by-products are formed with UV disinfection. Especially in smaller systems where finished water is not pumped long distances or held for long periods (reducing the need for residual chlorine), UV disinfection may be preferable to reduce dependence on chlorination.

21.9 Municipal and Premise Water Distribution Systems

Once drinking water leaves the treatment facility, the water often travels through many miles of municipal and premise distribution

pipes from the facility to the consumer (Figure 21.20). In addition to taste and odor problems often associated with source water, the long transit and residence times may also contribute to undesirable taste and odors from biological and chemical processes. Although undesirable, taste and odor alone usually do not signal a health threat. However, water distribution systems may also promote the growth of obligate or opportunistic pathogens, sequester and protect pathogens, or select for more pathogenic and resistant forms of microorganisms. Even though drinking water–associated disease often goes unreported, in the United States alone between 2007–2008, 36 disease outbreaks associated with drinking water affected at least 4000 persons and were linked to three deaths.

The Microbiology of Municipal Water Distribution Systems

Microbial growth in drinking water distribution systems can be eliminated only through complete nutrient removal (elimination of growth substrates originating from the source water and from distribution system structural materials) or by maintaining appropriate residual chlorine levels throughout the distribution system. In reality, neither of these is attainable. Growth is unavoidable as a consequence of reduction in chlorine concentration with increasing distance from the point of production together with the tendency for microorganisms to form biofilms on the pipe walls. Microorganisms in biofilms are more resistant to disinfection (☞ Section 19.4) and significant

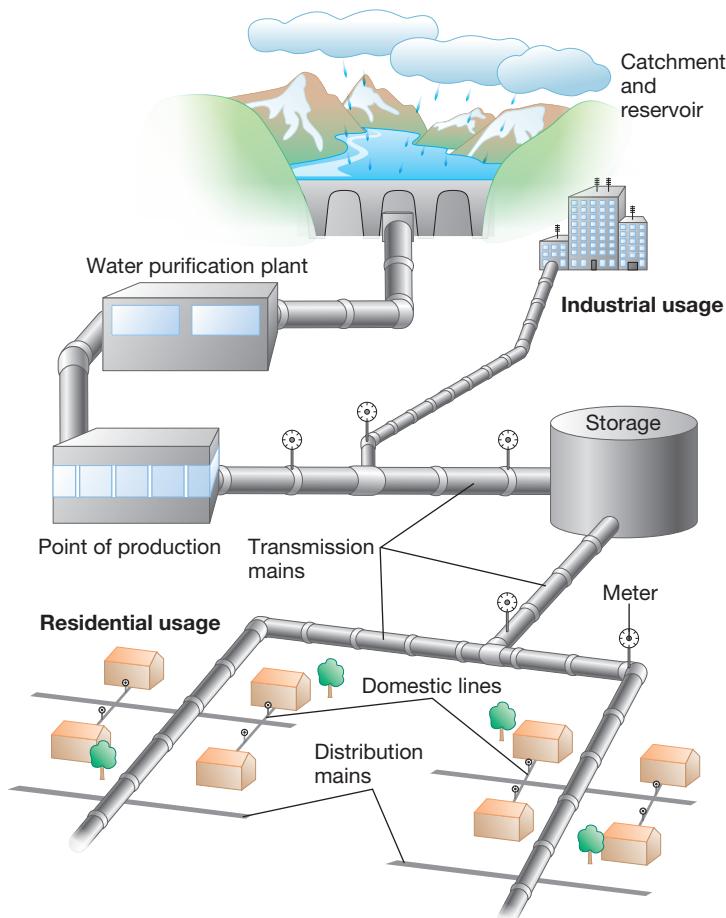

Figure 21.20 Drinking water distribution system. A municipal distribution system includes a surface reservoir, water purification plant, distribution mains, and domestic lines that encompass many miles of pipes in a typical community.

microbial accumulation is found in all distribution systems, over 90% of which is in the form of biofilms that coat the pipe walls.

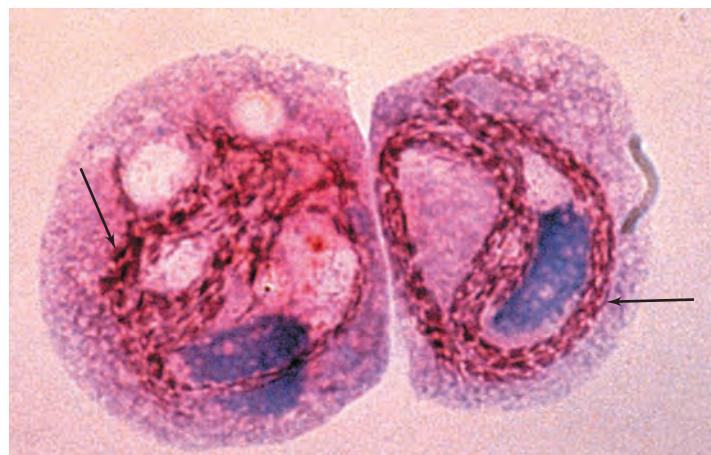

Only recently have culture-independent molecular techniques, including 16S rRNA sequence analysis (Section 18.5), begun to fully resolve the species that commonly colonize water distribution pipes. Although these studies are showing that pathogenic species are rare, some opportunistic pathogens (Section 23.6) are present and can infect susceptible humans, including infants and the elderly or individuals with compromised immune systems. Opportunistic pathogens that have been found in water distribution systems include (1) nontuberculous mycobacteria (including *Mycobacterium avium*, *M. intracellulare*, *M. kansasii*, and *M. fortuitum*) associated with many thousands of clinical cases each year in the United States; (2) *Legionella pneumophila* (the causative agent of Legionnaires' disease, Section 31.4); (3) *Pseudomonas aeruginosa* (which can infect the eyes, ears, skin, and lungs); and (4) opportunistic protozoan pathogens such as *Naegleria* and *Acanthamoeba* (Section 32.3) that can cause keratitis and encephalitis.

Because infection by these and other opportunistic pathogens is often of unclear origin and much waterborne disease goes unreported, the significance of water distribution systems as a source (or reservoir) for pathogenic microorganisms is unclear. However, because of the potential large-scale health risk, the issue of pathogens in drinking water has been receiving much greater attention in recent years, including the use of molecular microbial ecology (Chapter 18) to investigate the problem.

Water distribution systems also support numerous grazing protists that subsist by consuming bacteria. As many as 300 amoebae/cm² have been observed in some water distribution systems. Bacteria that survive and replicate following ingestion by these protists are potentially also less susceptible to clearance by the mammalian immune system. The best example of this is *Legionella*, an opportunistic pathogen that has emerged as a relatively new public health risk because of its ability to establish residence and replicate in protists inhabiting water handling systems (Figure 21.21), including premise plumbing, shower heads, and air conditioning systems. The basic cellular mechanisms *Legionella* uses to gain entry and replicate in a broad variety of protists (including *Acanthamoeba*, *Hartmannella*, *Naegleria* and *Tetrahymena*) also allow it to more easily infect human cells. It has even been suggested that protists have been the driving force in the evolution of pathogenic *Legionella*. Opportunistic pathogens now recognized to have the ability to survive or grow within protists include *Legionella*, *Pseudomonas*, and *Mycobacterium* species.

The Microbiology of Premise Water Distribution Systems

One of the best-recognized microbiological concerns with premise water is *Legionella pneumophila* (Section 31.4). This

CDC/Don Howard

Figure 21.21 Protists as reservoirs of *Legionella*. Two cells of the protist *Tetrahymena* contain chains of the rod-shaped pathogen *Legionella pneumophila* (arrows). In premise water systems, protists can persist and be reservoirs of bacterial pathogens.

pathogen multiplies in premise water systems at temperatures between 20 and 46°C. It survives for months in drinking water, and survival is augmented by the presence of other bacteria and protozoa—in which intracellular growth is possible (Figure 21.21)—and also through sequestration in biofilms. Temperatures greater than 50°C lead to a decrease in numbers, and temperatures greater than 60°C result in rapid elimination (cell death). Thus, to prevent growth of *L. pneumophila*, premise water must be kept below 20°C or above 50°C from storage units to the tap.

Nontuberculous mycobacteria (including *Mycobacterium avium*, *M. intracellulare*, *M. kansasii*, and *M. fortuitum*) are also more resistant to chlorine disinfection and protozoal grazing, and are now known to be enriched in showerheads receiving municipal water that still shows a chlorine residual. As yet the significance of showers as a reservoir of opportunistic pathogens is unknown. However, the increasing frequency of showering as opposed to bathing, and possible aerosolization of opportunistic pathogens through showering, has prompted additional research in this area. The general picture that is emerging is that changes in treatment processes and the architecture of water distribution systems, coupled with the aging condition of some systems, can compromise human health.

IV • Microbially Influenced Corrosion

Many billions of dollars' worth of metal, stone, and concrete infrastructure is lost to corrosion every year. Corrosion is a complex process that may be influenced and accelerated by microbial activity. Microorganisms accelerate corrosion through alteration of pH or redox, production of corrosive metabolites, and creation of corrosive microenvironments in biofilms. However,

since the balance between chemistry and biology is often not well resolved, corrosion in which microorganisms are implicated is referred to as **microbiologically influenced corrosion (MIC)**.

In this section we examine a few cases in which the microbial contribution to corrosion is relatively well understood. However, it is likely that the general models for MIC will be modified as we

learn more about how microorganisms interact with and modify different structural materials.

21.10 Microbially Influenced Corrosion of Metals

Iron is the most commonly used metal in the built environment. On a global basis, millions of miles of water, gas, and oil distribution pipelines are made of metal, and their corrosion contributes to the greatest loss of infrastructure in the built environment. Corrosion of iron by oxygen in air is thought to be solely an electrochemical process. However, much critical infrastructure is buried or submerged, restricting exposure to oxygen. At near-neutral pH, in the absence of oxygen, corrosion of iron and steel is significantly accelerated by microbial activity. Microbial groups implicated in MIC include sulfate reducers (Sections 13.18 and 14.9), ferric-iron-reducing bacteria (Sections 14.14 and 20.5), ferrous-iron-oxidizing bacteria (Sections 13.9, 14.15, and 20.5), and methanogens (Sections 13.20, 16.2, and 20.2).

Metal Corrosion by Sulfate-Reducing Bacteria

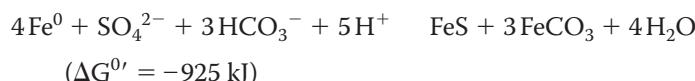

Metal structures submerged in the marine environment and pipelines used for transmission of low-grade oil are particularly subject to MIC through the activities of sulfate-reducing microorganisms. Corrosion by sulfate-reducing bacteria is partly attributable to the chemically corrosive nature of hydrogen sulfide (H_2S), the product of their metabolism (Section 14.9). Crude oils containing more than about 0.5% sulfur by weight are called “sour” and may be naturally corrosive because of the H_2S that is present. In oilfields near the ocean, such as the Middle East and Alaska, seawater is injected to maintain reservoir pressure and force oil into the producing well. Since seawater contains nearly 30 mM sulfate, an undesirable consequence of injection is further souring by stimulating the growth of sulfate-reducing microorganisms.

A strategy now used by the petroleum industry to control souring is inclusion of nitrate (NO_3^-) in the injection water, stimulating the growth of nitrate-reducing microorganisms. Since nitrate respiration is energetically more favorable than sulfate respiration (Sections 13.17 and 19.2), the nitrate reducers outcompete sulfate

reducers for usable organic electron donors in the oil. Nitrate also stimulates the growth of sulfide-oxidizing, nitrate-reducing microorganisms (Sections 13.8 and 14.11), thereby reversing the souring by removing the sulfide.

Mechanisms of Metal Corrosion

The mechanisms by which sulfate reducers contribute directly to corrosion are more controversial, as now represented by two major competing models. One model is based on the “cathodic depolarization theory,” in which hydrogen consumption by the sulfate reducer accelerates electrochemical pitting of the iron surface (Figure 21.22a). This model is based on the capacity of many sulfate reducers to use hydrogen (H_2) as an electron donor, thereby accelerating the energetically favorable but kinetically slow H_2 production originating from the chemical oxidation of iron ($Fe + 2H^+ \rightarrow Fe^{2+} + H_2$), with the following overall stoichiometry, whose free energy change (ΔG°) is highly favorable:

However, this model has been questioned because H_2 formation from the iron surface at neutral pH is an intrinsic bottleneck, controlled by the limited availability of protons required for the reactions generating H_2 .

Detailed electrochemical studies have since shown that some sulfate-reducing bacteria, such as *Desulfovibrio corrodens*, have the capacity to take up electrons directly from the metal (Fe^0 , Figure 21.22b). In this model, the sulfate reducers attached to the metal surface engage in direct (cathodic) electron uptake from the metal through an electroconductive sulfidic corrosion layer (Figure 21.22b). A similar ability to take up electrons directly from Fe^0 has been observed for a *Methanobacterium*-like methanogen that produces methane (CH_4) rather than sulfide from growth on elemental iron. The direct electron uptake model also suggests that associated with the cell surface are redox-active proteins, or other conductive structures, that conduct electrons from the corrosion layer to the cell. This represents yet another of a growing number

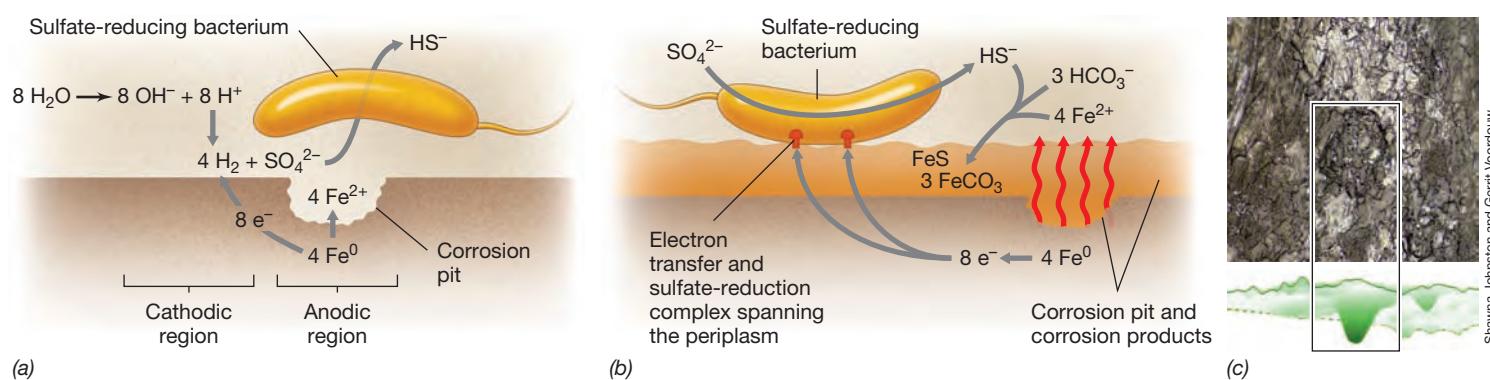

Figure 21.22 Corrosion of iron by sulfate-reducing bacteria. Two models for the activities of sulfate-reducing bacteria in metal corrosion. of examples of the microbial use of conductive cellular structures for the oxidation or reduction of insoluble electron acceptors or electron donors, respectively (☞ Sections 14.14 and 20.5).

MINIQUIZ

- How does a nitrate addition prevent sulfide souring of crude oil?
- Why is accelerated microbial corrosion of iron metal thought to require a direct interaction between the sulfate reducers and the metal surface?

21.11 Biodeterioration of Stone and Concrete

In the same way that microorganisms contribute to soil formation through the dissolution of mineral surfaces through combined physical and metabolic activities (☞ Section 19.6), building materials composed of natural stone or concrete are also subject to microbial colonization that may contribute to a slow loss of structural integrity through their metabolic activities. This process is referred to as *biodeterioration*.

Biodeterioration of Stone Building Materials

Microbial colonization of natural and structural stone building material is ubiquitous. Microorganisms can colonize the surface and penetrate several millimeters into rocky material depending on its physical characteristics (e.g., surface roughness, porosity, light penetration). Organisms can also grow on and within the facades of buildings constructed of limestone, sandstone, granite, basalt, and soapstone. These “within stone,” or *endolithic*, communities (☞ Section 17.16) are phylogenetically diverse, comprised of chemorganotrophic and chemolithotrophic *Bacteria*, *Archaea*, fungi, algae, and cyanobacteria. The cyanobacteria and algae primarily nourish the community, living in close or symbiotic association with other microbial members. For example, endolithic fungi have been observed to enclose the phototrophs in lichen-like associations.

Although not generally included in discussions of “extreme environments,” life on and within stone building materials requires adaptation to multiple extreme conditions, including intense solar radiation, desiccation, temperature and moisture fluctuations, and lack of nutrients. Protection from solar radiation is conferred by production of UV-absorbing pigments (for example, melanin, mycosporines, and carotenoids) by fungi and other community members. The fungi also play a central role in this process of slow biodeterioration through the production of oxalic acid, which dissolves and mobilizes mineral constituents of the stone. Mineral dissolution and mobilization provides the communities with nutrients and is believed to increase habitability by enlarging pore spaces within the stone and thereby accelerating deterioration.

Crown Corrosion of Wastewater Distribution Systems

A very rapid form of microbial biodeterioration is observed in the **crown corrosion** of concrete sewer tiles, a process leading ultimately to the collapse of the pipe. Corrosion is a consequence of a complex ecology between sulfate-reducing bacteria (☞ Sections 13.18 and 14.9) and chemolithotrophic sulfur-oxidizing bacteria (☞ Sections 13.8 and 14.11) in these underground wastewater transmission systems (Figure 21.23).

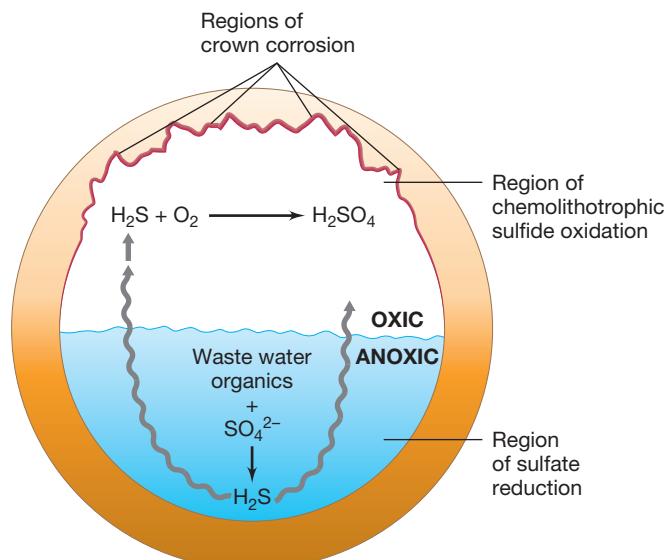

Figure 21.23 Crown corrosion of concrete sewer pipes. Corrosion is the result of a microbial sulfur cycle that develops within the transmission pipe. Sulfate-reducing bacteria consume organic material in the anoxic wastewater, producing H_2S . The latter is oxidized by sulfur-oxidizing chemolithotrophic bacteria that attach to the oxic upper (crown) pipe surface, accelerating corrosion from the production of H_2SO_4 (sulfuric acid).

The first step in crown corrosion is the reduction of sulfate in the sewage to H_2S by sulfate-reducing bacteria, using primarily organic electron donors available in the waste stream water for sulfate reduction. The H_2S then flows into the headspace of the pipe where conditions are oxic. The sulfide, or partially oxidized intermediates such as thiosulfate or sulfur, is then oxidized by neutrophilic thiobacilli such as *Thiobacillus thioparus* (☞ Section 14.11). As the pH drops to 4–5 with continued microbial production of sulfuric acid, acidophilic sulfur-oxidizing species such as *Acidithiobacillus thiooxidans* displace the neutrophilic species. Destruction and ultimate structural failure of the concrete results from reaction of sulfuric acid with the free lime in the concrete, producing $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (gypsum) that penetrates into the concrete. The gypsum then reacts with calcium aluminate in the concrete, leading to the production of $(\text{CaO})_3(\text{Al}_2\text{O}_3)(\text{CaSO}_4)_3 \cdot 32\text{H}_2\text{O}$ (ettringite), which by increasing internal pressure contributes to cracking and further acceleration of the corrosion process.

A series of steps and microbial ecology similar to that of crown corrosion contributes to the corrosion of concrete holding tanks and cooling towers, particularly those in or near the marine environment. In the United States alone such corrosion consumes many billions of dollars a year for replacement structures and control of the progressing corrosion.

MINIQUIZ

- How does the production of oxalic acid by fungi contribute to the deterioration of stone building materials?
- Prior to better regulatory control of metal release into domestic wastewater systems, crown corrosion of sewer tiles was less of a problem. Why?

BIG IDEAS

21.1 • The capacity of bacteria to oxidize Fe^{2+} aerobically at acidic pH is used to mine metals, principally copper-, uranium-, and gold-containing low-grade ores, through a process called microbial leaching. Bacterial oxidation of Fe^{2+} to Fe^{3+} is the key reaction in most microbial leaching processes because Fe^{3+} can oxidize extractable metals in the ores under either oxic or anoxic conditions.

21.2 • Spontaneous microbial oxidation of ferrous iron in pyritic ore or coal that has been exposed to air and water, such as occurs during some coal-mining operations, causes a type of pollution called acid mine drainage.

21.3 • Although an inorganic pollutant such as uranium cannot be destroyed, containment is possible by reducing its mobility. For example, metal-reducing microorganisms in a region of uranium contamination can be stimulated to reduce U^{6+} to U^{4+} , forming an immobile uranium mineral, *uraninite*, that does not move into the groundwater.

21.4 • Hydrocarbons are excellent carbon sources and electron donors for bacteria and are readily oxidized when O_2 is available. Hydrocarbon-oxidizing bacteria bioremediate spilled oil, and their activities can be assisted by addition of inorganic nutrients.

21.5 • Some xenobiotics (chemicals new to nature) persist, whereas others are readily degraded, depending on their chemistries. Dechlorination is a major means of detoxifying xenobiotics that reach anoxic environments. With the exception of readily degradable microbial plastics, recalcitrant synthetic plastics are major environmental concerns.

21.6 • Sewage and industrial wastewater treatment reduces the BOD of wastewater. Primary, secondary, and tertiary wastewater treatment employs physical, biological, and physicochemical processes. After secondary or tertiary treatment, effluent water has significantly reduced BOD and is suitable for release into the environment.

21.7 • Advanced wastewater treatment, such as enhanced biological phosphorus removal, is used to improve the quality of the treated wastewater. Of increasing concern are pharmaceuticals and ingredients in personal care products that are not degraded by conventional treatment systems and can have adverse environmental effects even at very low concentrations.

21.8 • Drinking water purification plants employ industrial-scale physical and chemical systems that remove or neutralize biological, inorganic, and organic contaminants from natural, community, and industrial sources. Water purification plants employ clarification, filtration, and chlorination processes to produce potable water.

21.9 • The many miles of pipes for municipal drinking water distribution systems and premise plumbing have created new microbial habitats. Most microorganisms are associated with the pipe walls as biofilms, resulting in a community that is more resistant to chlorine and that can sustain or sequester opportunistic pathogenic bacteria, such as *Mycobacterium*, *Legionella*, and *Pseudomonas*. The ability of some of these to grow within protist cells may increase their pathogenicity.

21.10 • Corrosion of metal structures exposed to the environment can be accelerated by microbial activity during microbially influenced corrosion. Structures in or near seawater are particularly prone to corrosion as a consequence of the direct and indirect activities of sulfate-reducing bacteria.

21.11 • Microbial contribution to the structural degradation of stone and concrete is called biodeterioration. Complex microbial communities colonize the stone and produce substances that dissolve and mobilize its mineral constituents. Crown corrosion of concrete sewer lines results from the concerted activities of sulfate-reducing and sulfur-oxidizing bacteria growing within the wastewater and the headspace of sewer pipes, respectively. Sulfuric acid is primarily responsible for the destruction of the concrete.

A Symbiotic Trio Sustains Seagrass Ecosystems

Seagrass meadows function as keystone habitats for various animals that live in coastal areas, including fish, migrating corals, water birds, and turtles. Seagrasses (top photo) also protect coastlines from erosion and function as important carbon and nutrient sinks. However, the remarkable success of seagrasses in temperate to tropical waters is enigmatic; how do these plants avoid being poisoned by the highly toxic hydrogen sulfide produced by sulfate-reducing bacteria that are especially active in coastal sediments? A research study has now solved this mystery.

The success of seagrass ecosystems is linked to the activities of a small clam (bottom photos), one of a variety of lucinid bivalve species that live near the root systems of the seagrass.¹ The clam functions as a sulfide sink, using oxygen released from roots of the seagrass to oxidize the sulfide. The ability of the clam to oxidize sulfide is in turn the result of its symbiotic association with sulfide-oxidizing bacteria residing in its gill tissue. These chemolithotrophic bacteria synthesize sugars that sustain both themselves and the clams. Experiments in which the seagrass was grown in isolation or in association with the clam confirmed the key role of the clams in sulfide depletion, thereby enhancing the growth of the plant.

Field surveys of seagrass beds confirmed a global association between lucinids and seagrass, and paleo-records show this association has existed ever since seagrasses evolved around 100 million years ago. The ecological success of seagrass can thus be attributed to a long and remarkably successful partnership between plant, animal, and bacterium—a symbiotic trio. An understanding of the importance of this unique partnership is essential for the restoration of seagrass meadows in coastal areas where these critical habitats are in decline from pollution.

In this chapter we consider relationships of microorganisms with other microorganisms or with macroorganisms—prolonged and intimate relationships of a type called **symbiosis**, a word that means “living together.” Microorganisms that live within or on plants and animals can be grouped according to how they affect their hosts. *Parasites* are microorganisms that benefit at some expense to the host, *pathogens* actually cause a disease in the host, *commensals* have no discernible effect on the host, and *mutualists* are beneficial to the host. One way or another, all microbial symbioses benefit the microorganism.

Pathogenic and parasitic associations will be addressed in Chapter 23 and in following chapters covering specific infectious

diseases. In this chapter we focus on **mutualisms**—relationships in which both partners benefit. We view the microorganisms as intimate evolutionary partners that influence both the evolution and physiology of their hosts. Many mutualistic symbioses of microorganisms with plants and animals have their origins many millions of years ago. A mutualism that persists over evolutionary time beneficially modifies the physiology of both partners. This process of reciprocal change between a microorganism and its host is called **coevolution**, and over time, the changes may be so extensive that the symbiosis becomes obligate—either the microorganism or the host (or both) cannot survive independent of the other.

I • Symbioses between Microorganisms

Many microbial species—both prokaryotes and eukaryotes—have intimate and beneficial associations with other microbial species. Direct microscopic observations of natural samples show that many microorganisms are not solitary entities but are associated with other microorganisms on surfaces or as suspended aggregates of cells. In most cases, the advantages conferred by an association are unknown. Because microbial ecologists have recognized that *communities* of interacting microbial populations—not individual organisms—control critical environmental processes, research to discover the advantages of strictly microbial symbioses has increased. We present in Part I two types of microbial mutualisms where the advantages to both partners are clear.

22.1 Lichens

Lichens are readily visible leafy or encrusting microbial symbioses often found growing on bare rocks, tree trunks, house roofs,

(a)

(b)

Figure 22.1 Lichens. (a) A lichen growing on a branch of a dead tree. (b) Lichens coating the surface of a large rock.

and bare soils—surfaces where other organisms typically do not grow (**Figure 22.1**). A lichen is a mutualistic association between two microorganisms, a fungus and either an alga or a cyanobacterium. The alga or cyanobacterium is the phototrophic partner and produces organic matter, which then feeds the fungus. The fungus, unable to carry out photosynthesis, provides a firm anchor within which the phototrophic partner can grow, protected from erosion by rain or wind. Cells of the phototroph are embedded in defined layers or clumps among cells of the fungus (**Figure 22.2**). The morphology of a lichen is primarily determined by the fungus, and many fungi are able to form lichen associations. Diversity among the phototrophs is much lower, and many different kinds of lichens can have the same phototrophic partner. Many cyanobacteria that partner in lichens are nitrogen-fixing species, organisms such as *Anabaena* or *Nostoc* (☞ Sections 3.17 and 14.3).

The fungus clearly benefits from associating with the phototroph in the lichen symbiosis, but how does the phototroph

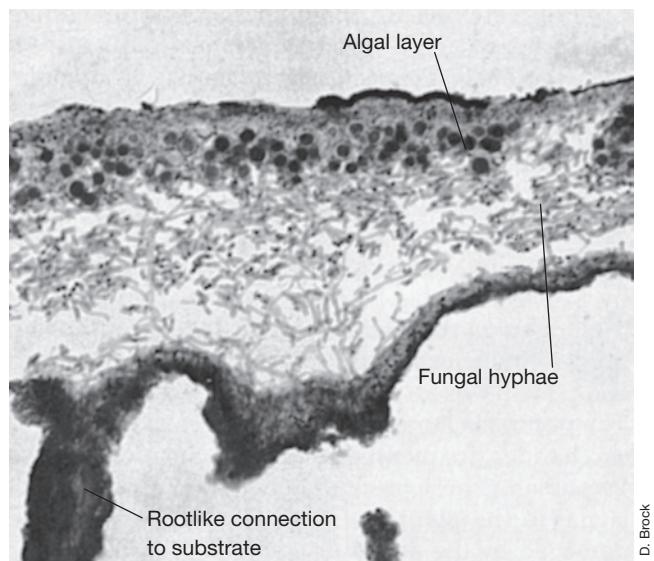

Figure 22.2 Lichen structure. Photomicrograph of a cross section through a lichen. The algal layer is positioned within the lichen structure near the top so as to receive the most sunlight.

benefit? *Lichen acids*, complex organic compounds secreted by the fungus, promote the dissolution and chelation of inorganic nutrients from the rock or other surface that are needed by the phototroph. Another role of the fungus is to protect the phototroph from drying; most of the habitats in which lichens live are dry, and fungi are, in general, better able to tolerate dry conditions than are the phototrophs. The fungus actually facilitates the uptake of water and sequesters some for the phototroph.

Lichens typically grow quite slowly. For example, a lichen 2 cm in diameter growing on the surface of a rock may be several years old. Lichen growth varies from 1 mm or less per year to over 3 cm per year, depending on the organisms composing the symbiosis and the amount of rainfall and sunlight received.

MINIQUIZ

- What are the benefits to both partners in the lichen mutualism?
- Besides organic compounds, of what benefit to the fungus is a mutualism with *Anabaena*?

22.2 “*Chlorochromatium aggregatum*”

In freshwater environments there are microbial mutualisms called **consortia**. A common consortium develops between nonmotile, phototrophic, green sulfur bacteria, which may be colored either green or brown (➡ Section 14.6), and motile, nonphototrophic bacteria. These consortia are found worldwide in stratified sulfidic freshwater lakes, and can account for up to 90% of the green sulfur bacteria and nearly 70% of the bacterial biomass in these lakes. The basis of the mutualism of these consortia is in the phototrophic production of organic matter by the green sulfur bacterium and the motility of the partner organism. Each consortium has been given a genus and species name, but since these names do not denote true species (because they are not a single organism), the names are enclosed in quotation marks. We examined the general biology of these consortia in Section 14.6.

Nature of the Consortium

The morphology of a green sulfur bacterial consortium depends upon the species composition. The consortium generally consists of 13–69 green sulfur bacteria, called *epibionts*, surrounding and attached to a central, colorless, flagellated, rod-shaped bacterium (Figure 22.3). Several distinct motile phototrophic consortia have been recognized based on the color, morphology, and presence or absence of gas vesicles (➡ Section 2.15) of the epibionts. For example, in “*Chlorochromatium aggregatum*” the central bacterium is surrounded by rod-shaped green bacteria. In “*Pelochromatium roseum*” the epibiont is brown. The consortium “*Chlorochromatium glebulum*” is bent and includes green epibionts that contain gas vesicles (Figure 22.3).

Green sulfur bacteria are obligately anaerobic phototrophs that form a distinct phylum (*Chlorobi*, ➡ Section 14.6). The green and brown species differ in the types of bacteriochlorophyll and carotenoids they contain. Both green and brown species are found in stratified lakes where light penetrates to depths at which the water contains hydrogen sulfide (H_2S). In the stratified lakes, the motile consortia reposition rapidly to remain where conditions

are favorable for photosynthesis in the constantly changing gradients of light, oxygen, and sulfide. Water samples collected from depths where these conditions are favorable are enriched in this morphologically conspicuous consortium (Figure 22.4). The consortia show dark aversion (scotophobotaxis, ➡ Section 2.19) and positive chemotaxis toward sulfide. Some free-living green sulfur bacteria, such as *Pelodictyon phaeoclastratiforme*, have gas vesicles that regulate buoyancy and vertical position in the water column. However, the time they require for repositioning is from one to several days, which is not fast enough for tracking the more rapidly changing gradients. By contrast, motile consortia move up and down in the water column fast enough to follow the gradients of light and sulfide as they change on a diel basis.

Although green bacterial consortia were discovered almost a century ago, only with the advent of molecular techniques and

newer culture methods has it become possible to study certain aspects of these remarkable associations. Sequencing of 16S ribosomal RNA (rRNA) genes revealed a significant biogeography of epibionts in lakes of Europe and the United States. *Biogeography* is the study of the geographic distribution of organisms; in this case, the genetically distinct phototrophic consortia in different lakes. Epibionts in neighboring lakes have identical 16S rRNA gene sequences, whereas the sequences of morphologically similar epibionts in widely separated lakes differ. Phylogenetic analysis has shown that the mechanisms of cell–cell recognition responsible for stable morphology have evolved between particular epibionts and their central bacterium.

Phylogeny and Metabolism of a Consortium

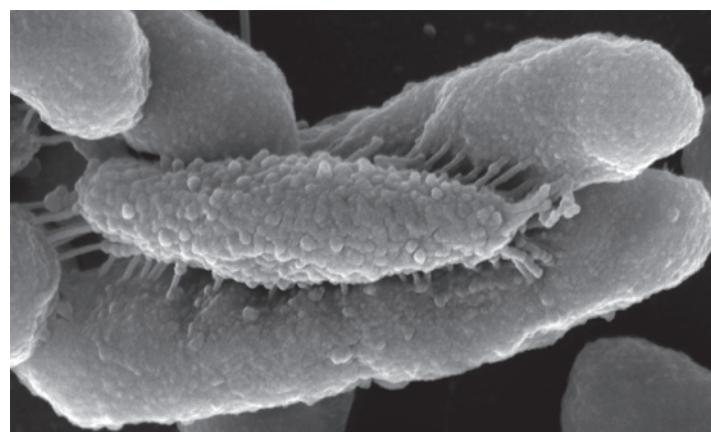

The epibiont of “*Chlorochromatium aggregatum*” has been isolated and grown in pure culture. Although this green sulfur bacterium, named *Chlorobium chlorochromati*, can be grown in pure culture, no naturally free-living variant has been observed, supporting the view that in nature, a symbiotic lifestyle is obligate for epibionts. The central bacterium of “*Chlorochromatium aggregatum*” belongs to the *Betaproteobacteria* (☞ Section 15.2). Interestingly, this bacterium requires α-ketoglutarate, an intermediate of the citric acid cycle (☞ Section 3.12), and this is presumably supplied to it by the epibiont. However, the central cell only assimilates fixed carbon in the presence of light and sulfide—conditions in which the epibionts are active and can transfer nutrients to the central bacterium.

Recent studies comparing the transcriptome and proteome (☞ Sections 6.7 and 6.8) of *C. chlorochromati* growing alone or in association with the central rod bacterium have identified some features specifically related to the symbiosis. Approximately 50 proteins are unique to the symbiotic state. Most of approximately 350 differentially regulated genes are repressed when the organism is symbiotically associated, whereas only 19 genes are more highly expressed. Many of these up-regulated genes encode proteins of amino acid metabolism and nitrogen regulation. These include the enzyme glutamate synthase and an ABC transporter of branched amino acids (☞ Section 2.9), suggesting that the metabolic coupling between the epibiont and central rod bacterium involves the exchange of amino acids. Although it is not yet known whether the central bacterium transfers any organic compounds to the epibiont, this hypothesis can be tested now that the genome sequence of the central bacterium is known.

Scanning electron microscopy of the consortium (Figure 22.5) has revealed that tubular extensions of the central bacterium’s periplasm (☞ Section 2.11) cover much of its surface and appear to fuse with the periplasm of the epibiont. If the two bacterial

II • Plants as Microbial Habitats

Plants interact closely with microorganisms through their roots and leaf surfaces and even more intimately within their vascular tissue and cells. Most mutualisms between plants and microorganisms increase nutrient availability to the plants or defend them against pathogens. We consider three examples in the fol-

lowing sections: (1) a mutualism (root nodules, Section 22.3), (2) a symbiosis that is harmful to the plant (crown gall disease, Section 22.4), and (3) a mutualism in which plants expand and interconnect their root system through association with a fungus (mycorrhizae, Section 22.5).

22.3 The Legume–Root Nodule Symbiosis

A plant–bacterial mutualism of great importance to humans is that of leguminous plants and nitrogen-fixing bacteria. *Legumes* are plants that bear their seeds in pods. This third largest family of flowering plants includes such agriculturally important plants as soybeans, clover, alfalfa, beans, and peas. These plants are key commodities for the food and agricultural industries, and the ability of legumes to grow without nitrogen fertilizer saves farmers millions of dollars in fertilizer costs yearly and reduces the polluting effects of fertilizer runoff.

The partners in a symbiosis are called *symbionts*, and most nitrogen-fixing bacterial symbionts of plants are collectively called *rhizobia*, derived from the name of a major genus, *Rhizobium*. Rhizobia are species of *Alpha-* or *Betaproteobacteria* (☞ Sections 15.1 and 15.2) (Figure 22.6) that can grow freely in soil or infect leguminous plants and establish a symbiotic relationship. The same genus (or even species) can contain both rhizobial and nonrhizobial strains. Infection of legume roots by rhizobia leads to the formation of **root nodules** (Figure 22.7) in which the bacteria fix gaseous nitrogen (N_2) (☞ Section 3.17). Nitrogen fixation in root nodules accounts for a fourth of the N_2 fixed annually on Earth and is of enormous agricultural importance, as it increases the fixed nitrogen content of soil. Nodulated legumes can grow well on unfertilized bare soils that are nitrogen deficient, while other plants grow only poorly on them (Figure 22.8).

Leghemoglobin and Cross-Inoculation Groups

In the absence of its bacterial symbiont, a legume cannot fix N_2 . Rhizobia, on the other hand, can fix N_2 when grown in pure culture under microaerophilic conditions (a low-oxygen environment is necessary because nitrogenases are inactivated by high levels of O_2 , ☞ Section 3.17). In the nodule, O_2 levels are precisely controlled by the O_2 -binding protein **leghemoglobin**. Production of this iron-containing protein in healthy N_2 -fixing nodules (Figure 22.9) is induced through the interaction of the plant and bacterial partners. Leghemoglobin functions as an “oxygen buffer,” cycling between the oxidized (Fe^{3+}) and reduced (Fe^{2+}) forms of iron to keep unbound O_2 within the nodule low.

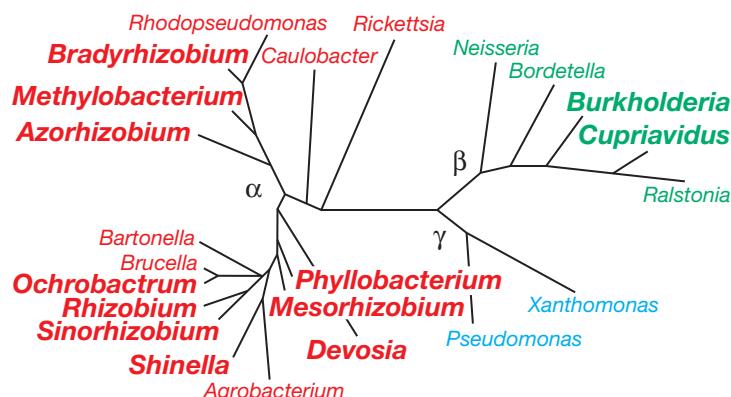

Figure 22.6 Phylogeny of rhizobial (names in boldface) and related genera inferred from analysis of 16S rRNA gene sequences. There are rhizobia in 12 genera and more than 70 species of *Alpha-* and *Betaproteobacteria*.

Joe Burton

Figure 22.7 Soybean root nodules. The nodules developed from infection by *Bradyrhizobium japonicum*. The main stem of this soybean plant is about 0.5 cm in diameter.

The ratio of leghemoglobin-bound O_2 to free O_2 in the root nodule is thus maintained on the order of 10,000:1.

There is a marked specificity between the species of legume and rhizobium that can establish a symbiosis. A particular rhizobial species is able to infect certain species of legumes but not others. A group of related legumes that can be infected by a particular rhizobial species is called a *cross-inoculation group*—there are, for example, a clover group, a bean group, an alfalfa group, and so on (Table 22.1). If legumes are inoculated with the correct rhizobial strain, leghemoglobin-rich, N_2 -fixing nodules develop on their roots (Figures 22.7–22.9).

Steps in Root Nodule Formation

How root nodules form is well understood for most rhizobia (Figure 22.10). The steps are as follows:

1. Recognition of the correct partner by both plant and bacterium and attachment of the bacterium to the root hairs
2. Secretion of oligosaccharide signaling molecules (Nod factors) by the bacterium
3. Bacterial invasion of the root hair
4. Movement of bacteria to the main root by way of the infection thread
5. Formation of modified bacterial cells (bacteroids) within the plant cells and development of the N_2 -fixing state
6. Continued plant and bacterial cell division, forming the mature root nodule

Another mechanism of nodule formation that does not require Nod factors is used by some species of phototrophic rhizobia. This mechanism has yet to be fully elucidated, but appears to

require the bacterial production of *cytokinins*. Cytokinins are plant hormones, derived from adenine or phenylurea, necessary for cell growth and differentiation.

Attachment and Infection

The roots of leguminous plants secrete organic compounds that stimulate the growth of a diverse rhizosphere microbial community. If rhizobia of the correct cross-inoculation group are in the soil, they will form large populations and eventually attach to the root hairs that extend from the roots of the plant (Figure 22.10). An adhesion protein called *rhicadhelin* is present on the cell surfaces of rhizobia. Other substances, such as carbohydrate-containing proteins called *lectins* and specific receptors in the plant cytoplasmic membrane, also play roles in plant–bacterium attachment.

After attaching, a rhizobial cell penetrates into the root hair, which curls in response to substances secreted by the bacterium.

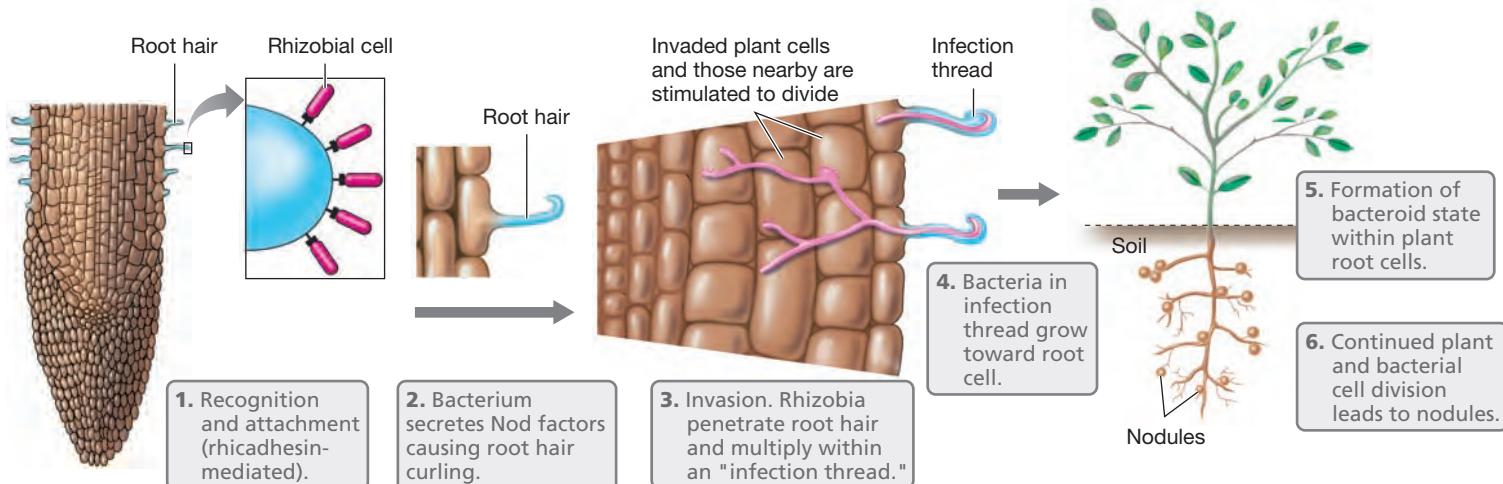

Figure 22.10 Steps in the formation of a root nodule in a legume infected by *Rhizobium*. Formation of the bacteroid state is a prerequisite for nitrogen fixation. See Figure 22.15 for physiological activities in the nodule.

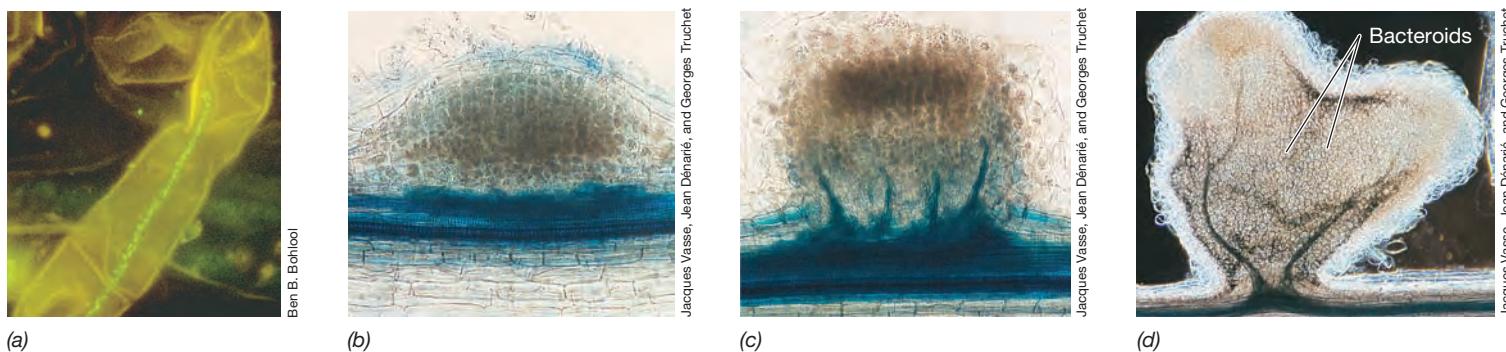

Figure 22.11 The infection thread and formation of root nodules. (a) An infection thread induced by cells of *Rhizobium leguminosarum* biovar *trifolii* in a root hair of white clover (*Trifolium repens*). The infection thread consists of a cellulosic tube through which bacteria move to root cells. (b–d) Nodules from alfalfa roots infected with cells of *Sinorhizobium meliloti* shown at different stages of development. Cells of both *R. leguminosarum* biovar *trifolii* and *S. meliloti* are about 2 mm long. The time course of nodulation events from infection to effective nodule is about 1 month in both soybean and alfalfa. Bacteroids are about 2 μm long. Photos b–d reprinted with permission from *Nature* 351: 670–673 (1991), © Macmillan Magazines Ltd.

The bacterium then induces formation by the plant of a cellulosic tube, called the **infection thread** (Figure 22.11a), which spreads down the root hair. Root cells adjacent to the root hairs subsequently become infected by rhizobia, and plant cells divide. Continued plant cell division forms the tumorlike nodule (Figure 22.11b–d). A different mechanism of infection is used by some rhizobia adapted to aquatic or semiaquatic tropical legumes (see Figure 22.16). These rhizobia enter the plant at the loose cellular junctions of roots emerging perpendicular from an established root (*lateral roots*). Following entry into the plant, some of the rhizobia develop infection threads, whereas others do not.

Bacteroids

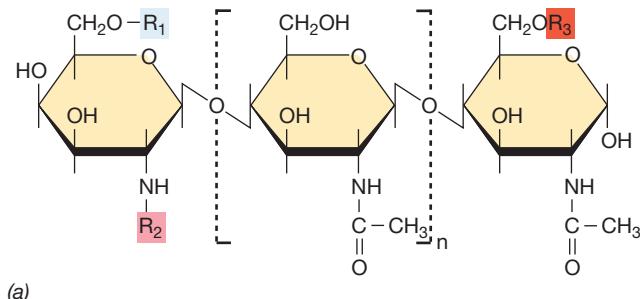

The rhizobia multiply rapidly within the plant cells and become transformed into swollen, misshapen, and branched cells called **bacteroids**. A microcolony of bacteroids becomes surrounded by portions of the plant cytoplasmic membrane to form a structure called the *symbiosome* (Figure 22.11d), and only after the symbiosome forms does N_2 fixation begin. Nitrogen-fixing nodules can be detected experimentally by the reduction of acetylene to ethylene (Section 3.17). When the plant dies, the nodule deteriorates, releasing bacteroids into the soil. Although bacteroids are incapable of division, a small number of dormant rhizobial cells are always present in the nodule. These now proliferate, using some of the products of the deteriorating nodule as nutrients. The bacteria can then initiate infection the next growing season or maintain a free-living existence in the soil.

Nodule Formation: *nod* Genes, Nod Proteins, and Nod Factors

Rhizobial genes that direct the steps in nodulation of a legume are called *nod genes*. It is thought that the ability to form nodules has independently emerged multiple times through the horizontal transfer of such genes as *nod* and *nif* that are located on plasmids or transferable regions of chromosomal DNA. In *Rhizobium leguminosarum* biovar *viciae*, which nodulates peas, ten *nod* genes have been identified. The *nodABC* genes encode proteins that

produce oligosaccharides called **Nod factors**; these induce root hair curling and trigger cell division in the pea plant, eventually leading to formation of the nodule (see Figure 22.15 for a description of root nodule biochemistry).

Nod factors are lipochitin oligosaccharides to which various substituents are bonded (Figure 22.12) that function as primary rhizobial signal molecules triggering legumes to develop new

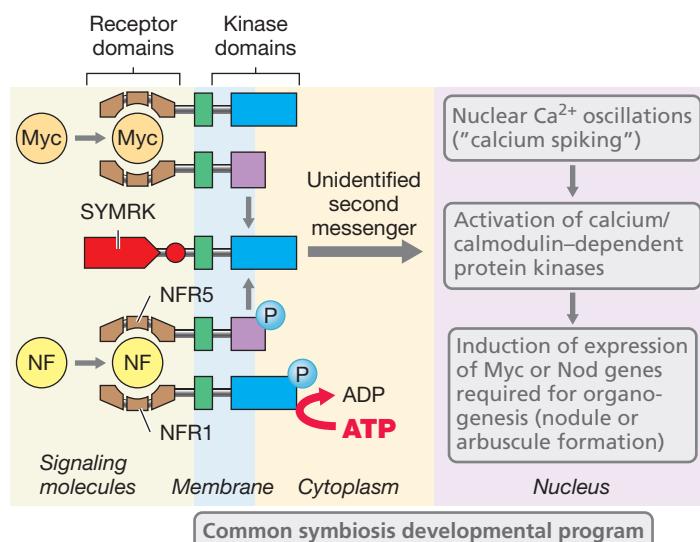

Figure 22.13 Nod and Myc signaling pathways in root nodule and arbuscule formation. Nod factor (NF) signaling involves at least three membrane-associated receptors (NFR1, NFR5, and SYMRK) that together initiate nodulation development via protein phosphorylation. NFR1 and SYMRK have active kinase domains (blue), whereas NFR5 kinase is inactive. The direct binding of NF to a complex of NFR1 and NFR5 at the plant cell cytoplasmic membrane initiates signal transduction by activation of the NFR1 kinase. The resulting auto- or trans-phosphorylation of the NFR cytoplasmic domains triggers events leading to formation of the infection thread. Signal transduction to the SYMRK by the NFR1-NFR5-Nod factor complex (or by an unidentified receptor for the Myc factor) is part of a conserved symbiosis program, in which induction of calcium signaling in the plant cell nucleoplasm triggers gene expression changes and production of plant growth hormones (cytokinins) required for nodule or arbuscule formation. Neither the identity of the second messenger nor participation of NFR-like receptors in the Myc signaling pathway have been established. See Section 22.5 for discussion of mycorrhizae.

plant organs: root nodules that host the bacteria as nitrogen-fixing bacteroids (Figure 22.13). Resolving the details of the signaling pathway triggered by Nod binding to cell surface receptors (NFR1 and NFR2) and leading to the induction of organogenesis (nodule formation) is an active area of research. It has recently been shown that many elements of the signaling pathway leading to nodulation are also used by the mycorrhizal fungi for infection of plant roots (Figure 22.13 and Section 22.5).

Which plants a given rhizobial species can infect is in part determined by the structure of the Nod factor it produces. Besides the *nodABC* genes, which are universal and whose products synthesize the Nod factor backbone, each cross-inoculation group contains *nod* genes that encode proteins that chemically modify the Nod factor backbone to form its species-specific molecule (Figure 22.12). In *R. leguminosarum* biovar *viciae*, *nodD* encodes the regulatory protein NodD, which controls transcription of other *nod* genes. After interacting with inducer molecules, NodD promotes transcription and is thus a positive regulatory protein (Section 7.4). NodD inducers are plant flavonoids, organic molecules that are widely secreted by plants. Some flavonoids that are structurally very closely related to *nodD* inducers in *R. leguminosarum* biovar *viciae* inhibit *nod* gene expression in other rhizobial species (Figure 22.14). This indicates that part of the specificity observed between plant and bacterium in the rhizobia-legume

symbioses lies in the chemistry of the flavonoids secreted by each species of legume.

Biochemistry of Root Nodules

As discussed in Section 3.17, N_2 fixation requires the enzyme *nitrogenase*. Nitrogenase from bacteroids shows the same biochemical properties as the enzyme from free-living N_2 -fixing bacteria, including O_2 sensitivity and the ability to reduce acetylene as well as N_2 . Bacteroids are dependent on the plant for the electron donor for N_2 fixation. The major organic compounds transported across the symbiosome membrane and into the bacteroid proper are citric-acid-cycle intermediates—in particular, the C_4 organic acids *succinate*, *malate*, and *fumarate* (Figure 22.15). These are used as electron donors for ATP production and, following conversion to pyruvate, as the ultimate source of electrons for the reduction of N_2 .

The product of N_2 fixation is ammonia (NH_3), and the plant assimilates most of this NH_3 by forming organic nitrogen compounds. The NH_3 -assimilating enzyme glutamine synthetase is present in high levels in the plant cell cytoplasm and can convert glutamate and NH_3 into glutamine (Section 3.15). This and a few other organic nitrogen compounds transport bacterially fixed nitrogen throughout the plant.

Stem-Nodulating Rhizobia

Although most leguminous plants form N_2 -fixing nodules on their roots, a few legume species bear nodules on their stems. Stem-nodulated leguminous plants are widespread in tropical regions where soils are often nitrogen deficient because of leaching and intense biological activity. The best-studied system is the tropical aquatic legume *Sesbania*, which is nodulated by the bacterium *Azorhizobium caulinodans* (Figure 22.16). Stem nodules typically form in the submerged portion of the stems or just above the water level. The general sequence of events by which stem nodules form in *Sesbania* resembles that of root nodules: attachment, formation of an infection thread, and bacteroid formation.

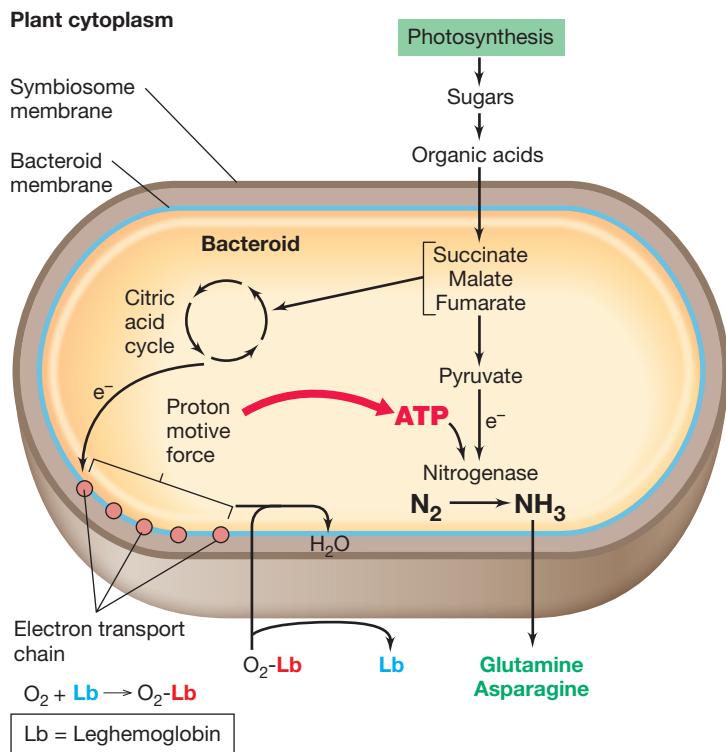

Figure 22.15 The root nodule bacteroid. Schematic diagram of major metabolic reactions and nutrient exchanges in the bacteroid. The symbiosome is a collection of bacteroids surrounded by a membrane originating from the plant.

Some stem-nodulating rhizobia produce bacteriochlorophyll α and thus have the potential to carry out anoxygenic photosynthesis (Section 13.3). Bacteriochlorophyll-containing rhizobia, called photosynthetic *Bradyrhizobium*, are widespread in nature, particularly in association with tropical legumes. In these species, light energy converted to chemical energy (ATP) in photosynthesis is likely to be at least part of the energy source needed by the bacterium to support N_2 fixation.

(b) Cyanobacterial symbiont *Anabaena azollae* as observed in crushed leaves of *A. pinnata*. Single cells of *A. azollae* are about 5 μm wide. Vegetative cells are oblong; the spherical heterocysts (lighter color, arrows) are differentiated for nitrogen fixation.

Nonlegume N₂-Fixing Symbioses: *Azolla*–*Anabaena* and *Alnus*–*Frankia*

Various nonleguminous plants form N₂-fixing symbioses with bacteria other than rhizobia. For example, the water fern *Azolla* harbors within small pores of its fronds a species of heterocystous N₂-fixing cyanobacteria (Section 14.3) called *Anabaena azollae* (Figure 22.17). *Azolla* has been used for centuries to enrich rice paddies with fixed nitrogen. Before planting rice, the farmer allows the surface of the rice paddy to become densely covered with *Azolla*. As the rice plants grow, they eventually crowd out the *Azolla*, causing its death and the release of its nitrogen, which is assimilated by the rice plants. By repeating this process each growing season, rice farmers can obtain high yields of rice without applying nitrogenous fertilizers.

The alder tree (genus *Alnus*) has N₂-fixing root nodules (Figure 22.18a) that harbor filamentous, N₂-fixing actinomycetes of

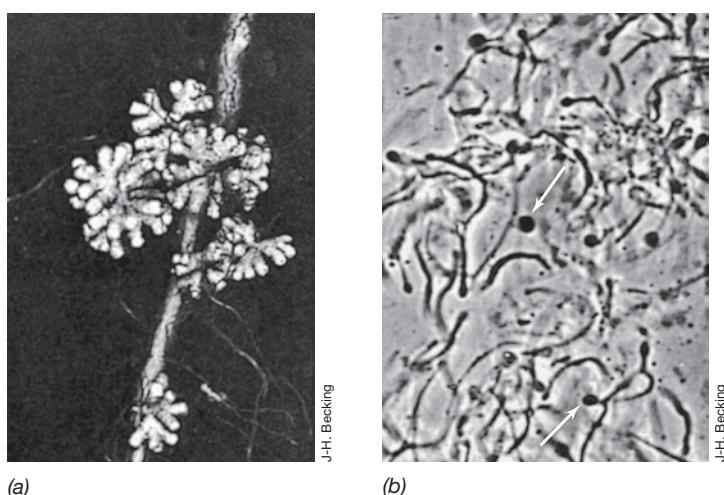

Figure 22.18 *Frankia* nodules and *Frankia* cells. (a) Root nodules of the common alder *Alnus glutinosa*. (b) *Frankia* culture purified from nodules of *Comptonia peregrina*. Note vesicles (arrows) on the tips of hyphal filaments.

the genus *Frankia*. When assayed in cell extracts the nitrogenase of *Frankia* is sensitive to O₂, but cells of *Frankia* fix N₂ at full oxygen tensions. This is because *Frankia* protects its nitrogenase from O₂ by localizing the enzyme in terminal swellings on the cells called *vesicles* (Figure 22.18b). The vesicles contain thick walls that retard O₂ diffusion, thus maintaining the O₂ tension within vesicles at levels compatible with nitrogenase activity. In this regard, *Frankia* vesicles resemble the heterocysts produced by some filamentous cyanobacteria as localized sites of N₂ fixation (Section 14.3).

Alder is a characteristic pioneer tree able to colonize nutrient-poor soils, probably because of its ability to enter into a symbiotic N₂-fixing relationship with *Frankia*. A number of other small or bushy, woody plants are nodulated by *Frankia*. However, unlike the rhizobial symbionts of legumes, a single strain of *Frankia* can form nodules on several different species of plants, suggesting that the *Frankia*–root nodule symbiosis is less specific than that of leguminous plants.

22.4 Agrobacterium and Crown Gall Disease

Some microorganisms develop parasitic symbioses with plants. The genus *Agrobacterium*, a relative of the root nodule bacterium *Rhizobium* (Figure 22.6), is such an organism, causing the formation of tumorous growths on diverse plants. The two species of *Agrobacterium* most widely studied are *Agrobacterium tumefaciens* (also called *Rhizobium radiobacter*), which causes *crown gall disease*, and *Agrobacterium rhizogenes*, which causes *hairy root disease*.

The Ti Plasmid

Although wounded plants often form a benign accumulation of tissue called a *callus*, the growth in crown gall disease (Figure 22.19) is different in that it is uncontrolled growth, resembling an animal tumor. *A. tumefaciens* cells induce tumor formation only if they contain a large plasmid called the **Ti plasmid** (Ti for tumor inducing). In *A. rhizogenes*, a similar plasmid called the *Ri plasmid* is necessary for induction of hairy root disease. Following infection, a part of the Ti plasmid called the *transferred DNA* (T-DNA) is integrated into the plant's genome. T-DNA carries the genes for tumor formation and also for the synthesis of a number of modified amino acids called *opines*. *Octopine* [N²-(1,3-dicarboxyethyl)-L-arginine] and *nopaline* [N²-(1,3-dicarboxypropyl)-L-arginine] are two common opines. Opines are produced by plant cells transformed by T-DNA and are a source of carbon and nitrogen, and sometimes phosphate, for the parasitic *A. tumefaciens* cells. These nutrients are the benefits for the bacterial symbiont.

Jo Handelsman

Figure 22.19 **Crown gall.** Photograph of a crown gall tumor (arrow) on a tobacco plant caused by the crown gall bacterium *Agrobacterium tumefaciens*. The disease usually does not kill the plant but may weaken it and make it more susceptible to drought and diseases.

Recognition and T-DNA Transfer

To initiate the tumorous state, *A. tumefaciens* cells attach to a wound site on the plant. Following attachment, the synthesis of cellulose microfibrils by the bacteria helps anchor them to the wound site, and bacterial aggregates form on the plant cell surface. This sets the stage for plasmid transfer from bacterium to plant.

The general structure of the Ti plasmid is shown in Figure 22.20. Only the T-DNA is actually transferred to the plant. The T-DNA contains genes that induce tumorigenesis. The *vir* genes on the Ti plasmid encode proteins that are essential for T-DNA transfer.

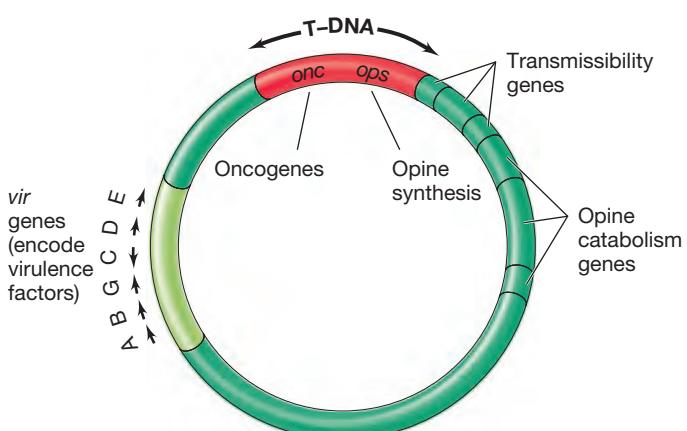

Figure 22.20 **Structure of the Ti plasmid of *Agrobacterium tumefaciens*.** T-DNA is the region transferred to the plant. Arrows indicate the direction of transcription of each gene. The entire Ti plasmid is about 200 kilobase pairs of DNA and the T-DNA is about 20 kilobase pairs.

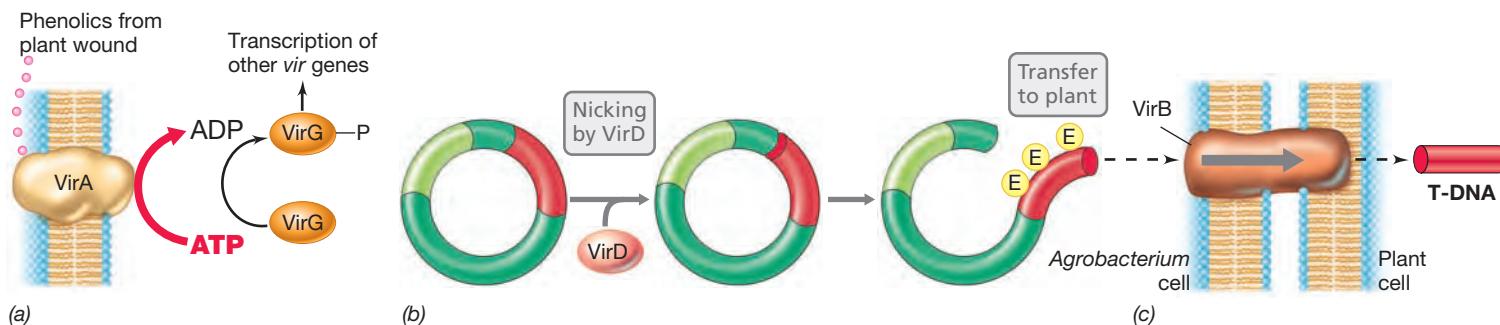

Figure 22.21 Mechanism of transfer of T-DNA to the plant cell by *Agrobacterium tumefaciens*. (a) VirA activates VirG by phosphorylation and VirG activates transcription of other *vir* genes. (b) VirD is an endonuclease that nicks the Ti plasmid, exposing the T-DNA. (c) VirB functions as a conjugation bridge between the *A. tumefaciens* cell and the plant cell, and VirE is a single-strand binding protein that assists in T-DNA transfer. Plant DNA polymerase produces the complementary strand to the transferred single strand of T-DNA.

Transcription of *vir* is induced by metabolites synthesized by wounded plant tissues. Examples of inducers include the phenolic compounds acetosyringone and ferulate. The transmissibility genes on the Ti plasmid (Figure 22.20) allow the plasmid to be transferred by conjugation from one bacterial cell to another.

The *vir* genes are the key to T-DNA transfer. The *virA* gene encodes a protein kinase (VirA) that interacts with inducer molecules and then phosphorylates the product of the *virG* gene (Figure 22.21). VirG is activated by phosphorylation and functions to activate other *vir* genes. The product of the *virD* gene (VirD) has endonuclease activity and nicks DNA in the Ti plasmid in a region adjacent to the T-DNA. The product of the *virE* gene is a DNA-binding protein that binds the single strand of T-DNA in the plant cell to protect it from destruction by nucleases. The *virB* operon encodes 11 different proteins that form a type IV secretion system (Section 4.14) for single-strand T-DNA and protein transfer between bacterium and plant (Figure 22.21) and thus resembles bacterial conjugation (Section 10.8). Laboratory studies of *A. tumefaciens* have shown that it can transfer T-DNA into many types of eukaryotic cells, including fungi, algae, protists, and even human cell lines.

Once inside the plant cell, T-DNA then becomes inserted into the genome of the plant. Tumorigenesis (*onc*) genes on the Ti plasmid (Figure 22.20) encode enzymes for plant hormone production and at least one key enzyme of opine biosynthesis. Expression of these genes leads to tumor formation and opine production. The Ri plasmid responsible for hairy root disease also contains *onc* genes. However, in this case the genes confer increased auxin responsiveness to the plant, and this promotes overproduction of root tissue and the symptoms of the disease. The Ri plasmid also encodes several opine biosynthetic enzymes.

Genetic Engineering with the Ti Plasmid

From the standpoint of microbiology and plant pathology, crown gall disease and hairy root disease both require intimate interactions that lead to genetic exchange from bacterium to plant. In other words, tumor induction in these diseases is the result of a natural plant-transformation system. Thus, in recent years interest in the Ti–crown gall system has shifted away from the disease

itself toward applications of this natural genetic exchange process in plant biotechnology.

Several modified Ti plasmids that lack disease genes but that can still transfer DNA to plants have been developed by genetic engineering. These have been used for the construction of genetically modified (transgenic) plants. Many transgenic plants have been constructed thus far, including crop plants carrying genes for resistance to herbicides, insect attack, and drought. We discuss the use of the Ti plasmid as a vector in plant biotechnology in Section 11.13.

22.5 Mycorrhizae

Mycorrhizae are mutualisms between plant roots and fungi in which nutrients are transferred in both directions. The fungus transfers nutrients—in particular, phosphorus and nitrogen—from the soil to the plant, and the plant in turn transfers carbohydrates to the fungus. These mutualisms are harnessed in agricultural applications. From fungal spores produced in culture or from root scrapings of infected plants, soil inoculants are produced that enhance plant growth.

Classes of Mycorrhizae

There are two classes of mycorrhizae. In *ectomycorrhizae*, fungal cells form an extensive sheath around the outside of the root with only a slight penetration into the root tissue itself (Figure 22.22). In *endomycorrhizae*, a part of the fungus becomes deeply embedded within the root tissue. Ectomycorrhizae are found mainly on the roots of forest trees, especially conifers, beeches, and oaks, and are most highly developed in boreal and temperate forests. In such forests, almost every root of every tree is mycorrhizal. The root system of a mycorrhizal tree such as a pine (genus *Pinus*) is composed of both long and short roots. The short roots, which

(b) Seedling of *Pinus contorta* (lodgepole pine), showing extensive development of the absorptive mycelium of its fungal associate *Suillus bovinus*. are characteristically dichotomously branched in *Pinus* (Figure 22.22a), show typical fungal colonization, and long roots are also frequently colonized. Most mycorrhizal fungi do not catabolize cellulose and other leaf litter polymers. Instead, they catabolize simple carbohydrates and typically have one or more vitamin requirements. They obtain their carbon from root secretions and obtain inorganic minerals from the soil. Mycorrhizal fungi are rarely found in nature except in association with roots, and many are probably obligate symbionts.

Despite the close symbiotic association between fungus and root, a single species of tree can form multiple mycorrhizal associations. One pine species can associate with over 40 species of fungi. This relative lack of host specificity allows ectomycorrhizal mycelia to interconnect trees, providing linkages for transfer of carbon and other nutrients between trees of the same or different species. Nutrient transfer from well-illuminated overstory plants to shaded trees is thought to help equalize resource availability, subsidizing young trees and increasing biodiversity by promoting the coexistence of different species.

Arbuscular Mycorrhizae

Although ectomycorrhizal fungi play a significant role in the ecology of forests, there is a greater diversity of endomycorrhizae. Most are *arbuscular mycorrhizae* (AM) that comprise a phylogenetically distinct fungal division, the *Glomeromycota* (➡ Section 17.12), of which all or most species are obligate plant mutualists (the word “arbuscular” means “little tree”). AM colonize 70–90% of all terrestrial plants, including most grassland species and many crop species. The association between plants and the *Glomeromycota* is thought to be the ancestral type of mycorrhizae, established 400–460 million years ago and an important evolutionary step in the successful invasion of dry land by terrestrial plants.

It is now known that AM fungi produce lipochitin oligosaccharide signaling factors (**Myc factors**) very closely related to Nod factors (Section 22.3), and these initiate formation of the mycorrhizal state (Figures 22.12 and 22.13). Root colonization by an AM fungus begins with germination of a soil-borne spore, producing a short germination mycelium that recognizes the host plant through reciprocal chemical signaling; the fungus then forms a contact structure called the *hyphopodium* with root epidermal cells (Figure 22.23). Penetrating hyphae extend into the

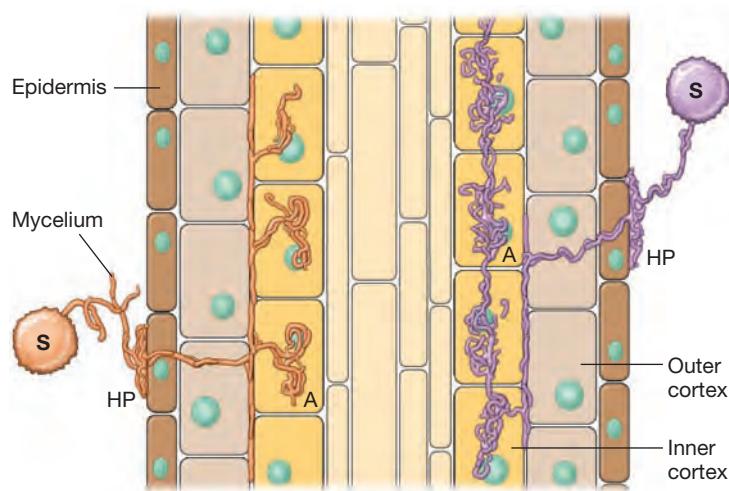

Figure 22.23 Arbuscular mycorrhizae root colonization. A spore (S) near a root generates a short mycelium that is attracted to the root by chemical signaling, forming an attachment structure called the hyphopodium (HP). The mycelium then enters the inner cortex region of the root by penetrating epidermal cells and cells of the outer cortex. Arbuscules (dichotomously branched invaginations, A) are formed by mycelia spreading either intercellularly (left) or intracellularly (right).

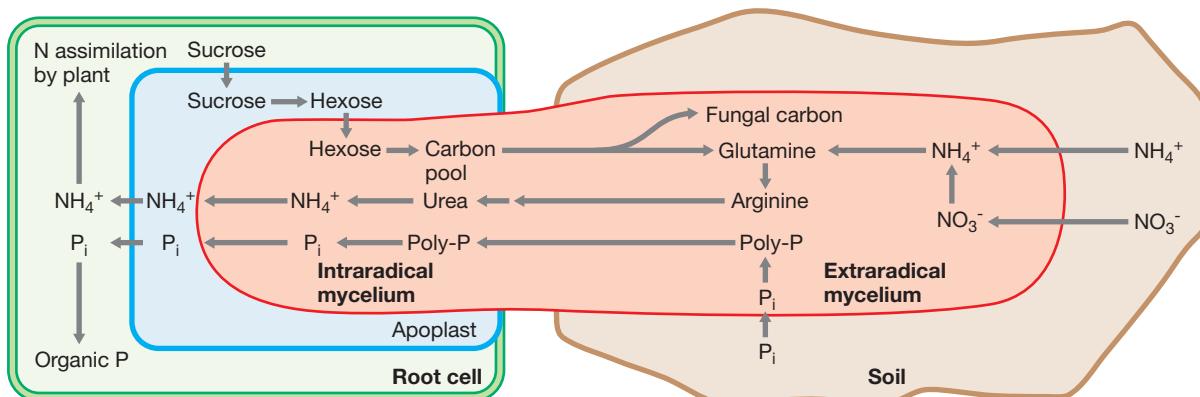

Figure 22.24 Pathways of N, P, and C exchange between plant and AM fungi. Inorganic nitrogen (NH_4^+ and NO_3^-) and phosphorus (P) mined from the soil by the extraradical (soil-associated) mycelia is translocated to the plant as arginine and polyphosphate (poly-P) through the mycelial network and delivered to the plant at the intraradical (plant cell–associated) mycelium. Ammonia and phosphate are regenerated in the intraradical mycelium for transfer to the plant cell. In exchange for the N and P, the plant provides organic carbon to the fungus.

plant from each hyphopodium, usually taking an intracellular path through epidermal and outer cortical cell layers of the root before forming dichotomously branched or coiled hyphal structures called **arbuscules** within cells of the plant's inner cortex, near to vascular tissues. However, the arbuscular hyphae remain separated from plant protoplasm by an extensive plant cytoplasmic membrane that forms a region called the *apoplast* (Figure 22.24), which functions to increase the surface area of contact between plant and fungus. Inorganic nitrogen and phosphorus are “mined” from the soil by the fungi, converted to arginine and polyphosphate, and then translocated through the hyphae to the plant (Figure 22.24).

Myc factors are very similar to the rhizobial Nod factors and only relatively minor modifications of the chitin backbone structure confer specificity (Figure 22.12). It is now suspected that the basic signaling and developmental systems used in the legume–root nodule symbiosis (Section 22.3), which arose about 60 million years ago, first evolved in the much more ancient AM fungi–plant symbiosis. Apparently the AM fungal system was recruited and adapted for the legume–root nodule symbiosis (Figure 22.13).

Although the arbuscular mycorrhizae are a much more ancient and widely distributed microorganism–plant symbiosis, understanding of their signaling and developmental program has been much slower to develop because the AM fungi cannot be maintained in pure culture. AM fungi are obligately *biotrophic* (meaning that they obtain their nutrients only from living cells of their symbiotic partner), and have no supporting genetic system as has been exploited to help unravel the complex developmental steps leading to legume–root nodule formation.

Benefits for the Plant

The beneficial effect of the mycorrhizal fungus on the plant is best observed in poor soils where plants that are mycorrhizal thrive, but nonmycorrhizal ones do not. For example, if trees planted in prairie soils, which ordinarily lack a suitable fungal inoculum, are artificially inoculated at the time of planting, they grow much more rapidly than uninoculated trees (Figure 22.25).

The mycorrhizal plant can absorb nutrients from its environment more efficiently and thus has a competitive advantage (Figure 22.24). This improved nutrient absorption is due to the greater surface area provided by the fungal mycelium. For example, in the pine seedling shown in Figure 22.22b, the ectomycorrhizal fungal mycelium makes up the overwhelming part of the absorptive capacity of the plant root system. The mycorrhizal plant is better able to function physiologically and compete successfully in a species-rich plant community, and the fungus benefits from a steady supply of organic nutrients.

In addition to helping plants absorb nutrients, mycorrhizae also play a significant role in supporting plant diversity. Field experiments have clearly shown a positive correlation between the

abundance and diversity of mycorrhizae in a soil and the extent of the plant diversity that develops in it.

Although most mycorrhizae are a true mutualistic symbiosis, there are also parasitic mycorrhizae. In these less common mycorrhizal symbioses, either the plant parasitizes the fungus or, in some cases, the fungus parasitizes the plant.

III • Mammals as Microbial Habitats

The evolution of animals has been shaped in part by a long history of symbiotic associations with microorganisms. To narrow our focus and look in depth at some details of these symbioses, we consider only mammals here. Microorganisms inhabit all sites on mammalian bodies, but the greatest diversity and density of microorganisms are found in the mammalian gut, and we center our discussion there. And finally, of the many mammals on Earth, we restrict our attention to ruminants and humans, the best-studied animals in terms of their gut microflora.

22.6 The Mammalian Gut

Some mammals are *herbivores*, consuming only plant materials, whereas others are *carnivores*, eating primarily the flesh of other animals. *Omnivores* eat both plants and animals. As Figure 22.26 indicates, closely related mammals have evolved adaptations for differing diets. Notice that mammals of different lineages independently evolved the herbivorous lifestyle, mostly during the Jurassic period, an era in Earth's history of roughly 60 million years beginning about 200 million years ago.

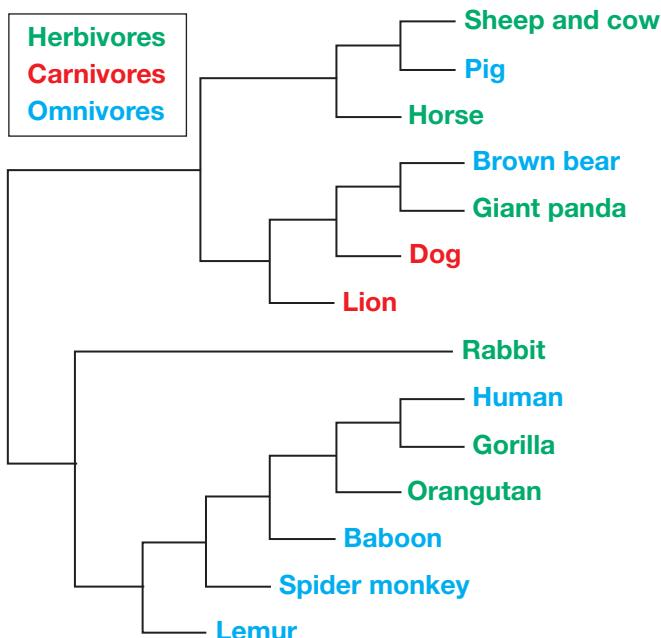

Figure 22.26 Phylogenetic tree showing multiple origins of herbivory among mammals. Some of the herbivores listed are foregut fermenters, while others are hindgut fermenters (Figure 22.27). Instead of animal flesh, some mammalian carnivores eat only insects (the insectivores, such as bats), or fish (the piscivores, such as the river otter).

The massive evolutionary radiation of mammals during the Jurassic led to the evolution of several feeding strategies. Most mammalian species evolved gut structures that foster mutualistic associations with microorganisms. As anatomical differences evolved, microbial fermentation remained important or essential in mammalian digestion. *Monogastric* mammals, such as humans, have a single compartment, the stomach, positioned before the intestine. Such animals may get a substantial part of their energy requirement from microbial fermentation of otherwise indigestible foods, but herbivores are totally dependent on such fermentations.

Plant Substrates

Microbial associations with various mammalian species led to the capacity to catabolize plant fiber, the structural component of plant cell walls. Fiber is composed primarily of insoluble polysaccharides of which cellulose is the most abundant component. Mammals—and indeed almost all animals—lack the enzymes necessary to digest cellulose and certain other plant polysaccharides. Only microorganisms have genes encoding the glycoside hydrolases and polysaccharide lyases required to decompose these polysaccharides.

As the most abundant organic compound on Earth and one composed exclusively of glucose, cellulose offers a rich source of carbon and energy for animals that can digest it. The two primary traits that evolved to support herbivory are (1) an enlarged anoxic fermentation chamber for holding ingested plant material and (2) an extended retention time—the time that ingested material remains in the gut. A longer retention time allows for a longer association of microorganisms with the ingested material and thus a more complete degradation of the plant polymers.

Foregut versus Hindgut Fermenters

Two digestive patterns have evolved in herbivorous mammals. In herbivores with a *foregut* fermentation, the microbial fermentation chamber *precedes* the small intestine. This gut architecture originated independently in ruminants, colobine monkeys, sloths, and macropod marsupials (Figure 22.27). These all share the common feature that ingested nutrients are degraded by the gut microbiota *before* reaching the acidic stomach and small intestine. We examine the digestive processes of ruminants, as examples of foregut fermenters, in the next section.

Horses and rabbits are herbivorous mammals, but they are not foregut fermenters. Instead, these animals are *hindgut* fermenters. They have only one stomach, but use an organ called the *cecum*, a digestive organ located between the small and large intestines, as their fermentation vessel. The cecum contains fiber- and cellulose-digesting (cellulolytic) microorganisms. Mammals, such as

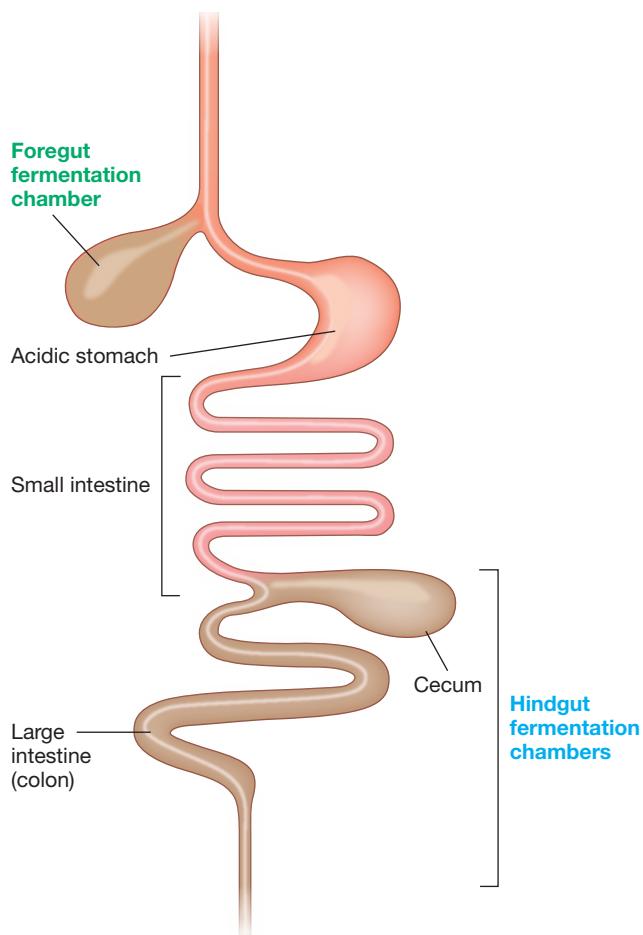

Figure 22.27 Variations on vertebrate gut architecture. All vertebrates have a small intestine, but vary in other gut structures. Most host absorption of dietary nutrients occurs in the small intestine, whereas microbial fermentation can occur in the foregut, cecum, or large intestine (colon). Foregut fermentation is found in four major clades of mammals and one avian species (the hoatzin). Hindgut fermentation, either in the cecum or large intestine/colon, is common to many clades of mammals (including humans), birds, and reptiles. Compare with Figure 22.26.

the rabbit, that rely primarily on microbial breakdown of plant fiber in the cecum are called *cecal fermenters*. In other hindgut fermenters, both the cecum and colon are major sites of fiber breakdown by microorganisms.

Anatomical differences among monogastric mammals, foregut fermenters, and hindgut fermenters are summarized in Figure 22.27. Nutritionally, foregut fermenters have an advantage over hindgut fermenters in that the cellulolytic microbial community of the foregut eventually passes through an acidic stomach. As this occurs, most microbial cells are killed by the acidity and become a protein source for the animal. By contrast, in animals such as horses and rabbits, the remains of the cellulolytic community pass out of the animal in the feces because of its position posterior to the acidic stomach.

22.7 The Rumen and Ruminant Animals

A very successful group of foregut fermenters are *ruminants*, herbivorous mammals that possess a special digestive organ, the **rumen**, within which cellulose and other plant polysaccharides are digested by microorganisms. Some of the most important domesticated animals—cows, sheep, and goats—are ruminants. Camels, buffalo, deer, reindeer, caribou, and elk are also ruminants. Indeed, ruminants are Earth's dominant herbivores. Because the human food economy depends to a great extent on ruminant animals, rumen microbiology is of considerable economic significance and importance.

Rumen Anatomy and Activity

Unique features of the rumen as a site of cellulose digestion are its relatively large size (capable of holding 100–150 liters in a cow, 6 liters in a sheep) and its position in the gastrointestinal system *before* the acidic stomach. The rumen's warm and constant temperature (39°C), narrow pH range (5.5–7, depending on when the animal was last fed), and anoxic environment are also important factors in overall rumen function.

Figure 22.28 The rumen. (a) Schematic diagram of the rumen and gastrointestinal system of a cow. Food travels from the esophagus into the reticulo-rumen, consisting of the reticulum and rumen. Cud is regurgitated and chewed until food particles are small enough to pass from the reticulum into the omasum, abomasum, and intestines, in that order. The abomasum is an acidic vessel, analogous to the stomach of monogastric animals like pigs and humans. (b) Photo of a fistulated Holstein cow. The fistula, shown unplugged, is a sampling port that allows access to the rumen.

Figure 22.28a shows the relationship of the rumen to other parts of the ruminant digestive system. The digestive processes and microbiology of the rumen have been well studied, in part because it is possible to implant a sampling port, called a *fistula*, into the rumen of a cow (Figure 22.28b) or a sheep and remove samples for analysis.

After a cow swallows its food, the food enters the first chamber of the four-compartment stomach, the reticulum. Partially digested plant materials flow freely between the rumen and reticulum, sometimes referred to together as the *reticulo-rumen*. The main function of the reticulum is to collect smaller food particles and move them to the omasum. Larger food particles (called cud) are regurgitated, chewed, mixed with saliva containing bicarbonate, and returned to the reticulo-rumen, where they are digested by rumen bacteria. Solids may remain in the rumen for more than a day during digestion. Eventually, small and more thoroughly digested food particles are passed to the omasum and from there to the abomasum, an organ similar to a true, acidic stomach. In the abomasum, chemical digestive processes begin that continue in the small and large intestine.

Microbial Fermentation in the Rumen

Food remains in the rumen for 20–50 h depending on the feeding schedule and other factors. During this relatively long retention time, cellulolytic microorganisms hydrolyze cellulose, which frees glucose. The glucose then undergoes bacterial fermentation with the production of **volatile fatty acids** (VFAs), primarily *acetic*, *propionic*, and *butyric* acids, and the gases carbon dioxide (CO_2) and methane (CH_4) (Figure 22.29). The VFAs pass through the rumen wall into the bloodstream and are oxidized by the animal as its main source of energy. The gaseous fermentation products CO_2 and CH_4 are released by eructation (belching).

The rumen contains enormous numbers of bacteria (10^{10} – 10^{11} cells/g of rumen contents). Most of the bacteria adhere tightly to food particles. These particles proceed through the gastrointestinal tract of the animal where they undergo further digestive processes similar to those of nonruminant animals. Bacterial cells that digest plant fiber in the rumen are themselves digested in the acidic abomasum. Because bacteria living in the rumen biosynthesize amino acids and vitamins, the digested bacterial cells are a major source of protein and vitamins for the animal.

Rumen Bacteria

Although some anaerobic microbial eukaryotes are present, anaerobic bacteria dominate in the rumen because it is a strictly anoxic compartment. Cellulose is converted to fatty acids, CO_2 , and CH_4 in a multistep microbial food chain, with several different

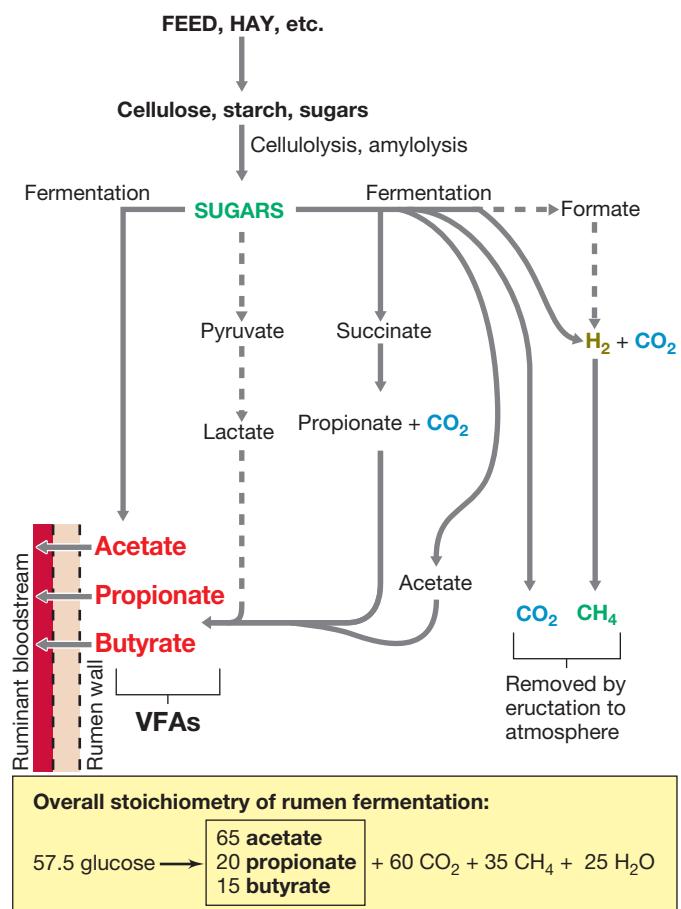

Figure 22.29 Biochemical reactions in the rumen. The major pathways are solid lines; dashed lines indicate minor pathways. Approximate steady-state rumen levels of volatile fatty acids (VFAs) are acetate, 60 mM; propionate, 20 mM; butyrate, 10 mM.

The results are pooled analyses of 14,817 sequences from several studies of ruminant animals, including cow, sheep, goat, and deer. They provide information primarily on diversity, not relative abundance. Data assembled and analyzed by Nicolas Pinel.

anaerobes participating in the process. Recent estimates of rumen microbial diversity from analysis of 16S rRNA gene sequences suggest that the typical rumen contains 300–400 bacterial “species” (defined as “operational taxonomic units” sharing less than 97% sequence identity, [Section 12.8](#)) (**Figure 22.30**). This is more than 10 times higher than culture-based diversity estimates. Molecular surveys show that species of *Firmicutes* and *Bacteroidetes* dominate the *Bacteria* in the rumen, while methanogens make up virtually the entire archaeal population (Figure 22.30).

A number of rumen anaerobes have been cultured and their physiology characterized (**Table 22.2**). Several different rumen bacteria hydrolyze cellulose to sugars and ferment the sugars to VFAs. *Fibrobacter succinogenes* and *Ruminococcus albus* are the two most abundant cellulolytic rumen anaerobes. Although both organisms produce cellulases, *Fibrobacter*, a gram-negative bacterium, produces enzymes localized to the outer membrane. *Ruminococcus*, a gram-positive bacterium which therefore lacks an outer membrane, produces a cellulose-degrading protein complex stabilized by scaffold proteins and bound to the cell wall. Both organisms therefore need to bind to cellulose particles in order to degrade them.

If a ruminant is gradually switched from cellulose to a diet high in starch (grain, for instance), the starch-digesting bacteria *Ruminobacter amylophilus* and *Succinomonas amyloytica* grow to high numbers in the rumen. On a low-starch diet these organisms are typically minor constituents. If an animal is fed legume hay, which is high in pectin, a complex polysaccharide containing both hexose and pentose sugars, then the pectin-digesting bacterium *Lachnospira multipara* (**Table 22.2**) becomes an abundant member of the rumen microbial community. Some

of the fermentation products of these rumen bacteria are used as energy sources by secondary fermenters in the rumen. For example, succinate is fermented to propionate plus CO₂ (**Figure 22.29**) by the bacterium *Schwartzia*, and lactate is fermented to acetate and other fatty acids by *Selenomonas* and *Megasphaera* (**Table 22.2**). Hydrogen (H₂) produced in the rumen by fermentative processes never accumulates because it is quickly consumed by methanogens for the reduction of CO₂ to CH₄. H₂ removal facilitates greater fermentative activity since H₂ accumulation negatively affects the energetics of fermentative reactions that produce H₂ ([Section 13.15](#)).

Dangerous Changes in the Rumen Microbial Community

Significant changes in the microbial composition of the rumen can cause illness or even death of the animal. For example, if a cow is changed abruptly from forage to a grain diet, the gram-positive bacterium *Streptococcus bovis* grows rapidly in the rumen. The normal level of *S. bovis*, about 10⁷ cells/g, is an insignificant fraction of total rumen bacterial numbers. But if large amounts of grain are fed abruptly, numbers of *S. bovis* can quickly rise to dominate the rumen microbial community to over 10¹⁰ cells/g. This occurs because grasses contain mainly cellulose, which does not support growth of *S. bovis*, while grain contains high levels of starch, on which *S. bovis* grows rapidly.

Because *S. bovis* is a lactic acid bacterium ([Sections 13.12](#) and [15.6](#)), large populations are capable of producing large amounts of lactic acid. Lactic acid is a much stronger acid than the VFAs produced during normal rumen function. Lactate production thus acidifies the rumen below its lower functional limit of about pH 5.5, thereby disrupting the activities of normal rumen bacteria. Rumen

^aExcept for the methanogens, which are Archaea, all organisms listed are species of *Bacteria*.

^bThese species also degrade xylan, a major plant cell wall polysaccharide.

^cAlso degrades starch.

^dAlso ferments amino acids, producing NH₃. Several other rumen bacteria ferment amino acids as well, including *Peptostreptococcus anaerobius* and *Clostridium sticklandii*.

acidification, a condition called *acidosis*, causes inflammation of the rumen epithelium, and severe acidosis can cause hemorrhaging in the rumen, acidification of the blood, and death of the animal.

Despite the activities of *S. bovis*, ruminants such as cattle can be fed a diet exclusively of grain. However, to avoid acidosis,

they must be switched from forage to grain *gradually* over a period of many days. The slow introduction of starch selects for VFA-producing, starch-degrading bacteria (Table 22.2) instead of *S. bovis*, and thus normal rumen functions continue and the animal remains healthy.

Protective Changes in the Rumen Microbial Community

The overgrowth of *S. bovis* is an example of how a single microbial species can have a deleterious effect on animal health. There is also at least one well-studied example of how a single bacterial species can *enhance* the health of ruminant animals; in this case, animals fed the tropical legume *Leucaena leucocephala*. This plant has a very high nutritional value, but contains an amino acid-like compound called *mimosine* that is converted to toxic 3-hydroxy-4(1H)-pyridone and 2,3-dihydroxypyridine (DHP) by rumen microorganisms (Figure 22.31). The observation that ruminants in Hawaii, but not Australia, could feed on *Leucaena* without toxic effect led investigators to hypothesize that further metabolism of DHP by bacteria present in Hawaiian ruminants alleviated DHP toxicity. This was subsequently confirmed by the isolation of the bacterium *Synergistes jonesii*, a unique anaerobe related to the *Defribacter* group (► Section 15.21) and not closely related to any other rumen bacteria. Inoculation of Australian ruminants with cells of *S. jonesii* conferred resistance to mimosine by-products, allowing the animals to feed on *Leucaena* without ill effect.

The success of this single-organism modification of the rumen microbial community has encouraged further studies of this sort, including genetic engineering of bacteria to improve their ability to utilize available nutrients or to detoxify toxic substances. A notable success has been inoculation of the rumen of sheep with genetically engineered cells of *Butyrivibrio fibrisolvens* (Table 22.2) containing a gene encoding the enzyme fluoroacetate dehalogenase; this successfully prevented fluoroacetate poisoning of sheep fed plants containing high levels of this highly toxic inhibitor of the citric acid cycle.

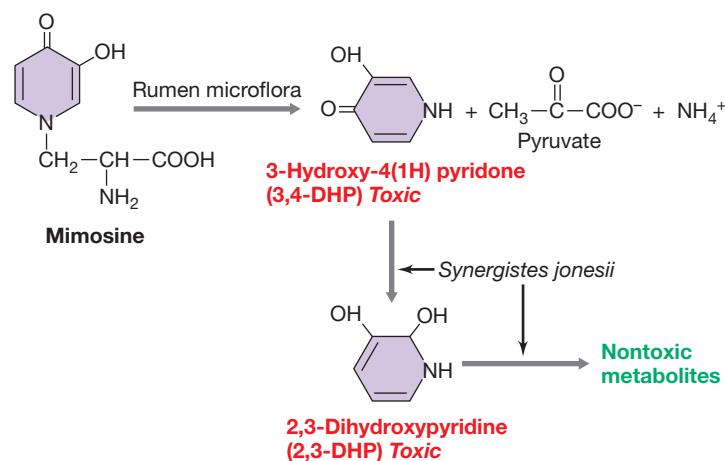

Figure 22.31 Conversion of mimosine to toxic pyridine and pyridone metabolites by ruminal microorganisms. Mimosine is converted to toxic 3,4-DHP by normal ruminal microbiota. *Synergistes jonesii* converts 3,4-DHP to nontoxic metabolites through a 2,3-DHP intermediate, preventing buildup of toxic metabolites of mimosine.

Rumen Protists and Fungi

In addition to huge populations of prokaryotes, the rumen has characteristic populations of ciliated protists (Chapter 17) present at a density of about 10^6 cells/ml. Many of these protists are obligate anaerobes, a property that is rare among eukaryotes. Although these protists are not essential for rumen fermentation, they contribute to the overall process. In fact, some protists are able to hydrolyze cellulose and starch and ferment glucose with the production of the same VFAs formed by cellulose-fermenting bacteria (Figure 22.29 and Table 22.2). Rumen protists also consume rumen bacteria and smaller rumen protists and are likely to play a role in controlling bacterial densities in the rumen. An interesting commensal interaction has been observed between rumen protists that produce VFAs and H_2 as products and methanogenic bacteria that consume the H_2 , producing CH_4 . Because their cells autofluoresce (► Section 13.20), methanogens are easily observed in rumen fluid bound to the surface of H_2 -producing protists.

Aerobic fungi also inhabit the rumen and play a role in its digestive processes. Rumen fungi are typically species that alternate between a flagellated and a thallus form, and studies with pure cultures have shown that they can ferment cellulose to VFAs. *Neocallimastix*, for example, is an obligately anaerobic fungus that ferments glucose to formate, acetate, lactate, ethanol, CO_2 , and H_2 . Although a eukaryote, this fungus lacks mitochondria and cytochromes and thus lives an obligately fermentative existence. However, *Neocallimastix* cells contain a redox organelle called the *hydrogenosome*; this mitochondrial analog evolves H_2 and has otherwise been found only in certain anaerobic protists (► Section 2.21).

Rumen fungi play an important role in the degradation of polysaccharides other than cellulose, including a partial solubilization of lignin (the strengthening agent in the cell walls of woody plants), hemicellulose (a derivative of cellulose that contains pentoses and other sugars), and pectin.

22.8 The Human Microbiome

The human microbiome encompasses all sites of the human body inhabited by microorganisms. These sites include the mouth, nasal cavities, throat, stomach, intestines, urogenital tracts, and skin (► Sections 23.1–23.5). It is estimated that the number of microorganisms in the human microbiome is approximately 10^{14} , which is ten times more than the total number of human cells in a single person.

Importance to Human Health

The gut microbial community in the healthy human was once considered to consist of microorganisms that were merely commensals, but we now know that this community is important in early development and overall health and predisposition to disease.

Recognition that the gut microflora function as mutualists that play a central role in human health has spawned two major international research programs. One, based in the United States, is called the *Human Microbiome Project* (HMP), and a second major project, supported by the European Commission, is called the *Metagenomics of the Human Intestinal Tract* (MetaHIT).

To date, the HMP has examined the microbial diversity in 250 healthy volunteers in two American cities by sequencing over 5000 samples taken from each subject one to three times and from 15 to 18 body sites (nine oral, four skin, one nasal, one stool, three vaginal). These and other ongoing studies of the human microbiome—including its relationship to disease, ethnicity, and diet—are coordinated under the International Human Genome Consortium. Some of the major questions posed by these integrated projects include: (1) Do individuals share a core human microbiome? (2) Is there a correlation between microbial population structure and host genotype? (3) Do differences in the human microbiome correlate with differences in human health? (4) Are differences in the relative abundance of different bacteria important?

Human microbiome studies based on surveys of the human gut microflora using 16S rRNA gene sequencing and metagenomic analyses have shown that the diversity between different persons is so great that no one microbial species is found at high abundance in all individuals. Similarities among individuals are more evident at higher bacterial taxonomic levels (such as phyla) and in the distribution of genes of similar function in the gut community. The possible benefits of these analyses for clinical medicine include the development of biomarkers for predicting predisposition to specific diseases, the design of drugs targeting selected members of the intestinal microbial community, personalized drug therapies, and tailor-made probiotics (► Section 23.4).

The Human Gut Microbial Community

Humans are monogastric and omnivorous animals (Figure 22.27). In the human duodenum, ingested food passed down from the stomach is blended with bile, bicarbonate, and digestive enzymes. About 1–4 h after ingestion, food reaches the gut (large intestine) and by this time it is near neutral pH, and bacterial numbers have increased from about 10^4 /g to about 10^8 /g (Figure 22.32). Both the host and its gut microorganisms share the easily digestible nutrients. The large intestine is the most heavily colonized area of the gastrointestinal tract and contains 10^{11} – 10^{12} bacterial cells per g.

Colonization of an initially sterile gut begins immediately after birth; a succession of microbial populations replaces each other in turn until a stable, adult microbial community is established. The source of early colonizers is not clear, although some species are clearly transmitted from mother to infant. The infant gut community is dominated by bifidobacteria, which are fermentative species of the bacterial class *Actinobacteria* (► Section 15.10) and does not reach an adultlike composition until about age 3. Recent studies have correlated frailty in the elderly population with two major factors: (1) a general decrease in gut diversity, and (2) reduced levels of *Firmicutes* and increased *Bacteroides*. This second factor also correlates with the lower amounts of free glutarate and the anti-inflammatory short-chain fatty acid butyrate in the elderly.

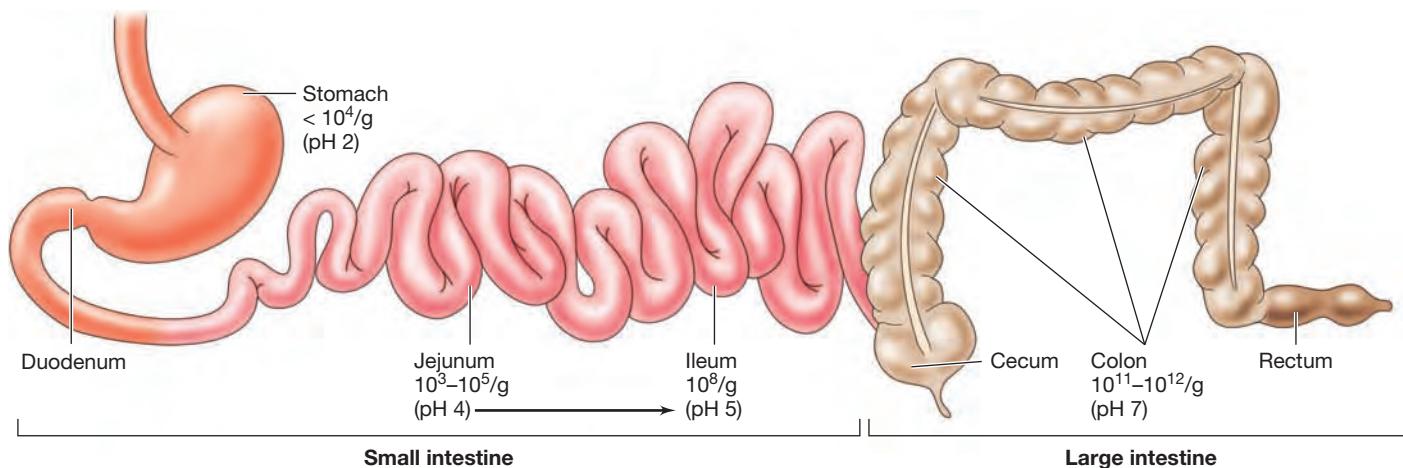

Figure 22.32 Numbers of bacteria in the monogastric human gastrointestinal tract. The small intestine is composed of the duodenum, jejunum, and ileum. Numbers in the individual sections are estimates of bacteria per gram of intestinal contents in healthy humans.

As is now recognized for most microbial communities, early descriptions of diversity based on culturing microorganisms greatly underestimated true diversity. For example, although we think of *Escherichia coli* as a significant gut bacterium, the entire phylum *Gammaproteobacteria* (to which *E. coli* belongs; [Section 15.3](#)) makes up less than 1% of all gut bacteria. *E. coli* simply grows extremely well in laboratory culture and can thus be readily detected even when present in low numbers.

Somewhat surprisingly, mammalian gut communities are composed of only a few major phyla and show a species composition distinct from that of any free-living microbial communities (Chapter 19). The vast majority (~98%) of all human gut phylo-

types fall into one of four major bacterial phyla: *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, and *Actinobacteria* ([Figure 22.33](#)). The *Bacteroidetes* and *Firmicutes* phyla dominate, but vary tremendously in relative abundance among individuals—differences in individual abundance range from >90% *Bacteroidetes* to >90% *Firmicutes*. In contrast to the limited phylum-level diversity, the species diversity in the mammalian gut is enormous. The most recent census of diversity in human fecal samples, based on millions of 16S rRNA sequences, has identified between 3,500 and 35,000 “species.” This large difference is mainly due to whether the 16S rRNA similarity threshold for defining a species ([Section 12.8](#)) is set at the 97% sequence identity cut-off or is more stringent

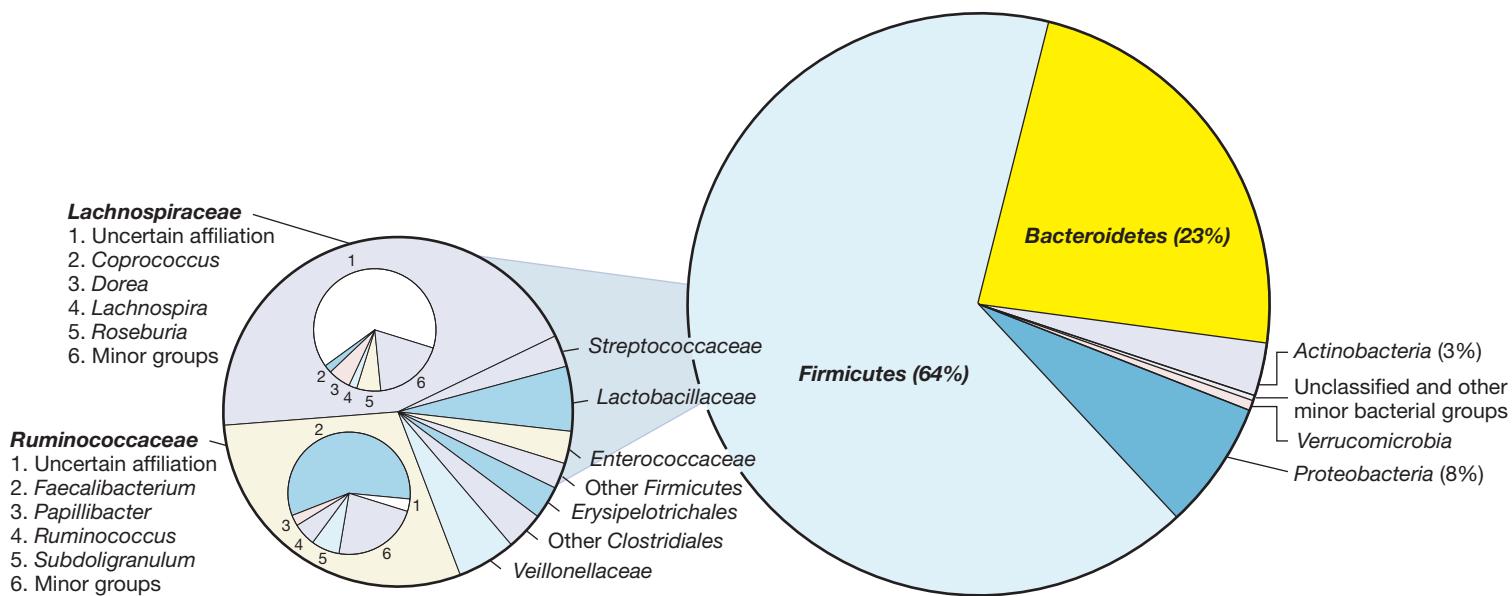

Figure 22.33 Microbial composition of the human colon inferred from 16S rRNA gene sequences. The results are pooled analyses of 17,242 sequences mostly obtained from the distal colon (fecal samples) of several individuals. The data provide information primarily of diversity, not relative abundance. Studies of abundance patterns have shown that the *Firmicutes*-*Bacteroidetes* ratio is highly variable among individuals. (~98–99% identity). *Archaea* (represented by a phylotype closely related to the methanogen *Methanobrevibacter smithii*), yeasts, fungi, and protists make up only a minor part of the human gut community (compare this with the rumen, Section 22.7).

Comparative studies have also shown that humans share more genera with each other than with other species of mammals. This suggests that the mammalian gut microflora may be “fine-tuned” to each mammalian species. Interestingly, although there is high variability from person to person in gut community composition, an individual’s community is relatively stable over long periods. Also, ongoing metagenomic sequencing studies hint at the existence of a limited number of distinct well-balanced general types of gut communities. Three such gut communities, called *enterotypes*, have been proposed. The association of an individual with any one enterotype transcends national borders, nutritional background, and ethnicity. Metabolic pathway reconstructions based on annotation of metagenomic gene sequences suggests that enterotypes are functionally distinct, for example, differing in their capacity for vitamin production. The existence of alternative symbiotic states, reflected by enterotypes, suggests that an individual’s enterotype might influence that person’s response to diet and drug therapy, or health status in general. If true, this could bring exciting new concepts and practices into the field of clinical medicine.

Contribution of Gut Microorganisms to Human Metabolism

Human gut microorganisms synthesize a large variety of enzymes that allow for the processing of complex dietary carbohydrates into monosaccharides and the production of VFAs. The genomes of *Bacteroides* species common in human adults encode enzymes that catabolize polysaccharides, consistent with these bacteria being adapted to a gut environment rich in polysaccharides. Even though the *Bacteroidetes*–*Firmicutes* ratio varies tremendously among individuals, the gut community metagenome (Section 6.10) presents a very similar set of genes related to complex carbohydrate degradation. Gut microorganisms also function in nitrogen metabolism. Of the 20 amino acids that humans require, 10 are said to be essential nutrients because we cannot synthesize them in adequate amounts. Although we obtain essential amino acids, such as lysine, from food, these nutrients may also be produced and secreted by certain gut microorganisms. For example, the infant microbiome has a higher level of folate-producing enzymes than that of adults, possibly associated with the ability of adults to obtain folate (an essential vitamin) from a more complex diet.

Gut microorganisms are also known to contribute to the “maturing” of the gastrointestinal tract. This includes triggering the expression of genes whose products catalyze nutrient uptake and metabolism in gut epithelial cells, priming the immune system early in life to recognize the normal gut microflora as nonforeign, and the development of a mucosal barrier to prevent colonization by foreign bacteria. Studies of experimental colonization of germ-free mice with individual microbial species or microbial communities have demonstrated that colonization triggers the expression of genes for glucose uptake and lipid absorption and transport in the ileum. This also indicates that there may be a link

between gut microbial composition and the ability of the host to harvest energy from its diet, contributing to nutritional abnormalities such as obesity, and we focus on this now.

Role of Gut Microorganisms in Obesity

Obesity is a significant health risk that contributes to high blood pressure, cardiovascular disease, and diabetes. Gut microorganisms likely play a part in human obesity, although mechanisms remain hypothetical. Initial evidence relating gut microorganisms to host fat accumulation came from studies using germ-free mice. In these experiments, normal mice had 40% more total body fat than those raised under germ-free conditions, although both mouse populations were fed the same rations. After germ-free mice were inoculated with cecal material from a normal mouse, they developed a gut microflora and their total body fat increased although there had been no changes in food intake or energy expenditure.

Mice that are genetically obese have microbial gut communities that differ from those of normal mice, with 50% fewer *Bacteroidetes*, a proportional increase in *Firmicutes*, and a greater number of methanogenic *Archaea* (Figure 22.34). Methanogens are thought to increase the efficiency of microbial conversion of fermentable substrates by removing hydrogen (H_2), as mentioned for fermentation in the rumen (Section 22.7). Hydrogen removal should stimulate fermentation, making more nutrients available for absorption by the host and thus contributing to obesity.

Animal model inferences have been more difficult to demonstrate with human subjects, since strict control of diet and host genotype is not feasible, and gut flora manipulation is much more difficult to achieve. Nevertheless, studies of humans, while not strictly confirming the *Bacteroidetes*–*Firmicutes* relationship established in mice, have shown that obese individuals are more likely to harbor species of *Prevotella* (a genus of *Bacteroidetes*) and methanogenic *Archaea*. Thus, the general model in humans appears to be the same as that for the mouse (Figure 22.34). That is, the methanogens are proposed to remove H_2 produced by *Prevotella*, facilitating fermentation by *Prevotella* and increasing short-chain fatty acids’ availability to the host. This general model is also supported by the study of mice co-colonized with *Bacteroides thetaiotaomicron* (having a metabolism similar to *Prevotella*) and the methanogen *Methanobrevibacter smithii*. Relative to monocolonized controls, these mice have a higher number of total gut bacteria, higher acetate levels in the intestinal lumen and blood, and greater body fat. The discovery that gut microflora can affect obesity offers at least one nongenetic explanation for why obesity often “runs in families.”

Remarkably, the increase in body fat associated with pregnancy may also be influenced by the gut microbiota. The period between the first and third trimester of pregnancy is associated with a decrease in gut microbial diversity and enrichment in the gut community of species of *Proteobacteria* and *Actinobacteria*. These changes are associated with the increased body fat and insulin insensitivity that develop later in gestation. A simple interpretation of these findings is that a pregnant woman’s body manipulates her gut microbiome as part of its preparations for a greater demand on stored energy reserves.

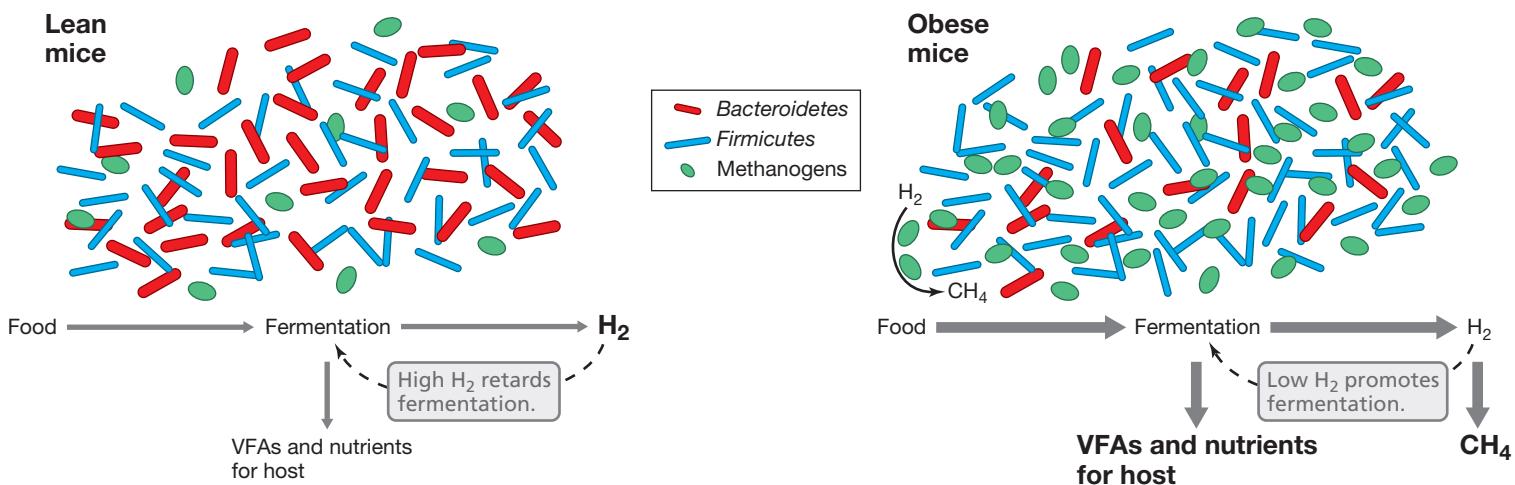

Figure 22.34 Differences in gut microbial communities between lean and obese mice. Obese mice have more methanogens, a 50% reduction in *Bacteroidetes*, and a proportional phylum-wide increase in *Firmicutes*. Nutrient production from fermentation is higher in obese mice due to removal of H_2 by methanogens.

Microbial Communities in the Human Mouth and Skin

Besides the gut, the mouth and skin are also sites heavily colonized by microorganisms. The oral microbiome is essentially as diverse as the gut, but individuals share greater proportions of common taxa for the mouth than for the gut. Abundant genera included *Streptococcus*, *Haemophilus*, *Veillonella*, *Actinomyces*, and *Fusobacterium*. As for all microbial communities reexamined by molecular methods, 16S rRNA-based sequence surveys of the oral cavity have shown that culture-based methods provided a very incomplete census of diversity. At least 750 species of aerobic and anaerobic microorganisms, including a minor representation of methanogenic *Archaea* and yeast, are known to reside in the oral cavity, distributed among teeth, tissue surfaces, and saliva. Because of the high species diversity, current research is focused on those genera having the largest representation in healthy adults.

The oral cavity provides a variety of habitats, each colonized by species that are present primarily as biofilms (Section 19.4). The primary colonizers of clean tooth surfaces are species of *Streptococcus*; obligate anaerobes such as *Veillonella* and *Fusobacterium* colonize habitats below the gum line. Most of these organisms contribute to the health of the host by keeping pathogenic species in check and not allowing them to adhere to mucosal surfaces. Tooth decay, gum inflammation, and periodontal disease are among the most visible manifestations of a breakdown in these generally stable mutualisms. We discuss the normal microbial community of the oral cavity in more detail in Section 23.3.

The skin is a critical human organ functioning primarily to prevent loss of moisture and restrict the entry of pathogens. Skin is also part of the human microbiome. Although total microbial numbers are typically low relative to the oral and gut communities, molecular analyses have shown that the skin harbors a rich and diverse microbial community of bacteria and fungi (primarily yeast) that vary significantly with location on the body. A 16S rRNA sequencing comparison of twenty diverse skin sites categorized as moist, dry, or oily, revealed tremendous diversity and variation among sites and individuals, but also showed some

common patterns. All together, nearly 20 bacterial phyla were detected, but most sequences affiliated with four groups: *Actinobacteria* (52%), *Firmicutes* (24%), *Proteobacteria* (16%), and *Bacteroidetes* (6%). More specific coverage of the normal flora of human skin can be found in Section 23.2 and Figure 23.2.

Changes in the Human Microbiome Associated with Disease

Changes in the human microbiome have long been associated with inflammatory bowel disease (IBD), the chronic inflammation of all or part of the digestive tract. It is widely accepted that IBD is not caused by a specific pathogen, but rather an imbalance between the immune system and the normal gut microbiota. This type of disruption of the homeostasis between microbiota and the host is called **dysbiosis**.

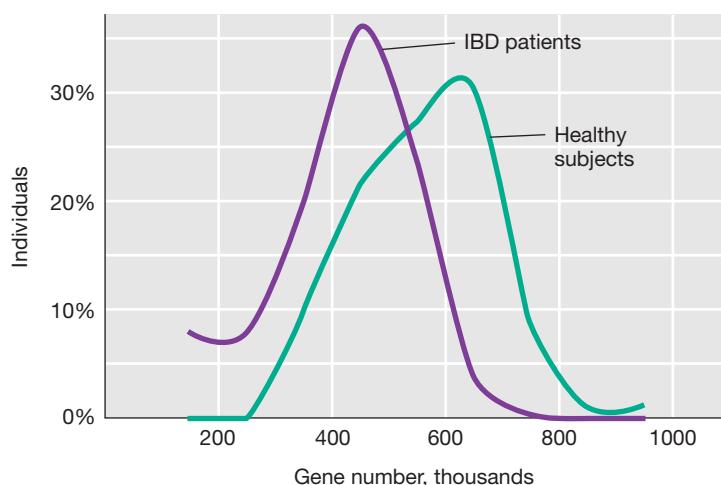

Figure 22.35 Reduced functional capacity of the gut microbiome of patients with inflammatory bowel disease. Metagenomic analysis of human gut microbiota in healthy subjects and patients with inflammatory bowel disease (IBD) revealed a tendency toward fewer nonredundant bacterial genes in patients with IBD.

Mice models point to a complex but transmissible etiology of IBD. Fostering or co-caging healthy mice with IBD-predisposed mice was sufficient to cause IBD development in the healthy mice and was correlated with the transfer of *Enterobacteriaceae* species *Klebsiella pneumoniae* and *Proteus mirabilis* from the IBD mice to the healthy mice. However, as for the relationship between the gut microbiome and obesity, IBD causality in humans is less well understood. Metagenomic analyses of healthy subjects and patients with IBD showed that the gut microbiota of IBD patients shared fewer genes in common with healthy subjects, relative to the number of genes shared among healthy subjects. The microbial community of IBD patients also tended to have significantly reduced functional capacity, as reflected by a reduction in the number of nonredundant genes relative to healthy subjects (Figure 22.35).

Other conditions known to be associated with changes in the human microbiome include type 2 (non-insulin-dependent)

diabetes, asthma, atopic dermatitis, colorectal cancer, kidney stones, periodontitis, and psoriasis. As we learn more about the relationship between the human microbiome and health and disease, therapeutic intervention may well be possible. This might include promoting the growth of protective symbiotic bacteria or inhibiting the growth of individual microorganisms (or assemblages of microorganisms) that compromise health, and transplanting microbial communities from healthy to diseased individuals.

IV • Insects as Microbial Habitats

Insects are the most abundant class of animals living today, with over one million species known. As many as 20% of all insects are thought to support symbiotic microorganisms in a mutually beneficial way. The symbioses contribute to the insects' ecological success by providing them either nutritional advantages or protection. Some symbionts are found on insects' outer surfaces or in their digestive tracts. *Endosymbionts* are intracellular bacteria and are typically localized to specialized organs within the insect.

22.9 Heritable Symbionts of Insects

How symbionts are transferred from one generation to the next determines how a mutualism functions and how stable it is. Microbial symbionts can either be acquired by a host from an environmental reservoir (horizontal transmission) or be transferred directly from the parent to the next generation (*heritable* or *vertical* transmission). The mode of symbiont transmission is related to the specificity and persistence of an association. In general, less specificity is associated with horizontal transmission. In this section we focus only on mutualisms in which the microbial symbiont has no free-living form; that is, the symbionts are transmitted in a vertical fashion.

Types of Heritable Symbionts

All known heritable symbionts of insects lack a free-living replicative stage. Thus, they are *obligate* symbionts. However, although these bacteria require the host for replication, not all hosts are dependent upon the symbiont. Relative to host dependence, heritable symbionts are either *primary symbionts* or *secondary symbionts*. Primary symbionts are required for host reproduction. They are restricted to a specialized region called the **bacteriome** present in several insect groups; within the bacteriome the bacterial cells reside in specialized cells called **bacteriocytes**. Secondary symbionts are not required for host reproduction. Unlike primary symbionts, secondary symbionts are not always present in every individual of a species and are not restricted to particular host tissues.

Secondary symbionts are broadly distributed among insect groups. Like pathogens, they invade different cell types and may live extracellularly within the insect's *hemolymph* (the fluid bathing the body cavity). In insects with bacteriomes, secondary symbionts can invade the bacteriocytes, co-residing with or sometimes displacing the primary symbionts (Figure 22.36). However, in order to persist in the insect host, the secondary symbiont must confer some advantage, such as a nutritional advantage or protection from environmental stresses such as heat. For example, whiteflies infected with *Rickettsia* bacteria (➡ Section 15.1) produce offspring at about twice the rate of uninfected flies, and more offspring survive to adulthood. Secondary symbionts may also provide protection against invasion by pathogens or predators. A *Spiroplasma* bacterium (➡ Section 15.9), which was first observed in *Drosophila neotestacea* in the 1980s, provides protection against a parasitic nematode worm. In

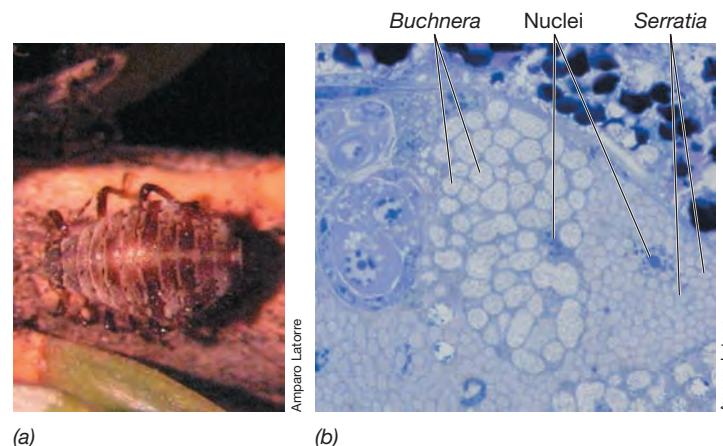

Figure 22.36 Primary and secondary symbionts of an aphid. (a) The cedar aphid *Cinara cedri*, a model organism for studies of symbioses. (b) Transmission electron micrograph of the bacteriome of *C. cedri* showing two bacteriocytes. Packed within each bacteriocyte are cells of *Buchnera aphidicola* (the primary symbiont) or *Serratia symbiotica*, the smaller, secondary symbiont. Arrows identify the nucleus of each bacteriocyte. The bacteriocyte containing *Buchnera* cells is about 40 µm wide.

most cases the basis for increased fitness or protection is unknown, but in one case a toxin encoded by a lysogenic bacteriophage (➡ Section 8.8) carried by the symbiont is known to confer protection on the insect from infection by a parasitic wasp.

There are heritable parasitic symbionts that manipulate the host's reproductive system, increasing the frequency of female progeny (sex ratio skewing, ➡ Figure 15.27). Because most heritable symbionts are transmitted maternally, the suppression of male progeny serves to expand the number of infected individuals and increase the rate of spread through an insect population. Since symbiont-conferred functions can spread rapidly within a population, acquisition of symbiont-encoded traits provides a mechanism for much more rapid adaptation than is possible through mutations in insect genes. *Rickettsia* infection of the whitefly population provides one example of how rapidly symbiont-conferred traits can spread through a population. Only 1% of whiteflies were infected with *Rickettsia* in 2000. In 2006, 97% of flies were infected. In another example, a strain of *Wolbachia* (➡ Section 15.1) swept through populations of *Drosophila simulans* in California in only 3 years.

An important applied benefit of improved basic understanding of insect symbionts is the increased use of symbionts in insect pest management and the control of vectorborne diseases, such as malaria and filariasis in humans (➡ Sections 32.5 and 32.7). For example, symbiotic *Wolbachia*, which are reproductive manipulators, are widely distributed among insect species (possibly infecting as many as 60–70% of all insect species). The sperm of *Wolbachia*-infected males can sterilize uninfected females. Although the mechanism for sterilization is not fully understood, the phenomenon is being tested as a means to suppress disease transmission. Release of a large number of *Wolbachia*-infected male *Culex quinquefasciatus* mosquitoes, the vector of the filarial nematode causing elephantiasis (➡ Section 32.7), in Myanmar (Burma) effectively eliminated the local mosquito population.

In some cases, the presence of the symbiont decreases insect transmission of disease. *Aedes aegypti* mosquitoes infected with *Wolbachia* are less likely to transmit the virus causing dengue fever (➡ Section 30.5). However, in some other cases, the presence of the symbiont increases disease transmission. For example, whiteflies infected with *Hamiltonella* bacteria (a symbiont affiliated with the *Enterobacteriaceae*) are more likely than uninfected flies to transmit tomato yellow leaf curl virus.

Nutritional Significance of Obligate Intracellular Symbionts of Insects

The association of bacteria and insects has allowed many insects to use food resources that are rich in some nutrients, but poor in others. To achieve adequate nutrition, some insects exploit the metabolic potential of their symbionts. For instance, aphids feed on the carbohydrate-rich but otherwise nutrient-poor sap of phloem vessels in plants. Early on it was suspected that obligate symbionts might benefit the insect by providing nutrients not provided by their primary diet, and this is now known to be true.

Molecular analyses have shown that most families of aphids harbor the bacterium *Buchnera* in their bacteriomes (➡ Section 6.5). The role of *Buchnera* in host nutrition was first indicated by experiments

using defined diets to examine the nutrient requirements of aphids. Compared with infected controls, symbiont-free aphids required a diet containing all amino acids that are either lacking or rare in phloem sap. Subsequent genomic studies documented the presence in *Buchnera* of genes encoding the biosynthesis of nine amino acids missing from the sap. There are also examples of synergy between host and symbiont where the synthesis of certain amino acids becomes a joint venture. For example, *Buchnera* lacks the enzyme needed for the last step in leucine biosynthesis, but the necessary gene is present in the aphid's genome. Presumably, this enzyme is made by the aphid and participates in the leucine biosynthetic pathway along with the bacterial enzymes.

A secondary symbiont can also contribute to a joint venture. For example, the *Buchnera* symbiont of the cedar aphid is unable to supply tryptophan to the aphid. Two genes in the tryptophan biosynthetic pathway are present in *Buchnera*, but the remaining genes for the pathway are located on the chromosome of a secondary endosymbiont (Figure 22.36). Thus, different parts of a required metabolic pathway can be encoded by different endosymbionts present in the same insect. The fungus-cultivating ants provide yet another example of a complex symbiosis that has formed between an insect and multiple microorganisms (see Explore the Microbial World, "The Multiple Microbial Symbionts of Fungus-Cultivating Ants").

Mealybugs (*Planococcus citri*) present one of the most unusual examples of a partnership between two symbionts infecting the same insect. Mealybugs have two stable bacterial symbionts, "*Candidatus Tremblaya princeps*" (a *Betaproteobacterium*) and "*Candidatus Moranella endobia*" (a *Gammaproteobacterium*) (the term "*Candidatus*" means that these organisms are not yet in pure culture). These symbionts cooperate in providing essential amino acids to the host missing in its diet, as is true for the symbionts of many sap-feeding insects. However, the *Moranella* bacterium lives inside of *Tremblaya*! This is the only known example of a bacterium-within-a-bacterium symbiosis. The highly reduced *Tremblaya* genome has lost all genes for tRNA synthetases, an essential function either supplied by the host or by the *Moranella* residing within its cytoplasm.

Genome Reduction and Gene Transfer Events

Common features of primary symbionts are extreme genome reduction (➡ Table 6.1), high adenine plus thymine content, and accelerated rates of mutation. Genomes of insect symbionts fall within a range from 0.14 to 0.80 Mbp and 16.5 to 33% G+C (Table 22.3). The 0.14-Mb genome of "*Candidatus Tremblaya princeps*" is the smallest genome known for any cell. In contrast, the genomes of related free-living bacteria range from 2 to 8 Mbp with a base composition closer to 50% G+C. Two common types of spontaneous mutation, cytosine deamination and the oxidation of guanosine, if not repaired, change a GC pair to an AT pair (➡ Section 10.2). Symbionts with reduced genomes have fewer DNA repair enzymes (➡ Section 10.4) and this likely facilitates a shift over time to genomes of lower G+C content.

The streamlined genomes of insect symbionts have lost genes from most functional categories (Chapter 6) and tend to retain only genes required for host fitness and essential molecular

EXPLORE THE MICROBIAL WORLD

The Multiple Microbial Symbionts of Fungus-Cultivating Ants

The attine ants are an example of an elaborate symbiotic association between multiple microbial species and insect. These ants have established an obligate mutualism with a fungus they cultivate in fungal gardens for food, using small leaf fragments to mulch these gardens. A close symbiotic relationship between ant and fungus was first indicated by the observation that one specific fungus was cultivated by each ant lineage. The ants and their mutualistic fungi can be divided into five agricultural systems, each requiring distinct lineages of ants and fungi. Ants grouped in the “lower attine agriculture” system form associations with specific groups of fungi they capture from the environment. By contrast, the “higher attine agriculture” group cultivates fungi that apparently are no longer capable of existing apart from the ant mutualism.

In addition to the close mutualistic relationship between ant species and the specific fungus they cultivate, this symbiosis is now known to include four other microbial symbionts: a small fungus that is parasitic on the garden fungus, nitrogen-fixing bacteria (Section 3.17) associated with the garden fungus, an actinobacterium that antagonizes the parasitic fungus, and a black yeast that interferes with the actinobacterium.

The fungus is vertically transmitted between ant generations by colony-founding queens. The queen collects a pellet of fungus prior to her mating flight, storing it in a pouch in the oral cavity. After mating, she uses the fungus pellet to establish a new nest and fungus garden (Figure 1a). Nitrogen-fixing *Klebsiella* and *Pantoea* species associated with the fungus enrich the nutritional quality of the garden by adding new nitrogen to the nitrogen-poor leaf growth substrate. A single leaf-cutter ant

colony may contribute as much as 1.8 kg of fixed nitrogen per year. This new nitrogen benefits the ant colony and also results in higher overall plant diversity near leaf-cutter colonies.

However, the garden is at risk of being destroyed by a parasitic fungus of the genus *Escovopsis*. To repel the parasitic microfungus, the ant has formed another symbiotic association with an actinobacterium (genus *Pseudonocardia*) that appears as a “waxy bloom” growing on the cuticle of the ant (Figure 1b). These bacteria, housed in specialized cuticular modifications on the ant’s body, secrete secondary metabolites that inhibit the growth of *Escovopsis*. The *Pseudonocardia* likely receive nourishment from the ant from glandular secretions through pores localized in regions of cuticular modification. Comparative genomic sequencing has revealed

good congruence between the phylogenies of the ants, fungal cultivars, *Escovopsis*, and *Pseudonocardia*, pointing to very specific interactions among microorganisms and ants in this complex symbiosis.

The fourth and final microorganism identified in this symbiosis is a yeast that grows in the same cuticular regions colonized by the bacterium *Pseudonocardia*. This black-pigmented yeast interferes with chemical protection of the garden by stealing nutrients from the *Pseudonocardia*, thereby indirectly reducing its ability to suppress *Escovopsis* growth. The attine ant–microbial symbiosis is thus a complex maze of interactions between ant, fungi, and bacteria. Another example of a symbiotic trio—in this case a plant, animal, and bacterium—was described on page 669.

processes, such as translation, replication, and transcription. Genome reduction implies that the symbionts are reliant on the host for many functions no longer encoded in the symbiont genome (Section 6.5). For example, in many cases genes needed for the biosynthesis of cell wall components are missing, including lipid A and peptidoglycan, suggesting that the host supplies these functions or that the structures are not required to form stable cells within the bacteriocyte.

There is an interesting genomic contrast between primary symbionts and typical disease-causing bacteria (pathogens). While primary symbionts tend to lose genes encoding proteins

required in *catabolic* pathways, pathogenic bacteria typically retain these, but lose genes for *anabolic* pathways. This reflects their differing relationships with their hosts; the insect symbiont provides the host with essential biosynthetic nutrients while the pathogen obtains important biosynthetic nutrients from the host.

Because genome sequences for a large number of insects and their symbionts are now appearing, microbiologists can begin to evaluate the frequency of gene transfer between them. Horizontal gene transfer is the movement of genetic information across normal mating barriers (Chapters 10 and 12). Although early

research demonstrated that DNA of *Wolbachia* bacteria has been transferred to the nuclear genomes of their insect and nematode hosts, inspection of other insect mutualisms for which both host and symbiont genome sequences have become available (e.g., aphid and body louse), indicate that DNA transfer is very rare. This suggests that horizontal transfer is highly variable for reasons yet to be determined.

22.10 Termites

Microorganisms are primarily responsible for the degradation of wood and cellulose in natural environments. However, the activities of free-living microbial species have been exploited by certain groups of insects that have established symbiotic associations with protists and bacteria that can digest lignocellulosic materials. Like the rumen of herbivorous animals, the insect gut provides a protective niche for microbial symbionts, and in return, the insect gains access to nutrients derived from an otherwise indigestible carbon source. Termites are among the most abundant representatives of this type of symbiotic alliance.

Termite Natural History and Biochemistry

Microbial symbionts in termites decompose the greater part of cellulose (74–99%) and hemicellulose (65–87%) in the plant material they ingest. In contrast to the insect examples discussed in the previous section, most termites do not harbor *intracellular* bacteria. Instead, the symbiotic bacteria are present in digestive organs (guts) as in the case of mammals.

Termite diets include lignocellulosic plant materials (either intact or at various stages of decay), dung, and soil organic matter (humus). About two-thirds of the terrestrial environment supports one or more termite species, with the greatest representation in tropical and subtropical regions, where termites may constitute as much as 10% of all animal biomass and 95% of soil insect biomass. In savannas, their numbers sometimes exceed 4000/m², and their biomass density (1–10 g/m²) may be higher than that of grazing mammalian herbivores.

Termites are categorized as higher or lower based on their phylogeny, and this classification correlates with different symbiotic strategies. The posterior alimentary tract of *higher* termites (family *Termitidae*, comprising about three-fourths of termite species) contains a dense and diverse community of mostly anaerobic bacteria, including cellulolytic species. In contrast, the *lower* termites harbor diverse populations of both anaerobic bacteria and cellulolytic protists. Bacteria of lower termites participate little or not at all in cellulose digestion; only the protists phagocytize and degrade the wood particles ingested by the termites. The termite itself produces cellulases in the salivary glands or the midgut epithelium, but the relative contributions of microbial and termite enzymes to lignocellulosic breakdown is unknown.

The termite gut consists of a foregut (including the crop and muscular gizzard), a tubular midgut (site of secretion of digestive enzymes and absorption of soluble nutrients), and a relatively large hindgut of about 1 microliter volume (Figure 22.37). In lower termites, the hindgut consists primarily of a single chamber, the *paunch* (Figure 22.37a). The hindgut of most higher termites is more complex, being divided into several compartments (Figure 22.37b). For both higher and lower termites, the hindgut harbors a dense and diverse microbial community and is a major site of nutrient absorption. Acetate and other organic acids are produced during microbial fermentation of carbohydrate in the hindgut, and these products are primary carbon and energy sources for the termite (Figure 22.37c). High O₂ consumption by bacteria near the gut wall keeps the interior of the hindgut anoxic. However, microsensor measurements (Section 18.8) have shown that O₂ can penetrate up to 200 µm into the gut before it is completely removed by microbial respiratory activity. Thus, this tiny gut compartment offers distinct microbial niches with respect to O₂ and can support diverse microbial activities.

Bacterial Diversity and Lignocellulose Digestion in Higher Termites

In termites of different genera, the microbial gut communities differ significantly. Analysis of 16S rRNA gene sequences from hindgut contents of species of the higher termite genus *Nasutitermes* revealed a high diversity of microbial species from 12 phyla of *Bacteria*, but few *Archaea* (Figure 22.38). Spirochetes of

(c) Photo of workers, gut architecture, and biochemical activities of the lower termite *Coptotermes formosanus*. Acetate and other products of microbial fermentations are assimilated by the termite. Hydrogen produced by fermentation is consumed primarily by CO_2 -reducing acetogens, with a smaller amount going to hydrogenotrophic methanogens. Methanogenesis and acetogenesis are discussed in Sections 13.20 and 13.19, respectively.

the genus *Treponema* (☞ Section 14.20) dominated, with a lesser contribution from thus far uncultured organisms distantly related to the phylum *Fibrobacteres* (☞ Section 15.21), a group also present in the rumen (Figure 22.30). Metagenomic analysis (☞ Section 6.10) of the *Nasutitermes* hindgut microbial community has revealed bacterial genes encoding glycosyl hydrolases that hydrolyze cellulose and hemicelluloses. These metagenomic data clearly implicate spirochetes and *Fibrobacteres* in the digestion of lignocellulose, although the corresponding cellulolytic bacteria have not yet been isolated from the higher termites (Figure 22.38). At every molting of an individual termite, gut symbionts are lost, yet there is good conservation of the gut community within each termite species. Stable horizontal transmission of gut symbionts likely occurs due to the intimate social behavior and close contact characteristic of termites.

Acetogenesis and Nitrogen Fixation in the Termite Gut

Genes encoding enzymes of the acetyl-CoA pathway are highly represented in the spirochetes of the *Nasutitermes* hindgut, consistent with their function as the major CO_2 -reducing acetogens (☞ Section 13.19). The termite gut microbial communities have long been recognized as important to host nitrogen metabolism, providing new fixed nitrogen through nitrogen fixation (☞ Section 3.17) and helping to conserve nitrogen by recycling excretory nitrogen back to the insect for biosynthesis. Consistent with this, metagenomic analyses reveal that many bacteria, including *Fibrobacteres* and treponeme spirochetes, contain genes encoding nitrogenase, the enzyme required to fix N_2 .

From a simple energetic viewpoint, methanogenesis from H_2 and CO_2 is more favorable than acetogenesis from the same substrates (-34 kJ/mol of H_2 versus -26 kJ/mol of H_2 , respectively), and thus methanogens should have a competitive advantage in all habitats in which the two processes compete (☞ Sections 13.19–13.20).

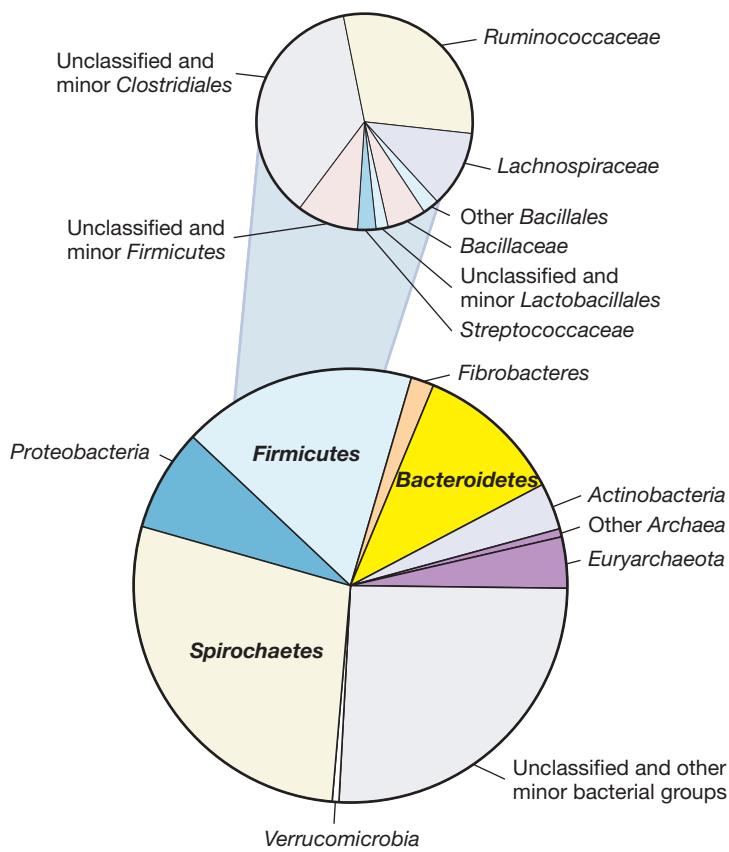

Figure 22.38 Microbial composition of termite hindgut inferred from 16S rRNA sequences. The results are pooled analyses of 5075 sequences from amplified or metagenomic sequencing studies of three genera of wood-feeding higher termites, *Nasutitermes*, *Reticulitermes*, and *Microcerotermes*. The data provide information primarily of diversity, not relative abundance. Data assembled and analyzed by Nicolas Pinel.

However, in termites they do not. There are at least two reasons for this. First, unlike methanogens, acetogens are able to use other substrates such as sugars or methyl groups from lignin degradation as electron donors for energy metabolism. Second, termite acetogens (which seem to consist mostly of spirochetes) can for some reason better colonize the H₂-rich termite gut center, whereas methanogens are largely restricted to the gut wall. On the wall, methanogens are located downstream of the H₂ gradient and thus receive only a fraction of the H₂ flux. In addition, the wall likely contains higher O₂ tensions, which may negatively affect the physiology of methanogens. So, despite the fact that termites are methanogenic, producing up to 150 teragrams of CH₄ per year on a global basis

(1 teragram = 10¹² grams), carbon and electron flow in the termite gut favor acetogenesis in this interesting anoxic microbial habitat.

V • Aquatic Invertebrates as Microbial Habitats

Thus far in this chapter we have discussed how certain macroorganisms that live in terrestrial environments provide habitats for microbial symbionts. Aquatic environments—especially marine environments—impose different constraints on symbioses and offer different opportunities and challenges for the evolution of symbioses between macroorganisms and microorganisms. Nevertheless, microbial symbioses with marine animals, especially with invertebrates, are common. By finding habitats in marine invertebrates, microorganisms establish a safe residence in a nutritionally rich environment. And the invertebrates benefit, too, as we will see with two well-studied examples: the squid and the hydrothermal vent animal symbioses. These, and the other microbial-animal associations discussed in this section, are thus true symbioses, with both partners benefiting from the relationship.

22.11 Hawaiian Bobtail Squid

The Hawaiian bobtail squid, *Euprymna scolopes*, is a small marine invertebrate (Figure 22.39a) that sequesters large populations of the bioluminescent gram-negative gammaproteobacterium *Aliivibrio fischeri* (➡ Section 15.4) in a light organ located on its ventral side. Squid and bacterium are partners in a mutualism. The bacteria emit light that resembles moonlight penetrating marine

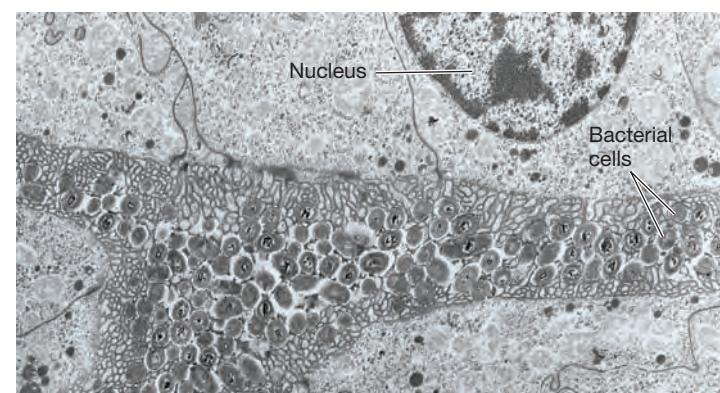

waters, and this is thought to camouflage the squid from predators that strike from beneath. Several other species of *Euprymna* inhabit marine waters near Japan and Australia and in the Mediterranean, and these contain *Aliivibrio* symbionts as well.

The Squid–*Aliivibrio* System as a Model Symbiosis

Many features of the *E. scolopes*–*A. fischeri* symbiosis have made it an important model for studies of animal–bacterial symbioses. These include the facts that the animals can be grown in the laboratory and that there is only a single bacterial species in the symbiosis in contrast to the huge number in symbioses such as those of the rumen (Figure 22.30) or the mammalian large intestine (Figure 22.33). In addition, the symbiosis is not an essential one; both the squid and its bacterial partner can be cultured apart from each other in the laboratory. This allows juvenile squid to be grown without bacterial symbionts and then experimentally colonized. Experiments can be done to study specificity in the symbiosis, the number of bacterial cells needed to initiate an infection, the capacity of genetically defined mutants of *A. fischeri* to initiate infection of the squid, and many other aspects of the relationship. Moreover, because the genome of *A. fischeri* has been sequenced, the powerful techniques of microbial genomics may be employed.

Establishing the Squid–*Aliivibrio* Symbiosis

Juvenile squid just hatched from eggs do not contain cells of *A. fischeri*. Thus, transmission of bacterial cells to juvenile squid is a horizontal (environmental) rather than a vertical (parent to offspring) event. Almost immediately after juveniles emerge from eggs, cells of *A. fischeri* in surrounding seawater begin to colonize them, entering through ciliated ducts that end in the immature light organ. Amazingly, the light organ becomes colonized specifically with *A. fischeri* and not with any of the many other species of gram-negative bacteria present in the seawater. Even if large numbers of other species of bioluminescent bacteria are offered to juvenile squid along with low numbers of *A. fischeri*, only *A. fischeri* establishes residence in the light organ. This implies that the animal in some way recognizes and accepts *A. fischeri* cells and excludes those of other species.

The squid–*Aliivibrio* symbiosis develops in several stages. Contact of the squid with any bacterial cells triggers recognition in a very general way. Upon contact with peptidoglycan (a component of the cell wall of *Bacteria*, [Section 2.10](#)), the young squid secretes mucus from its developing light organ. The mucus is the first layer of specificity in the symbiosis, as it makes gram-negative but not gram-positive bacteria aggregate. Within the aggregates of gram-negative cells that may contain only low numbers of *A. fischeri*, this bacterium somehow outcompetes the other gram-negative bacteria to form a monoculture. The monoculture is established within 2 h of a juvenile's hatching from an egg. The highly motile *A. fischeri* cells present in the aggregate migrate up the ducts and into the light organ tissues. Once there, they lose their flagella, become nonmotile, divide to form dense populations (Figure 22.39b), and trigger developmental events that lead to maturation of the host light organ. The light organ in a mature *E. scolopes* contains between 10^8 and 10^9 *A. fischeri* cells.

Colonization of *A. fischeri* by the squid is assisted by the gas nitric oxide (NO). Nitric oxide is a well-known defense response of animal cells to attack by bacterial pathogens; the gas is a strong oxidant and causes sufficient oxidative damage to bacterial cells to kill them ([Section 25.1](#)). Nitric oxide produced by the squid is incorporated into the mucus aggregates and is present in the light organ itself. As *A. fischeri* colonizes the light organ, NO levels diminish rapidly. It appears that cells of *A. fischeri* can tolerate exposure to NO and consume it through the activity of NO-inactivating enzymes. The inability of other gram-negative bacteria in the mucus aggregates to detoxify NO helps explain the sudden enrichment of *A. fischeri* in the ducts even before the actual colonization of the light organ. Then, after establishment, continued production of NO in the light organ prevents colonization by other bacterial species.

Propagating the Symbiosis

The squid matures into an adult in about two months and then lives a strictly nocturnal existence in which it feeds mostly on small crustaceans. During the day, the animal buries itself and remains quiescent in the sand. Each morning the squid nearly empties its light organ of *A. fischeri* cells and begins to grow a new population of the bacterium. The bacterial cells grow rapidly in the light organ; by midafternoon, the structure contains the dense populations of *A. fischeri* cells required for the production of visible light. The actual emission of light requires a certain density of cells and is controlled by the regulatory mechanism called *quorum sensing* ([Section 7.9](#)). The daily expulsion of bacterial cells is thought to be

a mechanism for seeding the environment with cells of the bacterial symbionts. This, of course, increases the chances that the next generation of juvenile squid will be colonized.

A. fischeri grows much faster in the light organ than in the open ocean, presumably because it is supplied with nutrients by the squid. Thus *A. fischeri* benefits from the symbiosis by having an alternative habitat to seawater in which rapid growth and dense populations are possible. Isolation studies have shown that *A. fischeri* is not a particularly abundant marine bacterium. Daily expulsion of *A. fischeri* cells from the light organ increases the bacterium's numbers in the microbial community. Thus, the symbiotic relationship of the bacterium with the squid probably helps maintain larger *A. fischeri* populations than would exist if all cells were free-living. Because the competitive success of a microbial species is to some degree a function of population size ([Section 19.1](#)), this boost in cell numbers may confer an important ecological advantage on *A. fischeri* in its marine habitat.

22.12 Marine Invertebrates at Hydrothermal Vents and Gas Seeps

Diverse invertebrate communities develop near undersea hot springs called *hydrothermal vents*. We covered the geochemistry and microbiology of hydrothermal vents in [Section 19.13](#). Here we focus on hydrothermal vent animals and their microbial symbionts.

Macroinvertebrates, including tube worms over 2 m in length and large clams and mussels, are present near these vents ([Figure 22.40](#)). Photosynthesis cannot support these invertebrate communities because they exist below the photic zone. However, hydrothermal fluids contain large amounts of reduced inorganic materials, including H_2S , Mn^{2+} , H_2 , and CO (carbon monoxide), and some vents contain high levels of ammonium (NH_4^+) instead of H_2S . All of these are good electron donors for chemolithotrophs, *Bacteria* and *Archaea* that use inorganic compounds as electron donors and fix CO_2 as their carbon source ([Chapter 13](#)). Thus, these hydrothermal vent invertebrates can exist in permanent darkness because they are nourished through a symbiotic association with these autotrophic bacteria.

Tube Worms, Mussels, and Giant Clams

Hydrothermal vent–associated animals either feed directly on free-living chemolithotrophs or have formed tight symbiotic associations with them. Mutualistic chemolithotrophs are either tightly attached to the animal surface (that is, as *epibionts*) or actually live within the animal tissues, supplying organic compounds to the animals in exchange for a safe residence and ready access to the electron donors needed for their energy metabolism. For example, the 2-m-long tube worms (Figure 22.40a) lack a mouth, gut, and anus, but contain an organ consisting primarily of spongy tissue called the *trophosome*. This structure, which constitutes half the worm's weight, is filled with sulfur granules and large populations of spherical sulfur-oxidizing

bacteria (Figure 22.41). Bacterial cells taken from trophosome tissue show activity of enzymes of the Calvin cycle, a major pathway for autotrophy (☞ Section 13.5), but interestingly, they also contain enzymes of the reverse citric acid cycle, a second autotrophic pathway (☞ Section 13.5). In addition, they show a suite of sulfur-oxidizing enzymes necessary to obtain energy from reduced sulfur compounds (☞ Sections 13.8 and 14.11). The tube worms are thus nourished by organic compounds produced from CO_2 and secreted by the sulfur chemolithotrophs.

Along with tube worms, giant clams and mussels (Figure 22.40b) are also common near hydrothermal vents, and sulfur-oxidizing bacterial symbionts have been found in the gill tissues of these animals. Phylogenetic analyses have shown that each individual animal harbors one or more different strains of bacterial symbiont and that a variety of species of bacterial symbionts inhabit different species of vent animal. With the exception of the symbiont of *Riftia*, which also has a free-living stage (Table 22.3), none of the bacterial symbionts of hydrothermal vent animals have yet been obtained in laboratory culture, even though they are fairly closely related to free-living sulfur chemolithotrophs (☞ Sections 13.8, 14.11, and 15.5).

The red plume of the tube worm (Figure 22.40a) is rich in blood vessels and is used to trap and transport inorganic substrates to the

bacterial symbionts. Tube worms contain unusual hemoglobins that bind H_2S and O_2 ; these are then transported to the trophosome where they are released to the bacterial symbionts. The CO_2 content of tube-worm blood is also high, about 25 mM, and presumably this is released in the trophosome as a carbon source for the symbionts. In addition, stable isotope analyses (☞ Section 18.9) of elemental sulfur from the trophosome have shown that its $^{34}\text{S}/^{32}\text{S}$ composition is the same as that of the sulfide emitted from the vent. This ratio is distinct from that of seawater sulfate and is further proof that geothermal sulfide is actually entering the worm in large amounts.

Other marine invertebrates have coevolved bacterial symbioses that supply their nutrition as well (Table 22.4). For example, methanotrophic (CH_4 -consuming) symbionts are present in giant clams that live near natural gas seeps at relatively shallow depths in the Gulf of Mexico. Although not autotrophs (CH_4 is an organic compound), the methanotrophs do provide nutrition to the clams; the methanotrophs use CH_4 as their electron donor and carbon source and secrete organic carbon to the clams. Molecular hydrogen (H_2) was recently shown to be used as an electron donor by the mussel *Bathymodiolus putoeserpentis*, the most abundant macrofauna in vent fields associated with the peridotite-hosted vent systems of the Mid-Atlantic Ridge (☞ Section 19.13). These systems release extremely high levels of H_2 and CH_4 , with measured H_2 concentrations as high as 19 mM. This mussel was previously shown to live in a dual symbiosis with methane-oxidizing bacteria and chemolithotrophic sulfur-oxidizing bacteria localized to the gill tissue. Remarkably, the sulfur-oxidizing symbiont of *B. putoeserpentis* also has the capacity to use H_2 as an energy source, making this mussel one of the most versatile of vent macrofauna.

Genomics and Hydrothermal Vent Symbioses

Genome sequencing is revealing additional features of the metabolic interaction and coevolution of marine invertebrates and their bacterial symbionts. The genome sequence of the gill endosymbiont of the giant vent clam *Calyptogena magnifica* offers direct evidence for carbon fixation via the Calvin cycle; the genome encodes

the key enzymes of the Calvin cycle, ribulose bisphosphate carboxylase (RubisCO) and phosphoribulokinase (Section 13.5), and genes encoding key sulfur oxidation processes. The genome of this symbiont also encodes the biosynthesis of most vitamins and cofactors and all 20 amino acids needed to support the host. However, because few substrate-specific transporters are encoded by the symbiont genome, it is suspected that the clam actually digests symbiont cells for nutrition, as do mussels (Table 22.4).

Like the obligate symbionts of insects, most symbionts of marine invertebrates have small genomes (Table 22.3), indicating reduced function and an obligate association with their host. The bacterial symbiont of the giant tube worm *Riftia pachyptila* is an exception, having a genome larger than some free-living sulfur-oxidizing chemolithotrophs (Table 22.3). The *R. pachyptila* symbiont is acquired by uninfected juvenile animals from the environment (horizontal transmission), and its larger genome is likely important for survival as a free-living bacterium.

22.13 Leeches

Leeches are parasitic annelids (segmented worms). Leeches are related to earthworms and share several properties with them. Some leeches live in marine environments, but our example here, the medicinal leech *Hirudo verbana* (Figure 22.42a), lives in freshwater.

Parasitic Lifestyle of Leeches

Like many animals that depend on a microbial partner, medicinal leeches have a restricted diet. They feed exclusively on vertebrate blood and secrete powerful anticoagulants and vasodilators that stimulate blood flow. In a single feeding, *H. verbana* can consume over five times its body weight in blood. The blood meal is stored in the *crop*, which is the largest compartment of the leech digestive tract (Figure 22.42b). During feeding, water and salts are absorbed from the crop content until most water is removed and the fluid is in osmotic balance with the leech hemolymph. Excess water and nitrogenous waste are secreted through several pairs of bladders. Both the digestive tract and the bladder house microbial communities. It is thought that one function of the symbionts is to provide essential nutrients, such as vitamin B₁₂, absent or in low amounts in the blood meal.

This amazing ability of medicinal leeches to remove blood and secrete pharmacologically active compounds has been used for ages for the medical practice of *bloodletting*, and in recent times most commonly in plastic and reconstructive surgery. A challenge for medical replants and transplants is the connection of the veins. If, after transplant surgery, the number of functional veins exiting from the surgically introduced tissue is insufficient, the flow of fresh oxygenated blood into the tissue is stopped. The lack of oxygen can result in failure of the transplant. Leeches applied to the area remove blood, letting fresh blood enter the introduced tissue, and this procedure increases the transplant success rate.

The Leech Microbial Community

The leech digestive tract has two major compartments that house microbial communities, the digestive tract (the large crop and the

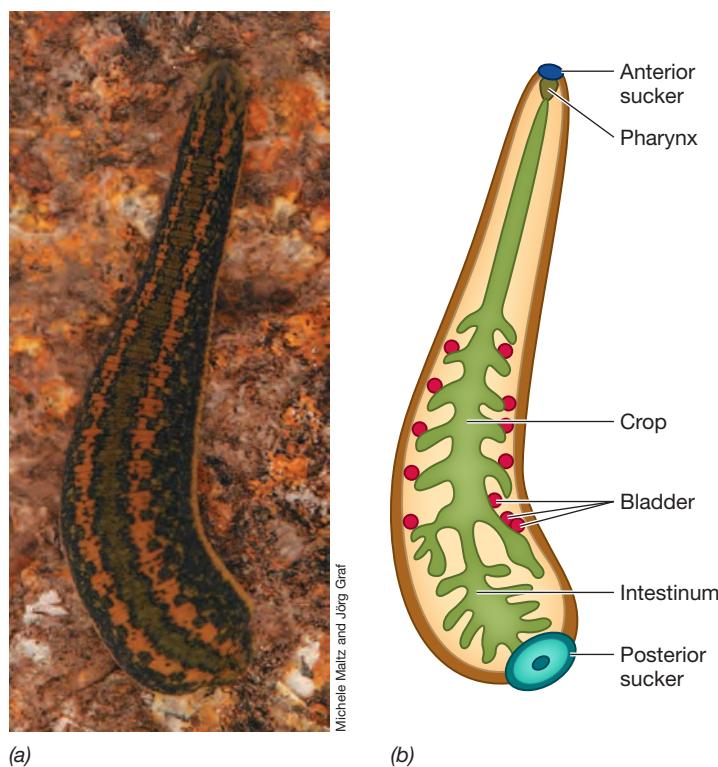

Figure 22.42 Medicinal leech *Hirudo verbana*. (a) An animal of about 6 cm in length. (b) Anatomy of *H. verbana*, showing the crop, intestinum, and bladder pairs.

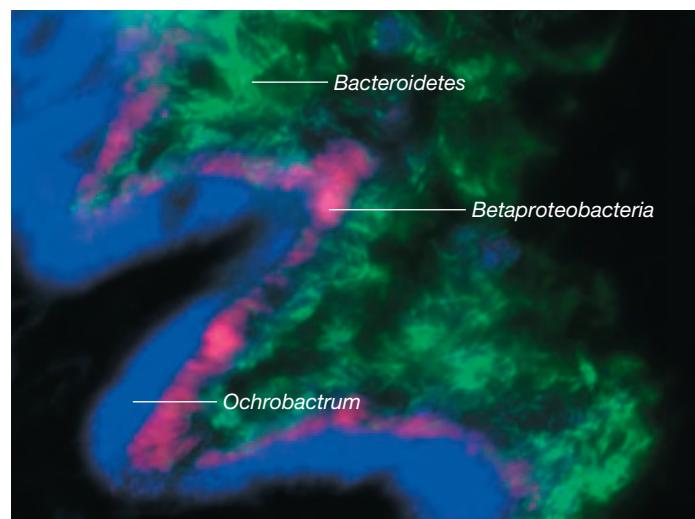

smaller intestine), where the digestion of the erythrocytes and absorption of nutrients are thought to occur, and the bladders (Figure 22.42b). The microbial community of the crop is surprisingly simple. Culture-independent studies using a combination of 16S rRNA gene analyses and fluorescence in situ hybridization (FISH,  Section 18.4) revealed that the microbial community inside the crop is dominated by two species, *Aeromonas veronii* (*Gammaproteobacteria*) and a *Rikenella*-like (*Bacteroidetes*) bacterium. Farther along the alimentary canal toward the intestine (Figure 22.42b) the complexity of the microbial community increases. In the intestine various *Alpha-* and *Gammaproteobacteria*, along with *Bacteroidetes* and *Firmicutes*, prevail.

The functional significance of the simple microbial community of the crop has been explored through a combination of metagenomic and metatranscriptomic analyses (Chapter 6), together suggesting that the *Rikenella*-like symbiont has the capacity to forage on sulfated- and sialated-mucin polysaccharides (glycans) that line the surface of the crop epithelium. Mucins comprise a family of heavily glycosylated proteins that form gels functioning in lubrication or as protective barriers on the surface of epithelial tissue. The sequence-based insight prompted the development of a mucin-based cultivation medium subsequently used for the successful selective enrichment and isolation of the *Rikenella*-like symbiont, confirming its ability to ferment host-derived polysaccharides to acetate. Since acetate is likely utilized by *Aeromonas veronii*, this discovery also provided a possible physiological link between the two major crop symbionts. Also, the ability of the *Rikenella*-like symbiont to utilize the leech-derived mucin may explain the ability of the symbionts to persist within the leech gut for up to 6 months between blood feedings.

The unusually simple microbial community inside the crop suggests that there are mechanisms that prevent other microorganisms from colonizing. Specificity of symbiotic associations can be affected by the mode of transmission and molecular mechanisms that interfere with colonization or maintenance of microorganisms that enter the gut habitat, as we saw for *Aliivibrio* colonization of the squid light organ (Section 22.11). For example, leech hemocytes, invertebrate macrophage-like cells ( Section 24.1), patrol the gut and phagocytose bacteria. *A. veronii* is able to prevent phagocytosis and colonize the leech gut by injecting toxins directly into the hemocytes, using a bacterial secretion system that functions like a molecular syringe ( Section 4.14).

The bladders of leeches (Figure 22.42b) house an interesting ensemble of microorganisms. The epithelial cells lining the lumen of the bladder are tightly packed with an *Ochrobactrum* species. These bacteria are related to beneficial and pathogenic alphaproteobacterial symbionts, such as *Sinorhizobium meliloti* (Section 22.3) and *Brucella abortus*. The microbial community in the lumen of the bladder displays a distinct stratification: Two species of *Bacteroidetes* colonize the epithelial side and two species of *Betaproteobacteria* colonize the luminal side of the biofilm-like structure that coats the bladder wall (Figure 22.43).

Symbiotic relationships require transmission of the microbial partners between host generations. Many gut symbionts are horizontally (environmentally) transmitted, but *A. veronii* appears to be vertically transmitted from the parent to the offspring through the “cocoons” in which the embryos develop (juvenile leeches removed from cocoons are already infected with cells of *A. veronii*).

A probe (red) targeted at the 16S rRNA of *Betaproteobacteria* and a probe (green) targeted at the 16S rRNA of *Bacteroidetes* reveal distinct layers of different bacteria in the lumen of the bladder. Staining with DAPI (blue), which binds to DNA, reveals the intracellular alphaproteobacterium *Ochrobactrum* and host nuclei.

Similarly, most of the bladder symbionts have been detected in juveniles taken from cocoons. Such vertical transmission of the symbionts ensures their safe transfer to the next host generation.

22.14 Reef-Building Corals

Coral reef ecosystems are the products of mutualistic associations between algae and simple marine animals. The extensive ecosystems associated with the worldwide distribution of these mutualisms support tens of thousands of species.

Phototrophic Symbioses with Animals

We saw in the beginning of this chapter that a lichen is a mutualism between a fungus and a phototrophic partner—an alga or cyanobacterium. Like the fungi, some animals establish mutualistic associations with photosynthetic algae or cyanobacteria (Table 22.5). The animals in most of these associations are in phyla that display very simple body plans; for example, the Porifera (sponges) and Cnidaria (corals, sea anemones, and hydroids). These mutualistic animal–bacterial associations live in clear tropical waters where nutrients for the animals are scarce, and the animal body typically has a large surface area relative to its volume and is thus well suited for capturing light.

The coral skeleton is an extremely efficient light-gathering structure that greatly enhances light harvesting. There are only a few instances of algae forming associations with more complex animals, such as those in the phyla Platyhelminthes (flatworms), Mollusca (snails and clams), and Urochordata (sea squirts).

Table 22.5 Symbioses between animals and phototrophic symbionts

Host	Common name	Symbionts
Porifera	Sponge	Cyanobacteria, <i>Chlorella</i> , <i>Symbiodinium</i>
Cnidaria	Coral, sea anemone	<i>Symbiodinium</i> , <i>Chlorella</i>
Platyhelminthes	Flatworm	Diatoms, primitive chlorophytes
Mollusca	Snail, clam	<i>Symbiodinium</i> , <i>Chlorella</i>
Ascidia	Sea squirt	Cyanobacteria

In these cases either the animal has a suitable surface-to-volume ratio or has evolved specific light-gathering surfaces. The unicellular phototrophic symbionts are phylogenetically diverse and include cyanobacteria (➡ Section 14.3), and red and green algae, diatoms, and dinoflagellates (Chapter 17). Most common are the green algae *Chlorella* (associating with sponges and freshwater hydras), cyanobacteria (associating with marine sponges), and species of the dinoflagellate genus *Symbiodinium*.

The most spectacular and ecologically significant of these mutualisms is between the cnidarian stony corals (order Scleractinia) and the dinoflagellate *Symbiodinium* (Figure 22.44). Together the corals and dinoflagellates form the trophic and structural foundation of the coral reef ecosystem. The cnidarians possess a very simple two-tissue-layer body plan (ectoderm and gastroderm) and harbor the dinoflagellate symbiont intracellularly in vacuoles called *symbiosomes* within cells of the inner (gastrodermal) tissue layer (Figure 22.44c). The algae receive key inorganic nutrients from host metabolism and pass photosynthetically produced organic compounds to the corals. This mutualism has allowed coral reefs to develop in large expanses of nutrient-poor ocean waters. Dinoflagellates and other alveolates comprise eight genera and around 2000 extant species (➡ Section 17.5). Although dinoflagellate mutualisms are common, most are between species of *Symbiodinium* and marine invertebrates or protists (Figure 22.44). We focus here on the symbiotic association between *Symbiodinium* and the stony coral cnidarians.

Transmission, Specificity, and Benefits of the *Symbiodinium*-Coral Association

Reef-building corals reproduce sexually by releasing gametes into the seawater (broadcast spawning). A male and a female gamete

fuse to form a free-swimming larva that later settles on a surface, where it may initiate a new coral colony. Algal symbionts are typically present in the egg before it is released from the parent (vertical transmission), although free-living *Symbiodinium* cells can also be ingested by juvenile corals (horizontal transmission). A developing coral that ingests dinoflagellates digests all of them except the particular *Symbiodinium* of its mutualism. After establishing an association, the coral controls the growth of *Symbiodinium* via chemical signaling and, following each cell division, each *Symbiodinium* daughter cell is allocated to a new symbiosome.

Both partners in the cnidarian–dinoflagellate mutualism have evolved adaptations for nutritional exchange. The dinoflagellates donate most of their photosynthetically fixed carbon (in the form of small molecules such as sugars, glycerol, and amino acids) to the cnidarian in exchange for inorganic nitrogen, phosphorus, and inorganic carbon from the host. Moreover, in addition to providing protection and inorganic nutrients, the calcium carbonate skeleton of corals is one of the most efficient collectors of solar radiation in nature, amplifying the incident light field for the symbionts by as much as fivefold; this benefits the symbiont in carrying out photosynthesis under a light-absorbing water column.

Coral Bleaching—The Risk of Harboring a Phototrophic Symbiont in a Changing World

Many of the extensive coral reef systems in the oceans worldwide are now threatened with extinction, primarily as a consequence of human activities. Ongoing loss of these beautiful and productive ecosystems is thought to be the result of elevated atmospheric CO₂; namely, increased sea surface temperature, rising sea levels, and ocean acidification (➡ Sections 20.6 and 20.8). Coastal development also threatens reef systems, contributing to pollution from sewage discharge, eutrophication from nutrient runoff, and overfishing. These environmental changes are contributing to high mortality through disease, loss of coral structure from reduced calcification caused by acidification, and bleaching. Healthy corals harbor millions of cells of *Symbiodinium* per square centimeter of tissue. Coral bleaching is the loss of color from host tissues caused by the lysis of these symbionts, revealing the underlying white limestone skeleton (Figure 22.45).

Coral reefs live close to their optimum temperature and it is the synergistic effect of increased sea surface temperature and irradiance

that causes massive bleaching. Elevated temperature and high irradiance impair the photosynthetic apparatus of the dinoflagellates, resulting in the production of reactive oxygen species (for example, singlet oxygen and superoxide (Section 5.16) that cause damage to both host and symbiont. Bleaching is thought to be caused by a protective immune response of the host that destroys compromised symbionts. Increases in sea surface temperatures as small as 0.5–1.5°C above the local maximum, if sustained for several weeks, can induce rapid coral bleaching. A significant decrease in temperature below the optimum range for coral growth can have a similar impact. Thermal stress, accentuated by seasonal increases in electromagnetic radiation of ultraviolet and some visible wavelengths, has resulted in bleaching of huge expanses of coral reefs.

Although coral reefs are clearly threatened, there is much uncertainty in projecting their future. The more ominous projections, based on projected increases in sea temperature, point to a collapse of Indian Ocean coral reef systems within only a few years and a possible global collapse of coral reefs by the middle of this century. However, these projections still lack basic knowledge about the vulnerability of individual coral species and the adaptive capacity of individual coral–symbiont mutualisms. For example, thermal tolerance is in part conferred by the species or strain of *Symbiodinium*, and following a bleaching event the mutualism can shift to a more thermally tolerant symbiont (Figure 22.46).

Molecular results have indicated that there are over 150 different *Symbiodinium* phylotypes, each possibly representing a distinct species with different stress tolerance. Both symbiont swapping and symbiont switching have been proposed as the underlying mechanism for shifting between symbionts. In switching, the symbiont is taken up from a water column population. In swapping, the shift results from differential growth of a genetic variant already associated with the coral, but in very low numbers, thereby swapping places with the previously dominant mutualist following the bleaching event. Most studies indicate that swapping is the more common adaptive mechanism, but uncertainty remains. Because the type of symbiont influences the ability of the coral to adapt to stresses associated with climate change, a more complete understanding of the alternative mechanisms of adaptive response, including possible symbiont switching, is essential to predicting the future health of corals, their symbionts, and the reefs they build.

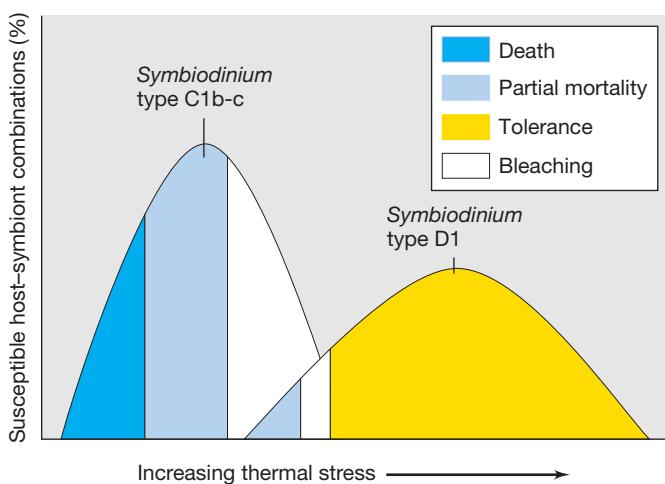

Figure 22.46 Differential stress tolerance of a coral species associated with different *Symbiodinium* phylotypes. *Pocillopora* corals symbiotically associated with *Symbiodinium* type C1b-c were much more sensitive to a thermal stress event than the same coral species associated with *Symbiodinium* type D1. The more tolerant *Symbiodinium*–*Pocillopora* association suffered very low mortality. The response also suggested additional genetic variation within each *Symbiodinium* type, since the two mutualisms displayed a range of sensitivity to increasing thermal stress.

BIG IDEAS

22.1 • Lichens are a mutualistic association between a fungus and an oxygenic phototroph.

22.2 • The consortium “*Chlorochromatium aggregatum*” is a mutualism between a phototrophic green sulfur bacterium and a motile heterotroph. Mutual benefit is based on the phototroph supplying organic matter to the heterotroph in exchange for motility that permits rapid repositioning in stratified lakes to obtain optimal light and nutrients.

22.3 • One of the most agriculturally important plant–microbial symbioses is that between legumes and nitrogen-fixing bacteria. The bacteria induce the formation of root nodules within which nitrogen fixation occurs. The plant provides the energy needed by the root nodule bacteria, and the bacteria provide fixed nitrogen for the plant.

22.4 • The crown gall bacterium *Agrobacterium* enters into a unique relationship with plants. Part of the Ti plasmid in the bacterium can be transferred into the genome of the plant, initiating crown gall disease. The Ti plasmid has also been used for the genetic engineering of crop plants.

22.5 • Mycorrhizae are mutualistic associations between fungi and the roots of plants that allow the plant to extend its root system via intimate interaction with an extensive network of fungal mycelia. Both ectomycorrhizae and endomycorrhizae are known. The mycelia network provides the plant with essential inorganic nutrients, and the plant, in turn, supplies organic compounds to the fungus.

22.6 • Microbial fermentation is important for digestion in all mammals. Several microbial mutualisms have evolved in different mammals that allow for the digestion of different types of food. Herbivores derive almost all of their carbon and energy from plant fiber.

22.7 • The rumen, the digestive organ of ruminant animals, specializes in cellulose digestion, which is carried out by microorganisms. Bacteria, protists, and fungi in the rumen produce volatile fatty acids that provide energy for the ruminant. Rumen microorganisms synthesize vitamins and amino acids and are also a major source of protein—all used by the ruminant.

22.8 • The human microbiome encompasses all sites of the human body inhabited by microorganisms. The microorganisms are critical to early development, health, and predisposition to

disease. The human gut microbial community is unique when compared with that of other mammals. The gut microflora affects energy recovery from food, and a shift in gut community structure may be a major factor in obesity.

22.9 • A large proportion of insects have established obligate mutualisms with bacteria, the basis of the mutualism often being bacterial biosynthesis of nutrients such as amino acids that are absent from the food the insect feeds on. Long-established obligate mutualisms are marked by extreme genome reduction of the symbiont, with retention of only those genes essential for the mutualism.

22.10 • Termites associate symbiotically with bacteria and protists capable of digesting plant cell walls. The unique termite gut configuration and the hindgut microbial community composed largely of cellulolytic bacteria and protists and acetogenic bacteria result in high levels of acetate, the primary source of carbon and energy for the termite.

22.11 • A light-emitting organ on the underside of the Hawaiian bobtail squid provides a habitat for bioluminescent cells of *Aliivibrio fischeri*. From the mutualism in the light organ, the squid gains protection from predators while the bacterium benefits from a habitat in which it grows quickly and contributes cells to its free-living population.

22.12 • Most invertebrates living on the seafloor near regions receiving hydrothermal fluids have established obligate mutualisms with chemolithotrophic bacteria. These mutualisms are nutritional, allowing the invertebrates to thrive in an environment enriched in reduced inorganic materials, such as H₂S, that are abundant in vent fluids. The invertebrates provide the symbionts an ideal nutritional environment in exchange for organic nutrients.

22.13 • Leeches and particular bacterial species form symbioses in regions of the host body that are important for host nutrition and nitrogen retention. The existence of mechanisms for vertical transmission of the symbionts indicates that these mutualisms are highly evolved and functionally important.

22.14 • The mutualism between the dinoflagellate *Symbiodinium* and the stony corals produces the extensive worldwide coral reef ecosystems that sustain a tremendous diversity of marine life. Coral bleaching caused by climate change threatens these ecosystems.

REVIEW OF KEY TERMS

Arbuscule branched or coiled hyphal structure within cells of the inner cortex of plants with a mycorrhizal infection

Bacteriocyte a specialized insect cell in which bacterial symbionts reside

Bacteriome a specialized region in several insect groups that contains insect bacteriocyte cells packed with bacterial symbionts

Bacteroid the misshapen cells of rhizobia inside a leguminous plant root nodule; can fix N₂

Coevolution evolution that proceeds jointly in a pair of intimately associated species owing to the effects each has on the other

Consortium a mutualism between bacteria, for example, a phototrophic green sulfur bacterium and a motile nonphototrophic bacterium

Dysbiosis an alteration or imbalance of an individual's microbiome relative to the normal, healthy state, primarily observed in the microbiota of the digestive tract or the skin.

Infection thread in the formation of root nodules, a cellulosic tube through which *Rhizobium* cells can travel to reach and infect root cells

Leghemoglobin an O₂-binding protein found in root nodules

Lichen a fungus and an alga (or cyanobacterium) living in symbiotic association

Mutualism a symbiosis in which both partners benefit

Myc factors lipochitin oligosaccharides produced by mycorrhizal fungi to initiate symbiosis with a plant

Mycorrhizae a symbiotic association between a fungus and the roots of a plant

Nod factors lipochitin oligosaccharides produced by root nodule bacteria that help initiate the plant–bacterial symbiosis

Root nodule a tumorlike growth on plant roots that contains symbiotic nitrogen-fixing bacteria

Rumen the first vessel in the multichambered stomach of ruminant animals in which cellulose digestion occurs

Symbiosis an intimate relationship between two organisms, often developed through prolonged association and coevolution

Ti plasmid a conjugative plasmid in the bacterium *Agrobacterium tumefaciens* that can transfer genes into plants

Volatile fatty acids (VFAs) the major fatty acids (acetate, propionate, and butyrate) produced during fermentation in the rumen

The Fungal Microbiome of the Skin

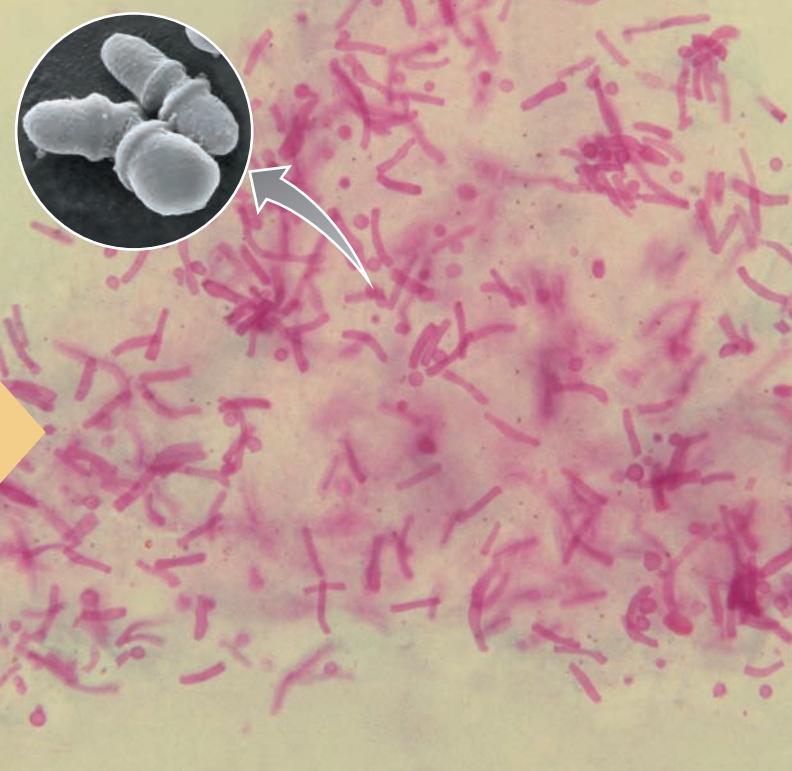

A major challenge to developing an accurate picture of the human microbiome is its incredible diversity and the issues inherent with capturing data that accurately reflect this diversity. Besides bacteria, other microorganisms inhabit the human body, in particular, fungi, and it is important to include these organisms when deriving a census of the human microbiome. A recent study does just that.¹

Ten healthy human volunteers were sampled at 14 different body sites and the samples processed for both fungal and bacterial diversity. Using genomic methods that analyzed a key phylogenetic gene in fungi, the researchers generated more than 5 million sequences to compare with 16S rRNA gene sequences derived from bacteria obtained from the same samples. By analyzing and comparing the diversity in their samples, they compiled an inclusive list of the human skin microbiome, which includes over 200 genera each of fungi and bacteria.

Analysis of the data showed that the fungus *Malassezia* (photos) was present at all body sites and was the predominant genus in all but sites on the foot. The latter showed high fungal diversity but relatively low bacterial diversity. In general, fungal diversity correlated with body site, with the greatest diversity on the foot. Bacterial diversity, on the other hand, depended more on the physiology of the skin sites (moist, dry, or oily), as we will explore further in this chapter.

Our understanding of the role of the skin in health and disease depends on our understanding of the normal skin microflora, including the fungi. The role of the normal microflora in protection against disease and the mechanism(s) by which the immune system learns to tolerate the normal microflora are important questions for the future of this field.

- I **Normal Human–Microbial Interactions 706**
- II **Pathogenesis 714**
- III **Host Factors in Infection and Disease 725**

Humans have an extensive population of microorganisms, including large populations of bacteria and fungi, on their skin and the mucous membranes lining the mouth, gut, and excretory and reproductive systems. The human body is composed of about 10^{13} cells, but about ten times as many microorganisms live on or in the body that are beneficial and even necessary to maintain good health.

Microorganisms called *pathogens* can invade, infect and damage the human body. Pathogens use attachment structures,

growth factors, enzymes, and toxins to gain access and damage host tissues. We begin our coverage here with microorganisms normally found in and on the human body. We then look at selected pathogens and some of their disease-producing strategies. We conclude by introducing the non-specific defense mechanisms our bodies use to suppress or destroy most pathogens.

I • Normal Human–Microbial Interactions

Through normal everyday activities, the human body is exposed to microorganisms in the environment. Hundreds of species and countless individual microbial cells, collectively called the **normal microflora**, grow on or in the human body. This is the *human microbiome*, the sum total of all microorganisms that live on or in the human body.

23.1 Beneficial Human–Microbial Interactions

The normal microflora have developed a symbiotic relationship with the mammalian host. They contribute to the health and well-being of the host by producing beneficial microbial products and inhibiting growth of dangerous microorganisms. In turn, the host contributes various microenvironments that support microbial growth. The normal microflora are first introduced at birth.

Colonization

Mammals develop in a microbially sterile environment in utero and have no exposure to microorganisms. **Colonization**, the growth of a microorganism after it has gained access to host tissues, begins as mammals are exposed to microorganisms in the birth process. The skin surfaces are readily colonized by many species. Likewise, the mucous membranes of the oral cavity and gastrointestinal tract acquire microorganisms through feeding and exposure to the mother's body, which, along with other environmental sources, initiates colonization of the skin, oral cavity, upper respiratory tract, and gastrointestinal tract (Figure 23.1).

Different populations of microorganisms colonize individuals in different localities and at different times. Moreover, the normal microflora are highly diverse and may differ significantly between individuals, even in a given population. As we go along we will point out patterns of colonization by particular groups of microorganisms that inhabit specific niches, presumably because of their ability to access nutritional and metabolic support at particular body sites.

Mammalian hosts are rich in the organic nutrients and growth factors required by bacteria and provide conditions of controlled pH, osmotic pressure, and temperature that are favorable for the growth of microorganisms. Bodies, however, are not uniform environments. Each body region such as the skin, respiratory tract, and gastrointestinal tract differs chemically and physically from others, providing a selective environment that favors the growth of certain microorganisms and prevents the growth

of others. Thus, these different environments each support the growth of a diverse and regionally unique microflora. For example, the relatively dry environment of the skin favors the growth of dehydration-resistant species such as gram-positive streptococci and staphylococci (Sections 15.6 and 15.7), while the anoxic environment of the large intestine supports growth of obligately anaerobic bacteria such as *Bacteroides* (Section 15.13).

Table 23.1 shows some of the major types of microorganisms normally found in association with various body surfaces in humans. Normal microflora do not colonize the internal organs, blood, lymph, or the nervous systems. The growth of microorganisms in these normally microbially sterile environments indicates serious infectious disease.

Colonization Sites

Colonization typically begins at sites in the **mucous membranes** (Figure 23.1). Mucous membranes consist of *epithelial cells*, tightly packed cells that interface with the external environment. They are found throughout the body, lining the urogenital, respiratory, and gastrointestinal tracts. The epithelial cells in mucous membranes secrete **mucus**, a thick liquid secretion that contains water-soluble proteins and glycoproteins. Mucus retains moisture and inhibits microbial attachment; invaders are usually swept away by physical processes like swallowing or sneezing, but some microorganisms adhere to the epithelial surface and colonize.

Microorganisms are also found on surfaces of the body that are not mucous membranes but are exposed to the environment, especially the skin. As we shall see next, the skin is actually a complex organ consisting of several distinct microenvironments, each with its own characteristic microflora.

MINIQUIZ

- At what body sites are microflora found?

23.2 Microflora of the Skin

An average adult human has about two square meters (2 m^2) of skin surface that varies greatly in chemical composition and moisture content. One distinct microenvironment includes moist skin areas such as the inside of the nostril, the armpit, and the umbilicus. Moist skin is separated by only a few centimeters from dry microenvironments such as the forearms and the palms of the hands. A third microenvironment consists of areas with high concentrations of sebaceous glands that produce an oily substance called *sebum*. Sebaceous areas are those by the side of the nose, the back of the scalp, and the upper chest and back.

The skin microflora has been examined by molecular ecology methods employing comparative rRNA gene sequencing ([Section 18.5](#)). In one study, nineteen different bacterial phyla were detected, but four phyla predominated: *Actinobacteria*, *Firmicutes*, *Proteobacteria*, and *Bacteroidetes* ([Figure 23.2a](#)). Over 200 different genera were identified, but members of three genera, *Corynebacteria* (*Actinobacteria*), *Propionibacteria* (*Actinobacteria*), and *Staphylococcus* (*Firmicutes*) comprised more than 60% of the sequences (Figure 23.2b). Each microenvironment showed a unique microbiota. Moist sites were dominated by corynebacteria and staphylococci while drier sites supported a mixed population dominated by *Betaproteobacteria*, corynebacteria, and *Flavobacteriales*. Sebaceous areas had predominantly propionibacteria and staphylococci (Figure 23.2b).

Analysis of these data provides an overview of the human normal microflora, but individuals showed variations from the composite patterns, meaning that there is no single normal microflora pattern. Instead, a predictable group of microorganisms is likely

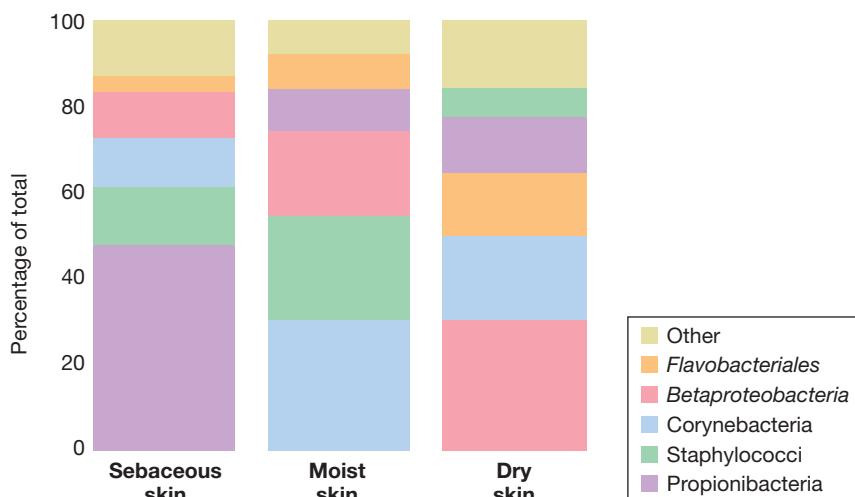

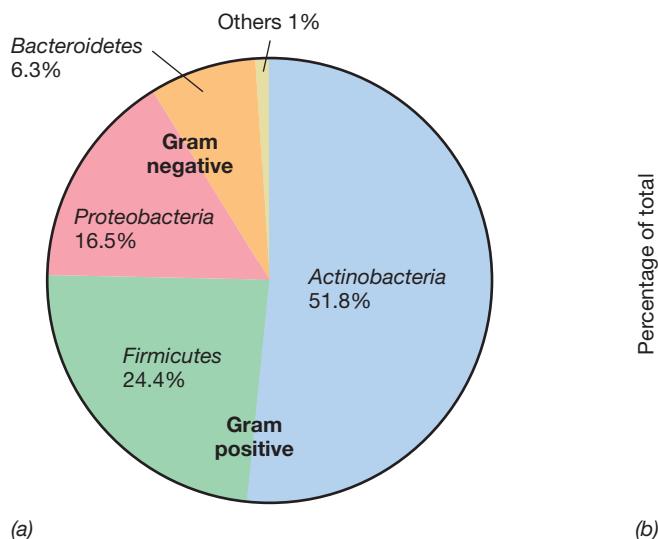

Figure 23.2 Normal skin microflora. (a) Analysis of the skin microbiome from 10 healthy human volunteers detected 19 bacterial phyla. Four phyla were predominant. (b) Composite populations of *Bacteria* from the same volunteers, divided according to sebaceous, moist, and dry skin microenvironments. to comprise the normal microflora of a given individual. As is the case for the microbiome of the gut (➡ Section 22.8), metagenomic analyses cannot define the total number of organisms present, but only estimate the number of different species present; thus, such analyses are estimates of *diversity* rather than *abundance*.

Eukaryotic microorganisms are also present on the skin. The chapter opening vignette (page 705) highlights microbiome studies that defined the genera and location of common fungi. *Malassezia* species are the most common fungi found on the skin, and at least five different species of this yeast are typically found in healthy individuals. In the absence of host resistance, as in patients with HIV/AIDS or whose normal microflora has been compromised, *Candida* and other fungi can also colonize the skin and cause serious infections.

Environmental and host factors influence the composition of the normal skin microflora. For example, the *weather* may cause an increase in skin temperature and moisture, which increases the density of the skin microflora. The *age* of the host also has an effect; young children have a more varied microflora and carry more potentially pathogenic gram-negative *Bacteria* than do adults. *Personal hygiene* influences the resident microflora; individuals with poor hygiene typically have higher microbial population densities on their skin. And finally, many microorganisms that would otherwise colonize skin cannot survive there simply because of its low moisture content and acidic pH.

MINIQUIZ

- Compare the populations of microorganisms in the three major skin microenvironments.

23.3 Microflora of the Oral Cavity

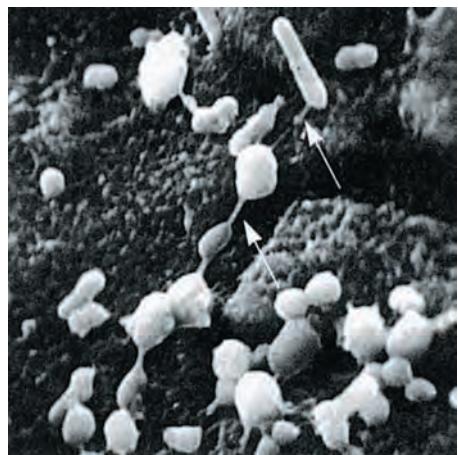

The oral cavity is a complex, heterogeneous microbial habitat. Several different microenvironments exist in the oral cavity that can support a broad microbial diversity.

The Oral Microenvironment

Saliva contains microbial nutrients, but it is not a good growth medium because the nutrients are present in low concentration and saliva contains antibacterial substances. In particular, saliva contains *lysozyme*, an enzyme that cleaves glycosidic linkages in peptidoglycan of the bacterial cell wall, weakening the wall and causing cell lysis (➡ Section 2.10). Another enzyme, *lactoperoxidase*, found in both milk and saliva, kills bacteria by a reaction in which singlet oxygen is generated (➡ Section 5.16). Despite the activity of these antibacterial substances, food particles and cell debris provide high concentrations of nutrients near surfaces such as teeth and gums, creating favorable conditions for extensive local microbial growth, tissue damage, and disease.

(b)

Note the diverse morphology of the organisms present and the slime layer (arrows) holding the organisms together.

The tooth consists of a mineral matrix of calcium phosphate crystals (enamel) surrounding living tooth tissue (dentin and pulp) (Figure 23.3). Bacteria found in the mouth during the first year of life (when teeth are absent) are predominantly aerotolerant anaerobes such as streptococci and lactobacilli, and a few aerobes. When the teeth appear, the newly created surfaces are rapidly colonized by anaerobes that are specifically adapted to growth in biofilms on the surfaces of the teeth and in the gingival crevices (Figure 23.4).

Oral Microflora

Metagenomic analysis of the human oral microflora show a complex microbial community. Samples acquired from a number of subjects show over 600 taxa (Table 23.2). Most of these microorganisms have facultatively aerobic metabolisms, but some, such as *Bacteroidetes*, are obligately anaerobic and some have aerobic metabolisms, such as the *Neisseria*, *Acinetobacter*, and *Moraxella* genera in the *Proteobacteria* phylum. The most abundant genera are among the *Firmicutes*; *Veillonella parvula*, an obligate anaerobe, is the most abundant single species and *Streptococcus* is the most abundant genus in the mouth, comprising about 25% of bacteria found in some individuals. The related *Firmicutes* genera *Abiotrophia*, *Gemella*, and *Granulicatella* are also extremely common; species from these genera were among the 10 taxa most frequently detected. Most are present in much lower numbers, with only 17 taxa each contributing more than 1% of the oral microbiome. As is the case for the skin microbiome (Section 23.2), not all taxa are present or similarly distributed in all individuals.

MINIQUIZ

- Compare the microbial microenvironments in the oral cavity in newborns and adults.
- Identify the microorganisms that predominate in the adult oral cavity by taxa and metabolic requirements.

23.4 Microflora of the Gastrointestinal Tract

The human gastrointestinal tract consists of the stomach, small intestine, and large intestine (Figure 23.5). The gastrointestinal tract is responsible for digestion of food and absorption of nutrients, and many important nutrients are produced by the indigenous microflora. Starting with the stomach, the digestive tract is a column of nutrients mixed with microorganisms, primarily *Bacteria*. The nutrients move through this column and as they do, they encounter ever-changing microbial communities. Here we examine the organisms as well as their functions and special properties throughout the entire gastrointestinal tract. In Section 22.8 we examined the microbial diversity of the human large intestine, emphasizing the symbiotic nature of the microbial community and its host.

The gastrointestinal tract has about 400 m^2 of surface area and is home to about 10^{14} microbial cells. Our current view of the diversity and numbers of microorganisms that reside here has come from a combination of culture-dependent methods and culture-independent molecular methods (Chapter 18).

The Stomach

Because stomach fluids are highly acidic (about pH 2), the stomach is a chemical barrier to the entry of microorganisms into the gastrointestinal tract. However, microorganisms do populate this seemingly hostile environment. The stomach microbial population consists of several different bacterial taxa. Each person has a unique population, but all contain several species of gram-positive bacteria as well as *Proteobacteria*, *Bacteroidetes*, *Actinobacteria*, and *Fusobacteria* (Figure 23.5). *Helicobacter pylori*, the most common single organism found, colonizes the stomach wall in many, but not all, individuals and can cause ulcers in susceptible hosts (➡ Section 29.10). Some of the bacteria that populate the stomach consist of organisms found in the oral cavity, introduced with the passage of food.

Distal to the stomach, the intestinal tract consists of the *small intestine* and the *large intestine*, each of which is divided into different anatomical segments. The composition of the intestinal microflora in humans varies considerably and is somewhat dependent on diet. For example, persons on a meat-based diet show higher numbers of *Bacteroides* and lower numbers of coliforms and lactic acid bacteria than do individuals with a vegetarian diet. Representative microorganisms found in the gastrointestinal tract are shown in Figure 23.5.

The Small Intestine

The small intestine has two distinct environments in the *duodenum* and the *ileum*, which are connected by the *jejunum*. The duodenum, adjacent to the stomach, is fairly acidic and its normal microflora resembles that of the stomach. From the duodenum to the ileum, the pH gradually becomes less acidic and bacterial numbers increase. In the lower ileum, cell numbers of

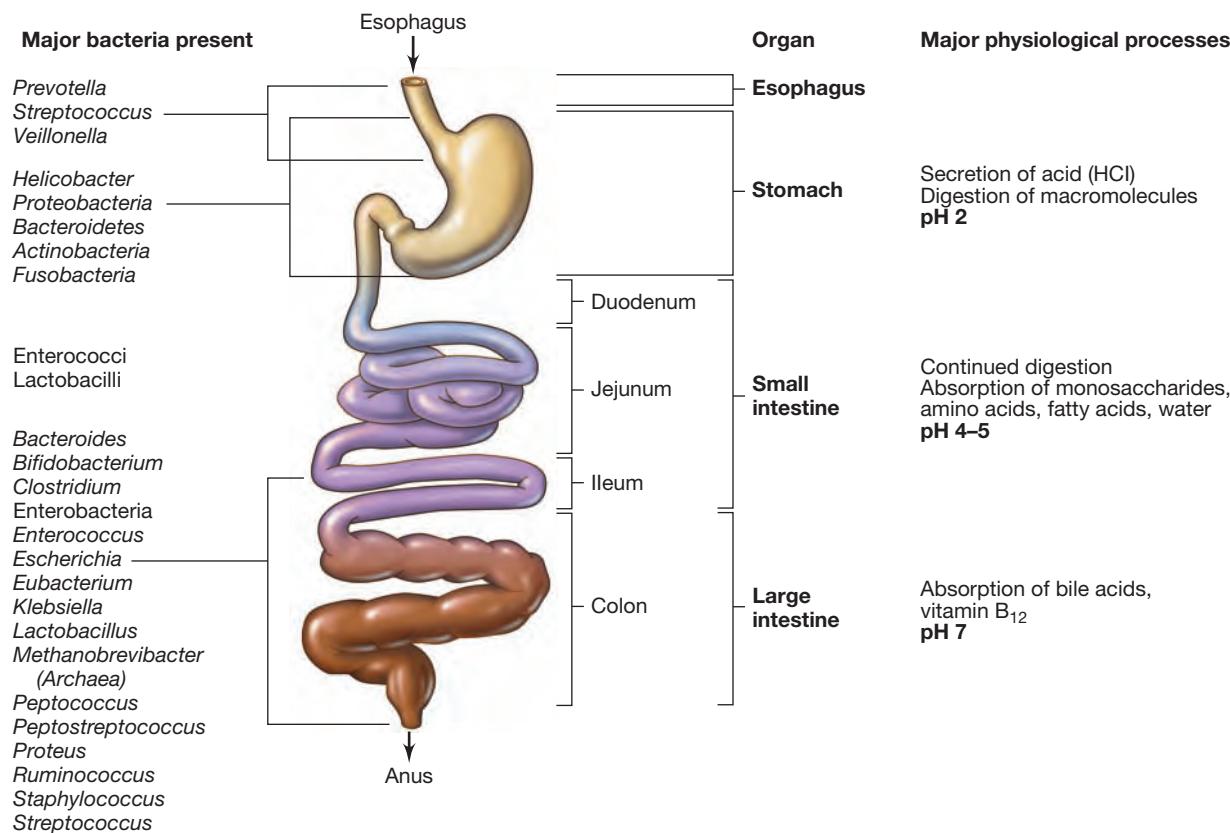

Figure 23.5 Microflora of the human gastrointestinal tract. These taxa are representative of microorganisms found in healthy adults. Not every individual harbors all of these microorganisms.

10^5 – 10^7 /gram of intestinal contents are common, even though the environment becomes progressively more anoxic. Fusiform anaerobic bacteria are typically present, attached to the intestinal wall at one end (Figure 23.6, ▶▶ Figure 1.10b).

The Large Intestine

The ileum empties into the *cecum*, the connecting portion of the large intestine. The *colon* makes up the rest of the large intestine. In the colon, prokaryotes are present in enormous numbers. The colon is essentially an *in vivo* fermentation vessel; many bacteria live here, using nutrients derived from the digestion of food (Figure 23.5). Facultative aerobes such as *Escherichia coli* are present but in smaller numbers than other bacteria; total counts of facultative aerobes are less than 10^7 /gram of intestinal contents. The facultative aerobes consume any remaining oxygen, making the large intestine strictly anoxic. Anoxia promotes growth of obligate anaerobes such as *Clostridium* and *Bacteroides* species.

The total number of obligate anaerobes in the colon is enormous. Bacterial counts of 10^{10} to 10^{11} cells/gram in distal gut and fecal contents are normal, with *Bacteroidetes* and gram-positive species accounting for greater than 99% of all *Bacteria*. The archaeal methanogen *Methanobrevibacter smithii* (▶▶ Section 16.2) may also be present in significant numbers. Protists are not found in the gastrointestinal tract of healthy humans but they can

cause gastrointestinal infections if ingested in contaminated food or water (Chapter 31). Section 22.8 gives a molecular snapshot of bacterial diversity in the human large intestine.

EXPLORE THE MICROBIAL WORLD

Probiotics

Microorganisms that are part of the normal microflora grow on and in the body and are essential to the well-being of all higher organisms. The microorganisms we acquire and retain compete at various sites in the body with pathogens, inhibiting colonization by these organisms. Commensals that reside in the gut are active participants in the digestion of food and manufacture of essential nutrients.

It follows that humans could manipulate their commensal bacteria, perhaps altering, regulating, or enhancing the normal flora to enhance the positive benefits of certain selected bacteria. In theory, the ingestion of selected microorganisms might be used to change or reestablish our gastrointestinal microflora to promote health, especially in individuals who experience major changes in their normal microflora due to disease, surgery, or other medical treatments, or whose normal microflora is altered for other reasons, such as poor diet. Intentionally ingested microorganisms used for this purpose are called *probiotics* (Figure 1). Probiotics are suspensions of live microorganisms that, when administered in adequate amounts, confer a perceived health benefit on the host.

Are probiotics really useful? Few studies conclusively show that the alteration of commensal microbial populations in normal healthy adults has major, long-lasting, positive health

effects. Most probiotic products (Figure 1) are directed toward replacing or reconstituting the intestinal microflora of humans by ingesting live, concentrated microbial cultures; the products are directed at preventing or correcting digestive problems. Probiotic products may thus confer short-term benefits, but there is little evidence for long-lasting establishment or reestablishment of an altered microflora without the continued consumption of the probiotic.

Probiotics are routinely used in production farm animals as part of their normal diet to prevent digestive problems. These same probiotic treatments may also be beneficial by reducing antibiotic use and preventing the development of antibiotic-resistant foodborne pathogens. The focus here is on the preventative nature of the treatments; animal probiotics are not used as a cure for disease. Strains of *Saccharomyces* (yeast), *Lactobacillus*, *Bacillus*, and *Propionibacterium* have been used for these purposes. Conceivably, similar treatments would also be beneficial for humans.

A number of human ailments respond positively to probiotics administration, although the mechanisms by which this occurs are unclear. For example, the watery diarrhea children experience from rotavirus infection can be shortened by administration of several probiotics preparations. *Saccharomyces* may

reduce the recurrence of diarrhea and shorten infections due to *Clostridium difficile*. Probiotic lactobacilli have also been used to treat urogenital infections in humans.

The composition of the gut microflora can change rapidly when probiotics are administered. In many cases, the makers of probiotics recommend that the microbial supplements should be consumed on a regular basis over a long period of time to achieve the intended result; if consumption is stopped, the gut microflora returns to its original state, indicating that the effects of probiotics are likely only short term. Thus, while probiotics may offer several benefits, especially for reestablishing the gut's normal microflora following catastrophic events such as severe diarrheal disease, evidence for positive and lasting benefits is not well established. Carefully designed and scientifically controlled studies must be conducted to document the outcomes of probiotic treatment. The studies must use standardized preparations of probiotics containing known organisms and administered in precise doses to test efficacy.

Products of Intestinal Microflora

Intestinal microorganisms carry out a variety of metabolic reactions that produce several important compounds (Table 23.3). The composition of the intestinal microflora and the diet influence the type and amount of compounds produced. Among these products are vitamins B₁₂ and K. These essential vitamins are not synthesized by humans (and vitamin B₁₂ is not present in plants) but are made by the intestinal microflora and absorbed from the colon. In addition, steroids, produced in the liver and released into the intestine from the gallbladder as bile acids, are modified in the intestine by the microflora; the modified bioactive steroid compounds are then absorbed from the gut.

Other products generated by the activities of fermentative bacteria and methanogens include gas and several odoriferous substances (Table 23.3). Normal adults expel several hundred milliliters of gas from the intestines each day (flatus), of which about half is nitrogen (N₂) from swallowed air. Some foods metabolized by fermentative bacteria in the intestines result in the production of hydrogen (H₂) and carbon dioxide (CO₂). Methanogens, found in the intestines of many but not all adults, convert H₂ and CO₂ produced by fermentative bacteria to methane (CH₄). The methanogens in the rumen of cattle (➡ Section 22.7) produce huge amounts of methane, up to a quarter of total global production.

During the passage of food through the gastrointestinal tract, water is absorbed from the digested material, which gradually becomes more concentrated and is converted to feces. Bacteria compose about one-third of the weight of fecal matter. Organisms living in the lumen of the large intestine are continuously displaced downward by the flow of material, and bacteria that are lost are continuously replaced by new growth, similar to an *in vitro* continuous culture system (➡ Section 5.7). The time needed for passage of material through the human gastrointestinal tract is about 24 h, and the growth rate of bacteria in the lumen is one to two doublings per day. In humans, about 10¹³ bacterial cells are shed each day in feces.

Changing the Normal Microflora

When an antibiotic is taken orally it inhibits the growth of the normal flora as well as the targeted pathogen(s), leading to the loss of antibiotic-susceptible bacteria in the intestinal tract; this

alteration of the intestinal microbial community is often signaled by the voiding of loose feces or diarrhea. In the absence of a full complement of normal flora, opportunistic pathogens such as antibiotic-resistant *Staphylococcus*, *Proteus*, *Clostridium difficile*, or the yeast *Candida albicans* can become established and can affect digestive functions or actually cause disease. For example, antibiotic treatment allows bacteria such as *C. difficile* that are less susceptible to antibiotics to grow without competition from the normal flora, causing infection and colitis.

When antibiotic therapy ends, the normal intestinal flora are quickly reestablished in adults. To speed this process, recolonization of the gut by desired species can be accomplished by the administration of **probiotics**, live cultures of intestinal bacteria that, when administered to a host, may confer a health benefit. Rapid recolonization of the gut may reestablish a competitive local flora that can outcompete pathogens and provide desirable microbial metabolic products (see Explore the Microbial World, "Probiotics").

23.5 Microflora of Mucosal Tissues

Mucous membranes support the growth of a normal microflora that prevents infection by pathogenic microorganisms. Here we discuss two mucosal environments and their resident microorganisms.

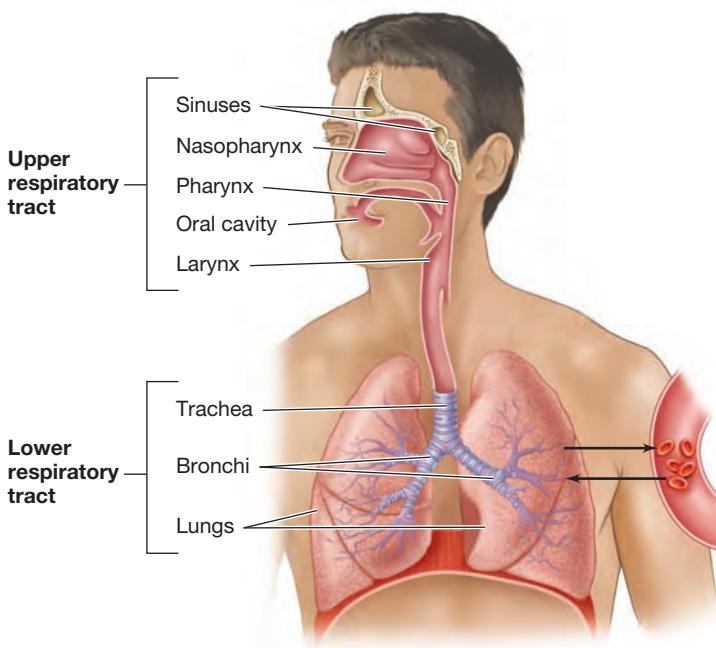

Figure 23.7 The respiratory tract. In healthy individuals the upper respiratory tract has a large variety and number of microorganisms. By contrast, the lower respiratory tract in a healthy person has few if any microorganisms.

Respiratory Tract

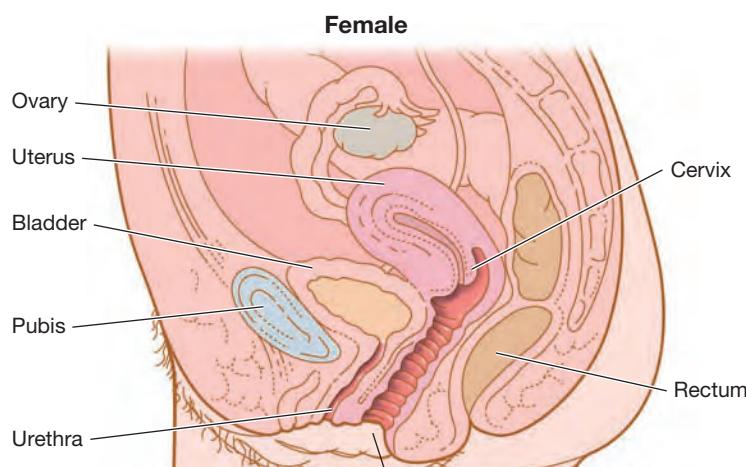

The anatomy of the respiratory tract is shown in [Figure 23.7](#). In the **upper respiratory tract** (nasopharynx, oral cavity, larynx, and pharynx), microorganisms live in areas bathed with secretions from the mucous membranes. Bacteria continually enter the upper respiratory tract from the air during breathing, but most are trapped in the mucus of the nasal and oral passages and expelled with nasal secretions, or swallowed. A few microorganisms, however, colonize respiratory mucosal surfaces in all individuals. The microorganisms most commonly present are staphylococci, streptococci, diphtheroid bacilli, and gram-negative cocci.

Occasionally, potential pathogens such as *Staphylococcus aureus* and *Streptococcus pneumoniae* are part of the normal flora in the nasopharynx of healthy individuals ([Table 23.1](#)). These individuals are *carriers* of the pathogens but do not normally develop disease, presumably because the other resident microorganisms compete successfully for nutritional and metabolic resources and limit pathogen activities. The innate immune system ([Section 24.2](#)) and components of the adaptive immune system such as secreted antibodies ([Section 25.7](#)) are particularly active at mucosal surfaces and inhibit growth and invasion by potential pathogens.

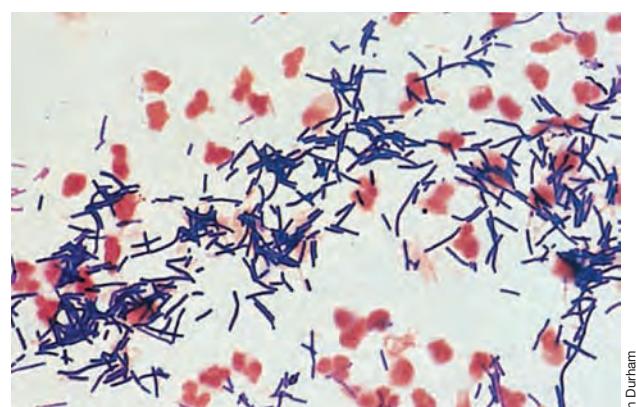

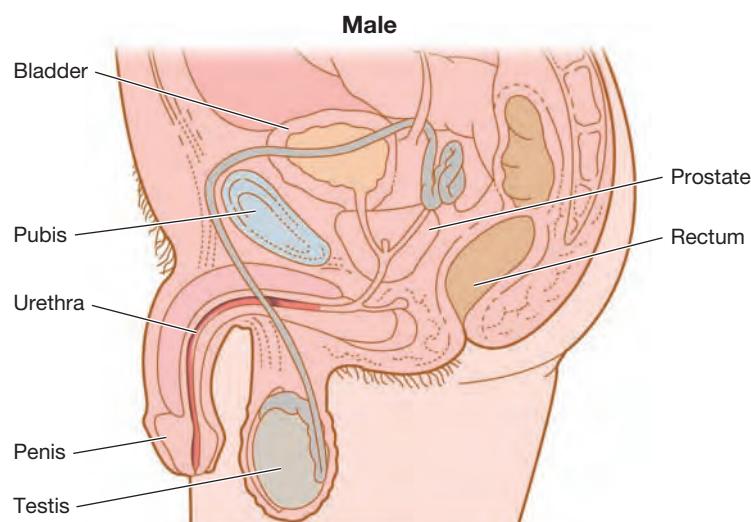

The **lower respiratory tract** (trachea, bronchi, and lungs) has no resident microflora in healthy adults, despite the large number of organisms potentially able to reach this region during normal breathing. Dust particles, which are fairly large, settle in the upper respiratory tract. As the air passes into the lower respiratory tract, the flow rate decreases, and organisms settle onto the walls of the respiratory passages. The walls of the entire respiratory tract are lined with ciliated epithelial cells, and the cilia, beating upward, push bacteria and other particulate matter toward the upper respiratory tract where they are then expelled in saliva and nasal secretions or are swallowed. Only particles smaller than about 10 µm in diameter reach the lungs. Nevertheless, some pathogens reach these locations and cause disease, most notably pneumonia caused by certain bacteria or viruses ([Sections 29.2 and 29.6](#)).

Urogenital Tract

In healthy male and female urogenital tracts ([Figure 23.8](#)), the kidneys and bladder are sterile; however, epithelial cells lining the distal urethra are colonized by facultatively aerobic gram-negative *Bacteria* ([Table 23.1](#)). Potential pathogens such as *Escherichia coli* and *Proteus mirabilis*, normally present in small numbers in the body or in the local environment, can multiply in the urethra

and cause disease if conditions such as changes in pH occur. Such organisms are a frequent cause of urinary tract infections, especially in females.

The vagina of the adult female is weakly acidic ($\text{pH} < 5$) and contains significant amounts of glycogen. *Lactobacillus acidophilus*, a resident organism in the vagina, ferments the polysaccharide glycogen, producing lactic acid that maintains a local acidic environment (Figure 23.8b). Other organisms, such as species of the yeasts *Torulopsis* and *Candida*, various streptococci, and *E. coli*, may also be present. Before puberty, *L. acidophilus* is absent, the female vagina is neutral and does not produce glycogen, and

the flora consist predominantly of staphylococci, streptococci, diphtheroids, and *E. coli*. After menopause, glycogen production ceases, the pH rises, and the flora again resembles that found before puberty.

II • Pathogenesis

Microbial pathogenesis is the process by which microorganisms cause disease. Microbial pathogenesis begins with exposure and adherence of microorganisms to host cells (Figure 23.1), followed by invasion, infection, and ultimately, disease (Figure 23.9). We begin with some important terms commonly used in medical microbiology.

23.6 Pathogenicity and Virulence

Infection is the growth of microorganisms that are not normally present within the host. A **host** is an organism that harbors a **pathogen**, another organism that lives on or in the host and causes disease. **Disease** is tissue damage or injury that impairs host function.

Unique properties of each pathogen contribute to its **pathogenicity**, the ability of a microorganism to cause disease. Pathogenicity differs considerably among pathogens, as does the resistance or susceptibility of the host to the pathogen. An **opportunistic pathogen** causes disease only in the absence of normal host resistance. For example, even normal microflora can cause infections and disease if host resistance is compromised, as may happen in diseases such as cancer and acquired immunodeficiency syndrome (AIDS) (☞ Section 29.14).

Virulence

The measure of pathogenicity is called **virulence**, the relative ability of a pathogen to cause disease. Virulence is the outcome of host-pathogen interactions, a dynamic relationship between the two organisms, influenced by ever-changing conditions in the pathogen, the host, and the environment. Neither the virulence of the pathogen nor the relative resistance of the host is a constant factor.

Virulence can be measured in experimental studies of the LD_{50} (lethal dose₅₀), the number of cells of a pathogen that kills 50% of the animals in a test group. Highly virulent pathogens frequently show little difference in the number of cells required to kill 100% of the test group as compared with the number required to kill 50%. This is illustrated in Figure 23.10 for experimental infections in mice. Only a few cells of virulent strains of *Streptococcus pneumoniae* are required to establish a fatal infection and kill all mice in a test population. As a result, the LD_{50} for *S. pneumoniae* in mice is not proportional to the number of cells delivered and is difficult to accurately determine. By contrast, the number of cells of a less virulent pathogen, *Salmonella enterica* serovar Typhimurium, necessary to kill all of the mice in the test population is about 10,000-fold greater than the highly virulent *S. pneumoniae* cells and the LD_{50} is proportionally related to the number of pathogen cells introduced into the test mice.

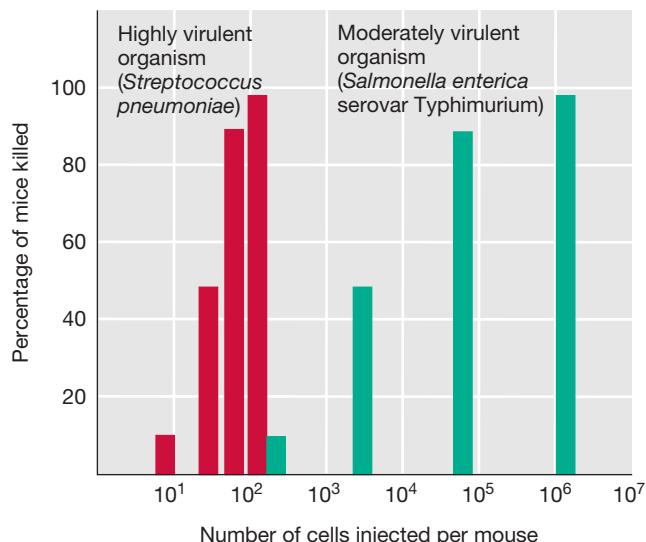

Figure 23.10 Microbial virulence. Differences in microbial virulence demonstrated by the number of cells of *Streptococcus pneumoniae* and *Salmonella enterica* serovar *Typhimurium* required to kill mice.

Attenuation

Attenuation is the decrease or loss of virulence of a pathogen. When pathogens are kept in laboratory culture rather than isolated from diseased animals, their virulence often decreases, or is even completely lost. Strains that have either a reduced virulence or are no longer virulent are said to be *attenuated*. Attenuation probably occurs because nonvirulent or weakly virulent mutants grow faster than virulent strains in laboratory media, where virulence has no selective advantage. After successive transfers in fresh media, such mutants are therefore selectively favored. If an attenuated culture is reinoculated into an animal, the organism may regain its original virulence, especially with continued *in vivo* passage. But in many cases, a loss of virulence is permanent. Nevertheless, attenuated strains can be very valuable because they are often used for the production of vaccines, especially viral vaccines. For example, measles, mumps, and rubella vaccines, and rabies vaccines for animals other than humans, employ attenuated strains of each virus.

MINIQUIZ

- What circumstances can contribute to attenuation of a pathogen?

23.7 Adherence

Bacteria or viruses able to initiate infection often adhere to epithelial cells through specific interactions between molecules on the pathogen and molecules on the host tissues. In addition, pathogens often adhere to each other, forming biofilms (➡ Section 19.4). In medical microbiology, **adherence** is the enhanced ability of a microorganism to attach to a cell or surface.

Noncovalent Adherence Factors

Some macromolecules responsible for bacterial adherence are not covalently attached to the bacteria. These surface molecules are collectively known as a **glycocalyx**, a polymer secreted by a bacterium that coats the surface of the bacterium. These are usually macromolecular polysaccharide polymers. For example, in the case of *Bacillus anthracis* (the bacterium that causes anthrax), the glycocalyx is a capsule composed of a polymer of D-glutamic acid. This capsule can be readily visualized, and the encapsulated cells of *B. anthracis* typically form smooth slimy colonies (Figure 23.11).

Cell surface structures were considered in Section 2.13. A loose network of polymers extending outward from a cell is called a **slime layer** (Figure 23.4b). A coat consisting of a dense, well-defined polymer layer surrounding the cell is called a **capsule** (Figure 23.12a). Slime layers and capsules are important for adherence to other bacteria as well as to host tissues, but many pathogens, for example *Vibrio cholerae*, the causative agent of the disease cholera, do not require slime layers or capsules for attachment (Figure 23.12b).

Capsules are particularly important for protecting pathogenic bacteria from host defense mechanisms. For example, the only known virulence factor for *Streptococcus pneumoniae* is

This organism has no capsule.

its polysaccharide capsule (Figure 23.13). Encapsulated strains of *S. pneumoniae* grow in lung tissues in enormous numbers, where they initiate host responses that lead to pneumonia, interfere with lung function, and cause extensive host damage or even death (Section 29.2). By contrast, nonencapsulated strains are quickly and efficiently ingested and destroyed by phagocytes, white blood cells that ingest and kill bacteria by a process called *phagocytosis*. Thus, *S. pneumoniae* capsules (Figure 23.13b) are essential for pathogenicity; the capsules defeat a major defense mechanism used by the host to prevent invasion (Section 24.2).

Other Adherence Factors: Fimbriae, Pili, and Flagella

Many pathogens selectively adhere to particular types of cells through cell surface structures other than capsules or slime layers. For example, *Neisseria gonorrhoeae*, the pathogen that causes the sexually transmitted disease gonorrhea, adheres specifically

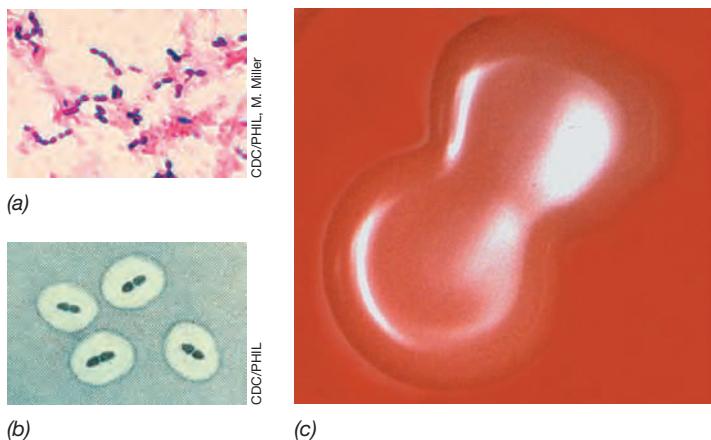

Figure 23.13 Capsules and colonies in *Streptococcus pneumoniae*. (a) Gram stain of *S. pneumoniae* cells; capsules are not visible. (b) *S. pneumoniae* treated with anticapsular antibodies (Quellung reaction) that make the capsule visible. to mucosal epithelial cells in the genitourinary tract, eye, rectum, and throat; other tissues are not infected. *N. gonorrhoeae* has a cell surface protein called Opa (opacity associated protein) that binds specifically to a host protein called CD66 found only on the surface of these cells, allowing adherence of the pathogen to host cells (Table 23.4). Likewise, influenza virus targets lung mucosal cells and attaches specifically to lung epithelial cells by way of the protein hemagglutinin present on the virus surface (Section 29.8).

Fimbriae and pili are bacterial cell surface protein structures (Section 2.13) that function in the attachment process. For instance, the pili of *Neisseria gonorrhoeae* play a key role in attachment to urogenital epithelia, and fimbriated strains of *Escherichia coli* (Figure 23.14) are more frequent causes of urinary tract infections than strains lacking fimbriae. Among the best-characterized fimbriae are the type I fimbriae of enteric bacteria (*Escherichia*, *Klebsiella*, *Salmonella*, and *Shigella*). Type I fimbriae are uniformly distributed on the surface of cells. Pili are typically longer

than fimbriae, with fewer pili found on the cell surface. Both pili and fimbriae function by binding host cell surface glycoproteins, initiating adherence. Flagella can also increase adherence to host cells (see Figure 23.17).

Studies of diarrhea caused by some pathogenic strains of *E. coli* indicate specific interactions between the mucosal epithelium and pathogens. Most strains of *E. coli* are nonpathogenic inhabitants of the cecum and the colon (Figure 23.5). Several nonpathogenic strains of *E. coli* are usually present in the body at the same time, and large numbers routinely pass through the body and are voided in feces. However, pathogenic enterotoxigenic strains of *E. coli* contain genes encoding fimbrial colonization factor antigens; these proteins adhere specifically to cells in the host small intestine. From here, they multiply and produce enterotoxins that cause diarrhea as well as other illnesses (Section 31.11).

Another notorious pathogen, *Streptococcus pyogenes*, the causative agent of strep throat and scarlet and rheumatic fevers (Section 29.2), utilizes fimbriae-associated lipoteichoic acid, along with two specific proteins, F and M, to facilitate attachment to host cells (Table 23.4). M protein is also responsible for resistance to phagocytosis by neutrophils, immune cells important in antibacterial resistance (Sections 24.2 and 29.2).

23.8 Invasion, Infection, and Virulence Factors

The initial inoculum of a pathogen is usually insufficient to cause host damage, even if a pathogen gains access to tissues. The pathogen must therefore multiply and colonize the tissue (Figure 23.9). To do so the pathogen must find appropriate nutrients and environmental conditions to grow and cause infection in the host.

Invasion

Following colonization a pathogen must usually invade tissues to initiate disease. **Invasion** is the ability of a pathogen to enter into host cells or tissues, spread, and cause disease. In most cases, microbial infections begin at breaks or wounds in the skin or on the mucous membranes of the respiratory, digestive, or genitourinary tract, surfaces that are normally microbial barriers. In some cases, growth may also begin on intact mucosal surfaces, especially if the normal flora has been altered or eliminated, for example, by antibiotic therapy.

Some pathogens remain localized after initial entry, multiplying and invading at a single focus of infection such as the boil that may arise from *Staphylococcus* skin infections (Section 29.9). If bacterial growth occurs, organisms may cause **bacteremia**, the presence of bacteria in the bloodstream, from where they can travel to distant parts of the body. Spread of the pathogen through the blood and lymph systems can also result in a bloodborne systemic infection called **septicemia**, and the organism may spread to other tissues. Septicemia may lead to massive inflammation, culminating in septic shock and rapid death, as we discuss in Section 24.5. Bacteremia and septicemia usually start as an infection in a specific organ such as the intestine, kidney, or lung.

Infection and Disease

Infection refers to any situation in which a microorganism not a member of the local flora is established and growing in a host, whether or not the host is harmed. Infection is not synonymous with disease because growth of a microorganism, even a pathogen, on a host does not always cause host damage. The normal microflora also grow on the host and are usually harmless, but may infect the host as opportunistic pathogens and cause disease if host resistance is compromised, for instance by cancer or acquired immunodeficiency syndrome (AIDS) (Section 29.14).

Infection requires growth of microorganisms after they have attached to surfaces. This requires that the host environment supply adequate nutrients to support growth. However, not all growth factors, both organic as well as trace metals, are in adequate supply in all tissues at all times, even in a vertebrate host. For example, iron is a major growth-limiting micronutrient that influences microbial growth. Host proteins called *transferrin* and *lactoferrin* are very high-affinity iron-binders and function to sequester iron in the host, which can limit infection. But many pathogens produce iron-chelating compounds called *siderophores* to counter host iron sequestration, and some of these are so effective that they can actually remove iron from host tissues.

The attachment and infection process has been well studied with the formation of biofilms (Section 19.4) on tooth surfaces by the oral microflora. Even on a freshly cleaned tooth surface, acidic glycoproteins from the saliva form a thin organic film several micrometers thick; this film provides an attachment site for bacterial cells. Streptococci quickly colonize the glycoprotein film. These include, in particular, the two species implicated in tooth decay, *Streptococcus sobrinus* and *S. mutans* (Figure 23.15). *S. sobrinus* has an affinity for salivary glycoproteins secreted onto smooth tooth surfaces (Figure 23.4). *S. mutans*, by contrast, resides in crevices and small fissures where it produces dextran, a strongly adhesive polysaccharide that it uses to attach to tooth

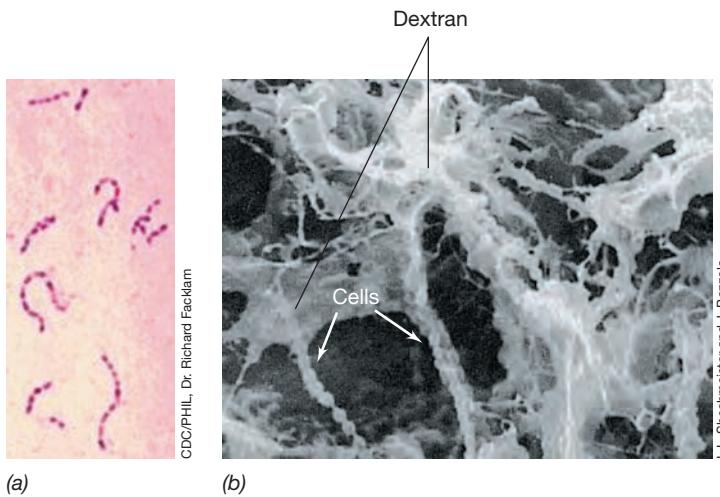

Figure 23.15 The cariogenic bacterium *Streptococcus mutans*. (a) Stained cells in a light micrograph show the characteristic cell chains of streptococci. surfaces (see Figure 23.16). Both *S. sobrinus* and *S. mutans* are lactic acid bacteria that ferment glucose to lactic acid, the agent that destroys tooth enamel.

Extensive bacterial growth results in a thick oral biofilm called **dental plaque** (Figure 23.16). As plaque continues to form, filamentous anaerobes such as *Fusobacterium* species appear. The filamentous bacteria embed in the matrix formed by the streptococci and extend perpendicular to the tooth surface, making an ever-thicker biofilm. Associated with oral filamentous bacteria are spirochetes such as *Borrelia* species, gram-positive rods, and gram-negative cocci. In heavy plaque, filamentous obligately anaerobic organisms such as *Actinomyces* may predominate. Dental plaque is thus a mixed-culture biofilm composed of several different genera and their accumulated products.

The microbial populations within dental plaque exist in a microenvironment of their own making and maintain themselves in the face of wide variations in the macroenvironmental conditions of the oral cavity. As dental plaque accumulates, the microflora produce locally high concentrations of organic acids, in particular lactic acid, that cause decalcification of the tooth enamel resulting in **dental caries** (tooth decay). Tooth enamel is calcified tissue, and the ability of microorganisms to invade this tissue plays a major role in the extent of dental caries. Thus, dental caries is an infectious disease.

Virulence Factors

Many pathogens produce *virulence factors* that indirectly or directly enhance invasiveness by promoting pathogen infection. Many of these virulence factors are enzymes. For example, streptococci, staphylococci, and certain clostridia produce *hyaluronidase* (Table 23.5), an enzyme that promotes spreading of organisms in tissues by breaking down the polysaccharide hyaluronic acid. The latter is an intercellular cement in animals, and its breakdown allows the pathogens to spread from an initial infection site. Similarly, the clostridia that cause gas gangrene (Section 30.9)

produce *collagenase*, which destroys collagen and enables these organisms to spread through the body. Many pathogenic streptococci and staphylococci also produce proteases, nucleases, and lipases that degrade host proteins, nucleic acids, and lipids, respectively (Table 23.5).

Two virulence factors are enzymes that affect fibrin, the insoluble blood protein that forms clots. The clotting mechanism, triggered by tissue injury, isolates the pathogens, limiting infection to a local region. Some pathogens counter this process by producing fibrinolytic enzymes that dissolve the fibrin clots and make further invasion possible. One fibrinolytic substance produced by *Streptococcus pyogenes* is called *streptokinase* (Table 23.5).

By contrast to the destructive activity of streptokinase, some pathogens produce enzymes that actually promote the formation of fibrin clots. These clots protect the pathogen from host responses. For example, *coagulase* (Table 23.5), produced by pathogenic *Staphylococcus aureus*, causes insoluble fibrin to be deposited on *S. aureus* cells, protecting them from attack by host cells. The fibrin matrix produced as a result of coagulase activity may account for the localized nature of many staphylococcal

infections, as in boils and pimples (Section 29.9). Coagulase-positive *S. aureus* strains are usually more virulent than coagulase-negative strains.

Virulence in *Salmonella*: Pathogenicity Islands and Plasmids

Salmonella species infect humans, leading to various gastrointestinal illnesses. *Salmonella* species encode a large number of virulence factors that are important in adherence and infection (Figure 23.17). Several genes that direct the invasion process in *Salmonella* and related gram-negative pathogens are found clustered together on the chromosome as *pathogenicity islands* (Section 6.13). For example, *Salmonella* pathogenicity island 1 (SPI1) is a collection of virulence genes of *Salmonella* that encode at least 10 different proteins that promote invasion. One is *invH*, which encodes a surface adhesion protein. Other *inv* genes encode proteins important for trafficking of virulence proteins. The *InvJ* regulator protein controls assembly of structural proteins *InvG*, *PrgH*, *PrgI*, *PrgJ*, and *PrgK* that form a type III secretion system called the *injectisome*, an organelle in the bacterial envelope that allows direct transfer of virulence proteins into host cells through a needle-like assembly (Figure 23.17, Figure 4.43).

Another *Salmonella* pathogenicity island, SPI2, contains genes that are responsible for causing more systemic disease and resistance to host cell defenses. In addition, several plasmid-borne virulence factors such as antibiotic resistance genes encoded on R plasmids can be spread between most *Salmonella* species as well as other enteric bacteria (Section 4.3). Pathogenicity islands and R plasmids allow for the facile and rapid transfer of virulence factors. It is thus not uncommon for genes encoding factors in one pathogen to be very similar if not identical to those in another because of transfer of parts or all of the islands between species by horizontal gene exchange.

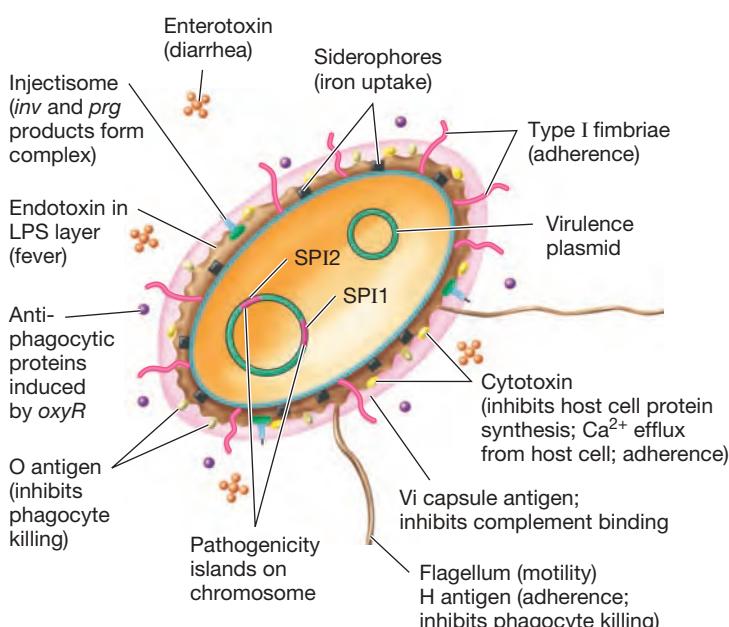

Figure 23.17 Virulence factors in *Salmonella*. Factors important for virulence and the development of pathogenesis in this gram-negative enteric pathogen are shown.

23.9 Exotoxins

Toxicity is the ability of an organism to cause disease by means of a preformed toxin that inhibits host cell function or kills host cells. **Exotoxins** are toxic *proteins* released from the pathogen as it grows. These toxins travel from a site of infection and cause damage at distant sites. Table 23.5 provides a summary of the properties and actions of some of the known bacterial exotoxins as well as other extracellular virulence factors released from growing bacteria.

Exotoxins fall into three categories in terms of mechanisms: the *cytolytic toxins*, the *AB toxins*, and the *superantigen toxins*. Cytolytic toxins work by degrading cytoplasmic membrane integrity, causing lysis. AB toxins consist of two subunits, A and B. The B component binds to a host cell surface molecule, facilitating the transfer of the A subunit across the cytoplasmic membrane, where it damages the cell. Superantigen toxin work by stimulating large numbers of immune cells, resulting in extensive inflammation and tissue damage (Section 24.9).

A subset of the exotoxins is the **enterotoxins**, exotoxins whose activity affects the small intestine, generally causing secretion of fluid into the intestinal lumen resulting in vomiting and diarrhea. Usually acquired by ingestion of contaminated food or water, enterotoxins are produced by a variety of bacteria, including the food-poisoning organisms *Staphylococcus aureus*, *Clostridium perfringens*, and *Bacillus cereus* and the intestinal pathogens *Vibrio cholerae*, *Escherichia coli*, and *Salmonella enterica* serovar Typhimurium (Chapter 31). As with the other exotoxins, enterotoxins may be cytolytic toxins, AB toxins, or superantigen toxin.

Cytotoxins

Cytotoxins, also called cytolytic toxins, are secreted, soluble, extracellular proteins produced by a variety of pathogens. Cytolytic toxins damage the host cytoplasmic membrane, causing cell lysis and death. Because the lytic activity of these toxins is most easily observed in assays that use red blood cells (erythrocytes), the toxins are often called *hemolysins* (Table 23.5). However, hemolysins also lyse cells other than erythrocytes. The production of hemolysins is demonstrated in the laboratory by streaking the pathogen on a blood agar plate (a rich medium containing 5% sterile blood). During growth of the colonies, hemolysin is released and lyses the surrounding red blood cells, releasing hemoglobin and creating a clear area, called a zone of *hemolysis*, around the growing colonies (Figure 23.18).

Some hemolysins attack the phospholipid of the host cytoplasmic membrane. Because the phospholipid lecithin (phosphatidylcholine) is often used as a substrate, these enzymes are called *lecithinases* or *phospholipases*. An example is the α -toxin of *Clostridium perfringens*, a lecithinase that dissolves membrane lipids, resulting in cell lysis (Table 23.5, Figure 23.18b). Because

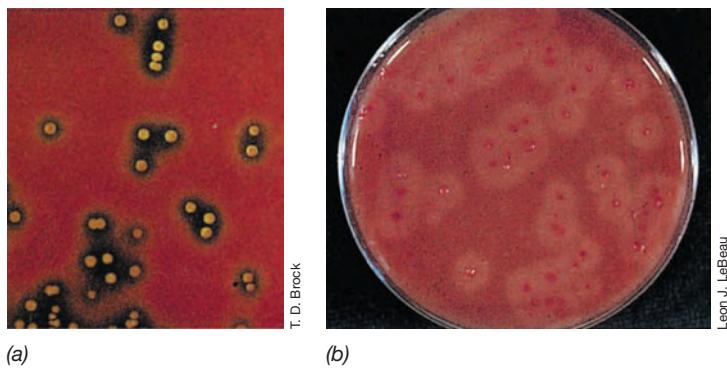

Figure 23.18 **Hemolysis.** (a) Zones of hemolysis around colonies of *Streptococcus pyogenes* growing on a blood agar plate. (b) Action of lecithinase, a phospholipase, around colonies of *Clostridium perfringens* growing on an agar medium containing egg yolk, a source of lecithin. Lecithinase dissolves the cytoplasmic membranes of red blood cells, producing cloudy zones of hemolysis around each colony.

the cytoplasmic membranes of all organisms contain phospholipids, phospholipases can destroy bacterial as well as animal cell cytoplasmic membranes.

Some hemolysins, however, are not phospholipases. Streptolysin O, a hemolysin produced by streptococci, affects the sterols of the host cytoplasmic membrane. *Leukocidins* (Table 23.5) lyse white blood cells and may decrease the host immune response. Staphylococcal α -toxin (Figure 23.19 and Table 23.5) kills nucleated cells and lyses erythrocytes. Toxin subunits first bind to the phospholipid bilayer. The subunits then oligomerize into nonlytic heptamers, now associated with the membrane. Following oligomerization, each heptamer undergoes conformational changes to produce a membrane-spanning pore. The pore releases the cytoplasmic contents and allows the influx of extracellular material, thus killing the cell (Figure 23.19).

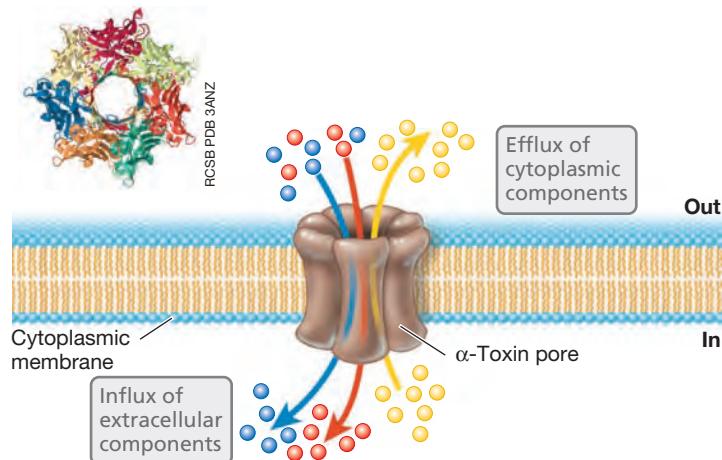

Figure 23.19 **Staphylococcal α -toxin.** Staphylococcal α -toxin is a pore-forming cytotoxin that is produced by growing *Staphylococcus* cells. Released as monomers, seven identical protein subunits oligomerize in the cytoplasmic membrane of target cells. The oligomer forms a pore, releasing the contents of the cell. In red blood cells, hemolysis occurs, visually indicating cell lysis. The thumbnail photo on top shows the structure of α -toxin looking down through the pore. Each of the seven identical subunits is shown in a different color.

Diphtheria Toxin

The diphtheria toxin produced by *Corynebacterium diphtheriae* is an AB toxin and an important virulence factor of the pathogen (► Section 29.3). Diphtheria toxin inhibits protein synthesis in eukaryotes. Rats and mice are relatively resistant to diphtheria toxin, but humans and many other animals are very susceptible, with only a single molecule of toxin sufficient to kill a cell.

Diphtheria toxin is secreted by *C. diphtheriae* as a single polypeptide. One component, subunit B, specifically binds to a host cell protein on eukaryotic cells, the heparin-binding epidermal growth factor (Figure 23.20). After binding, proteolytic cleavage between subunit B and the remaining portion of the protein, subunit A, allows subunit A to move across the host cytoplasmic membrane into the cytoplasm. Here subunit A disrupts protein synthesis by blocking transfer of an amino acid from tRNA to growing polypeptide chains. Diphtheria toxin specifically inactivates elongation factor 2 (EF-2), a protein that functions in growth of the polypeptide chain, by catalyzing the attachment of adenosine diphosphate (ADP) ribose from NAD⁺. Following ADP-ribosylation, the activity of the modified EF-2 decreases dramatically and protein synthesis stops.

Diphtheria toxin is not encoded by the bacterium but instead by a viral gene called *tox* present in the genome of the lysogenic bacteriophage β . Lysogenic phages are those whose genomes have become integrated into their host's chromosome (► Section 8.8). Toxigenic, pathogenic strains of *C. diphtheriae* are infected with phage β and hence produce the toxin. Nontoxigenic, nonpathogenic strains of *C. diphtheriae* can be converted to pathogenic strains by infection with phage β , a process called *phage conversion* (► Section 10.7).

Exotoxin A of *Pseudomonas aeruginosa* functions similarly to diphtheria toxin, also modifying EF-2 by ADP-ribosylation (Table 23.5). The enterotoxin produced by *Shigella dysenteriae*, called *Shiga toxin*, and the Shiga-like toxin produced by enteropathogenic *E. coli* O157:H7 (► Section 31.12), are also AB toxins (Table 23.5). The Shiga-like toxins target cells of the small intestine near where the pathogen colonized, shutting down protein synthesis and leading to bloody diarrhea and hemolytic uremic syndrome, a kidney disease that may result in kidney failure, especially in children.

Botulinum and Tetanus Toxins

Clostridium botulinum and *Clostridium tetani* are endospore-forming bacteria commonly found in soil. These organisms occasionally cause disease in animals from highly poisonous AB exotoxins that function as *neurotoxins* (► Sections 30.9 and 31.9). Neither *C. botulinum* nor *C. tetani* is very invasive, and therefore pathogenicity is almost exclusively due to neurotoxicity. Botulinum toxin and tetanus toxin both block release of neurotransmitters involved in muscle control, but the mode of action and disease symptoms are quite distinct (Figure 23.21 and Figure 23.22).

C. botulinum sometimes grows directly in the body, causing infant or wound botulism. Frequently, however, *C. botulinum* grows and produces toxin in improperly preserved foods. As a result, infection and growth in the body are unnecessary, and ingestion of preformed toxin is the common method of acquiring

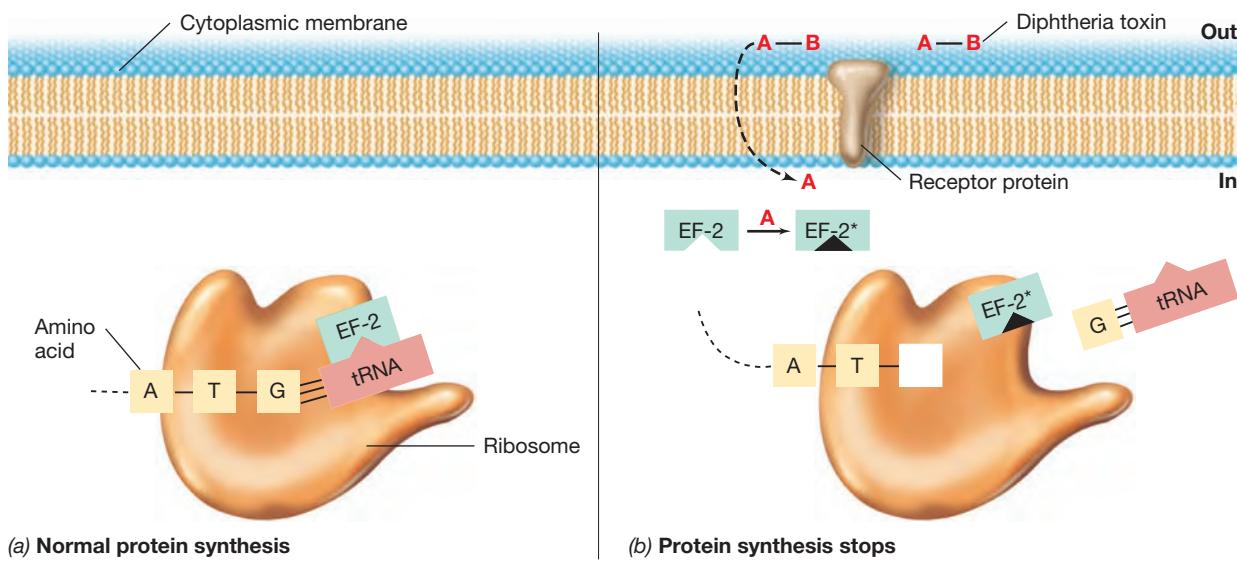

Figure 23.20 Diphtheria toxin activity. Diphtheria toxin is an AB toxin produced by *Corynebacterium diphtheriae*. (a) In eukaryotic cells, elongation factor 2 (EF-2) normally binds to the ribosome and facilitates attachment of an amino acid–charged tRNA to the ribosome, resulting in protein elongation. (b) Diphtheria toxin binds to the cytoplasmic membrane by way of its B subunit. Cleavage of the toxin allows the A subunit to enter the cell where it catalyzes ADP-ribosylation of elongation factor 2 ($\text{EF-2} \rightarrow \text{EF-2}^*$). The modified elongation factor no longer binds to the ribosome, resulting in the cessation of protein synthesis and cell death.

(a) Upon stimulation of peripheral and cranial nerves, acetylcholine (A) is normally released from vesicles at the neural side of the motor end plate. Acetylcholine then binds to specific receptors on the muscle, inducing contraction. botulism. Botulinum toxins, the most potent biological toxins known, are seven related AB toxins. One nanogram (10^{-9} g) of botulinum toxin is sufficient to kill a guinea pig. Of the seven distinct botulinum toxins known, at least two are encoded on lysogenic bacteriophages specific for *C. botulinum*. The major toxin is a protein that forms complexes with nontoxic botulinum proteins to yield a bioactive protein complex. The complex then binds to presynaptic membranes on the termini of the stimulatory motor neurons at the neuromuscular junction, blocking the release of acetylcholine. Normal transmission of a nerve impulse to a muscle cell requires acetylcholine interaction with a muscle receptor; botulinum toxin prevents the poisoned muscle from receiving the excitatory acetylcholine signal (Figure 23.21). This prevents muscle contraction and leads to a flaccid paralysis and death by suffocation, the fatal outcome of botulism.

In contrast to *C. botulinum*, *C. tetani* grows in the body in deep wounds that become anoxic, such as punctures. *C. tetani* cells rarely leave the wound where they were first introduced, growing relatively slowly at the wound site. The toxin spreads systemically via the neural cells and causes spastic paralysis, the hallmark of tetanus (Section 30.9 and Figure 30.22b). On contact with the central nervous system, tetanus toxin is transported through the motor neurons to the spinal cord, where it binds specifically to ganglioside lipids at the termini of the inhibitory interneurons.

The inhibitory interneurons normally work by releasing an inhibitory neurotransmitter, typically the amino acid glycine, which binds to receptors on the motor neurons. Glycine from the inhibitory interneurons then stops the release of acetylcholine by the motor neurons and inhibits muscle contraction, allowing relaxation of the muscle fibers. However, if tetanus toxin blocks glycine release, the motor neurons cannot be inhibited, resulting in the continual release of acetylcholine and uncontrolled contraction of the poisoned muscles (Figure 23.22). The outcome is a spastic, twitching paralysis, as affected muscles are constantly contracted. If the muscles of the mouth are involved, the prolonged contractions restrict the mouth's movement, resulting in a condition called *lockjaw*. If respiratory muscles are involved, prolonged contraction may result in death due to asphyxiation.

Cholera Toxin

Cholera toxin, an AB-type enterotoxin produced by *V. cholerae*, causes cholera (Section 31.3). Cholera is characterized by massive fluid loss from the intestines, resulting in severe diarrhea, life-threatening dehydration, and electrolyte depletion (Figure 23.23). The disease starts by ingestion of *V. cholerae* cells from contaminated food or water. The organism travels to the intestine, where it colonizes and secretes cholera toxin (Figure 23.23). In the gut, the B subunit of the toxin, consisting of five identical

Glycine acts on the motor neurons to block excitation and release of acetylcholine (A) at the motor end plate. (b) Tetanus toxin binds to the interneuron to prevent release of glycine from vesicles, resulting in a lack of inhibitory signals to the motor neurons, constant release of acetylcholine to the muscle fibers, irreversible contraction of the muscles, and spastic paralysis. For purposes of illustration, the inhibitory interneuron is shown near the motor end plate, but it is actually in the spinal cord.

Cholera toxin is a heat-stable AB enterotoxin that activates a second messenger pathway, disrupting normal ion flow in the intestine, resulting in potentially life-threatening diarrhea. monomers, binds specifically to GM1 ganglioside, a complex glycolipid found in the cytoplasmic membrane of intestinal epithelial cells.

The B subunit targets the toxin specifically to the intestinal epithelium but has no toxicity itself; toxicity is a function of the

A subunit, which crosses the cytoplasmic membrane and activates adenylate cyclase, the enzyme that converts ATP to cyclic adenosine monophosphate (cAMP). This molecule is a cyclic nucleotide (► Figure 7.14) that mediates several regulatory systems in cells, including ion balance. The increased cAMP induced by cholera enterotoxin induces secretion of chloride and bicarbonate (HCO_3^-) from small intestine epithelial cells into the intestinal lumen. This change in ion concentrations leads to the secretion of large amounts of water; the rate of water loss into the small intestine is greater than the possible reabsorption of water by the large intestine, resulting in a large net fluid loss and watery diarrhea.

23.10 Endotoxins

Endotoxins are the toxic lipopolysaccharides found in most gram-negative *Bacteria*. They are structural components of the gram-negative outer membrane (► Section 2.11) and thus unlike exotoxins are not soluble products of growing bacteria.

Endotoxin Structure and Biology

The structure of lipopolysaccharide (LPS) was shown in Figures 2.28 and 2.29. LPS consists of three covalently linked subunits: the membrane-distal O-specific polysaccharide, lipid A, and a membrane-proximal core polysaccharide. The lipid A portion of LPS is responsible for toxicity, whereas the polysaccharide fraction makes the complex water-soluble and immunogenic, but both the lipid and polysaccharide fractions must be delivered as a unit for toxicity. In contrast to exotoxins, which are the secreted products of living cells, endotoxins are cell bound and released

in toxic amounts only when the cells lyse. Endotoxins have been studied in *Escherichia*, *Shigella*, and especially *Salmonella*, where they are another of the many virulence factors that contribute to pathogenesis (Figure 23.17). The properties of exotoxins and endotoxins are compared in **Table 23.6**.

Endotoxins cause a variety of physiological effects. Fever is an almost universal result of endotoxin exposure because endotoxin stimulates host cells to release cytokines, soluble proteins secreted by phagocytes and other cells that function as *endogenous pyrogens*, proteins that affect the temperature-controlling center of the brain, causing fever. Cytokines released due to endotoxin exposure can also cause diarrhea, a rapid decrease in the numbers of lymphocytes and platelets, and generalized inflammation (➡ Section 24.5). Large doses of endotoxin can cause death from hemorrhagic shock and tissue necrosis. Endotoxins are, however, generally less toxic than most exotoxins. For instance, in mice the LD₅₀ for endotoxin is 200–400 micrograms per animal, whereas the LD₅₀ for botulinum toxin is about 25 picograms, about 10 million times less.

Limulus Amoebocyte Lysate Assay for Endotoxin

Because endotoxins induce fever, pharmaceuticals such as antibiotics and intravenous solutions must be free of endotoxin. An endotoxin assay of very high sensitivity has been developed using lysates of amoebocytes from the horseshoe crab, *Limulus*

polyphemus. Endotoxin specifically causes lysis of the amoebocytes (Figure 23.24). In the *Limulus* amoebocyte lysate (LAL) assay, *Limulus* amoebocyte extracts are mixed with the solution to be tested. If endotoxin is present, the amoebocyte extract forms a gel and precipitates, causing a change in turbidity. This reaction is measured quantitatively with a spectrophotometer and can detect as little as 10 pg/ml of LPS.

The LAL assay is used to detect endotoxin in clinical samples such as serum or cerebrospinal fluid. A positive test is presumptive evidence for infection by gram-negative bacteria. Drinking water, water used for formulation of injectable drugs, and injectable aqueous solutions are routinely tested using the LAL to identify and eliminate endotoxin contamination from gram-negative organisms. A commercially available assay uses horseshoe crab factor C made by recombinant DNA techniques (factor C is the key protein activated by endotoxin in the LAL assay). This allows for a more standardized assay protocol and has the advantage of being free of animal products.

III • Host Factors in Infection and Disease

Humans have certain innate resistance factors that keep them from contracting most infectious diseases. These include a number of chemical and physical barriers to microbial infection, the usual prerequisite for disease. In addition, the condition of the host can play a role in whether or not the diseased state can become established. We conclude this chapter with a discussion of these factors, which are often the tipping point between health and disease.

23.11 Innate Resistance to Infection

The presence of the normal microflora is a critically important mechanism for resisting pathogen infection, especially on the skin and in the gut. Pathogens do not easily infect tissues on which normal microflora are already colonized because the normal microflora limit available microbial nutrients and sites for infection. Here we introduce several other resistance factors common

to vertebrate hosts. These factors nonspecifically inhibit infection by most pathogens (Figure 23.25).

Natural Host Resistance

The ability of a particular pathogen to cause disease in an individual animal species is highly variable. In the disease rabies, for instance, certain animal species are much more susceptible than others. For example, raccoons and skunks are extremely susceptible to rabies as compared with opossums, which rarely develop the disease. Anthrax infects many species of animals, causing disease symptoms varying from fatal blood poisoning in cattle to the mild pustules of human cutaneous anthrax (► Section 30.8). Introduction of the same pathogen by other routes, however, may challenge the resistance of the host. For example, pulmonary or airborne anthrax, such as that induced by weaponized strains used for bioterrorism (► Section 28.8), is typically fatal in humans. Anthrax causes a localized infection when acquired through the skin, but a lethal, systemic infection when acquired through the mucous membranes of the lungs.

As another example of innate host resistance, diseases of warm-blooded animals are rarely transmitted to cold-blooded species, and vice versa. Presumably, the anatomical and metabolic features of one group are not compatible with pathogens that infect the other group.

Infection Site and Tissue Specificity

Most pathogens must adhere and infect at the site of exposure to initiate infection. Even if pathogens adhere to an exposure site, the organisms cannot infect the host if the site is not compatible with the pathogen's nutritional and metabolic needs. For example, if cells of *Clostridium tetani* were ingested, tetanus would not normally result because the pathogen is either killed by the acidity of the stomach or cannot compete with the well-developed normal intestinal microflora. If, on the other hand, *C. tetani* cells or endospores were introduced into a deep wound, the organism would grow and produce tetanus toxin in the anoxic zones created by local tissue death. Conversely, enteric bacteria such as *Salmonella* and *Shigella* do not normally cause wound infections but often infect the intestinal tract and cause disease.

In some cases, pathogens interact exclusively with members of a few closely related host species because the hosts share tissue-specific receptors. Human immunodeficiency virus (HIV), for instance, infects only higher primates including the great apes and humans. This is because a protein called CXCR4 found on human T lymphocytes (cells in the immune system) and a protein called CCR5 found on human macrophages (a phagocyte found in many human tissues) are also expressed in great apes. These proteins are the only cell surface receptors for HIV and specifically bind the gp120 protein of HIV (► Section 29.14). Other animals, even most primates, lack the CXCR4 and CCR5 proteins, cannot bind HIV, and are therefore not susceptible to HIV infection. Likewise, influenza viruses are specific for their species of origin, normally infecting only birds or humans and occasionally swine (► Section 29.8). Table 23.7 presents some examples of pathogen specificity.

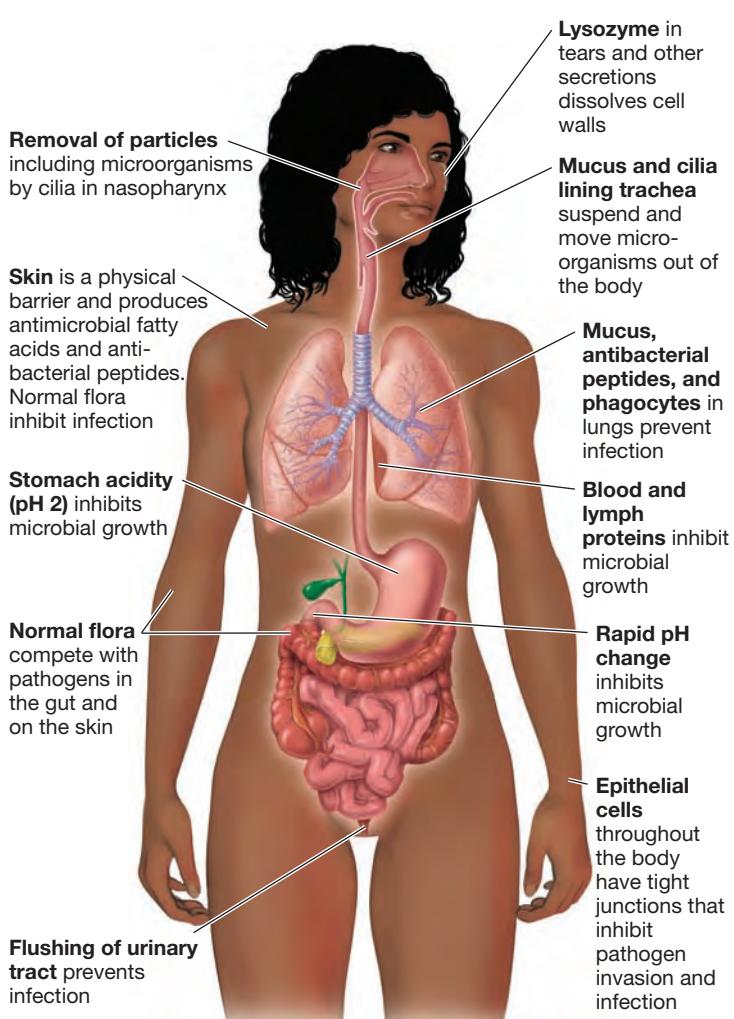

Figure 23.25 Physical, chemical, and anatomical barriers to infection. These barriers provide natural resistance to colonization and infection by pathogens.

Physical and Chemical Barriers

The structural integrity of tissue surfaces poses a barrier to penetration by microorganisms. The tight junctions between epithelial cells in all body tissues inhibit invasion and infection. In the skin and mucosal tissues, potential pathogens must first adhere to tissue surfaces and then grow at these sites before traveling elsewhere in the body. Mucosal surfaces are bathed in mucus. Epithelial cells have cilia that expel suspended pathogens and keep them from adhering to tissues. In addition to the normal microflora growing at potential infection sites, resistance to infection and invasion is enhanced by antibacterial peptides called *defensins*, produced in the skin, lungs, and gut.

Sebaceous glands in the skin secrete fatty acids and lactic acid, lowering the acidity of the skin to pH 5 and inhibiting colonization of many pathogenic bacteria (blood and internal organs are about pH 7.4). Microorganisms inhaled through the nose or mouth are removed by ciliated epithelial cells on the mucosal surfaces of the nasopharynx and trachea. Potential pathogens ingested in food or water must survive the strong acidity (pH 2) and digestive enzymes such as pepsin in the stomach. The pH changes rapidly

in the lower intestinal tract and, if pathogens survive, they must then compete with the abundant resident microflora present in the small and large intestines (Figure 23.5). The lumen of the kidney, the eye, the respiratory system, and the cervical mucosa are constantly bathed with secretions such as tears and mucus containing lysozyme, an enzyme that can kill bacteria by digesting the cell wall. Altogether the body is protected by numerous physical structures, chemicals, and secretions, all aimed at suppressing pathogen invasion and infection.

- Identify physical and chemical barriers to pathogens. How might these barriers be compromised?

23.12 Risk Factors for Infection

In addition to the barriers to infection discussed in the previous section, a number of innate factors contribute to the susceptibility of the host to infection and disease. We conclude our consideration of microbial interactions with the host by considering how these factors may facilitate invasion by pathogens and lead to infectious disease.

Age, Stress, and Diet

Age of the host is an important factor for determining susceptibility to infectious disease. In general, infectious diseases are more common in the very young and in the very old. In the infant, for example, an intestinal microflora develops quickly, but the normal flora of an infant is not the same as that of an adult. Before the development of an adult flora, and especially in the days immediately following birth, pathogens thus have a greater opportunity to become established and produce disease. Thus, infants under

one year of age often acquire diarrhea caused by enteropathogenic strains of *Escherichia coli* or viruses such as rotavirus.

In adults over 65 years of age, infectious diseases are much more common than in younger adults. For example, the elderly are much more susceptible to respiratory infections such as those caused by influenza virus, probably because of a declining ability to generate an effective immune response to respiratory pathogens. Anatomical changes associated with age may also encourage infection. For example, enlargement of the prostate gland, a common condition in men over the age of 50, frequently leads to a decreased urinary flow rate, allowing pathogens to infect the male urinary tract more readily and cause infections (Figure 23.8).

Stress can predispose a healthy individual to disease. In studies with animals, physiological stressors such as fatigue, exertion, poor diet, dehydration, or drastic climate changes increase the incidence and severity of infectious diseases. For example, rats subjected to intense physical activity for long periods show a higher mortality rate from experimental *Salmonella* infections compared with rested control animals. Hormones that are produced under stress inhibit immune responses and may play a role in stress-mediated disease. For example, cortisol, a hormone produced at high levels in the body in times of stress, is an anti-inflammatory agent that inhibits the activation of phagocytes and the immune response.

Diet plays a role in host susceptibility to infection. Inadequate diets low in protein and calories alter the normal flora, allowing opportunistic pathogens a better chance of multiplying and increasing the overall susceptibility of the host to known pathogens. For example, the number of *Vibrio cholerae* cells necessary to produce cholera in an individual is drastically reduced if the individual is malnourished. Moreover, the consumption of pathogen-contaminated food is an obvious way to acquire infections, and ingestion of pathogens with food can sometimes enhance the ability of the pathogen to cause disease. The number of organisms necessary to induce cholera, for example, is greatly reduced when the *V. cholerae* is ingested in food, presumably because the food neutralizes stomach acids that would normally destroy the pathogen on its way to colonizing the small intestine.

The presence of a particular substance in the diet can also be the trigger for disease. We discussed dental caries in Section 23.8. Perhaps the most important factor in the development of dental caries is a diet high in sucrose (table sugar). A common lactic acid bacterium present in oral plaque, *Streptococcus mutans*, produces dextran through the activity of the enzyme dextranase but only in the presence of sucrose, the substrate for this enzyme:

The sticky dextran provides a scaffold for further growth of *S. mutans* and allows coinfection by *S. sobrinus*, the organism that along with *S. mutans* causes dental caries (Figures 23.15 and 23.16). Without dietary sucrose, the highly cariogenic *S. mutans* is unable to synthesize the dextran layer needed to keep the bacterial cells attached to the teeth.

The Compromised Host

A *compromised host* is one in whom one or more resistance mechanisms are inactive and in whom the probability of infection is

therefore increased. Many hospital patients with noninfectious diseases (for example, cancer and heart disease) acquire microbial infections more readily because they are compromised hosts (➡ Section 27.2). Such *healthcare-associated infections*, also called *nosocomial infections*, affect up to 2 million individuals each year in the United States, causing up to 100,000 deaths. Invasive medical procedures such as catheterization, hypodermic injection, spinal puncture, biopsy, and surgery may unintentionally introduce microorganisms into the patient. The stress of surgery and the anti-inflammatory drugs given to reduce pain and swelling can also reduce host resistance. For example, organ transplant patients are treated with immunosuppressive drugs to prevent immune rejection of the transplant, but suppressed immunity also reduces the ability of the patient to resist infection.

Some factors can compromise host resistance even outside the hospital. Smoking, excess consumption of alcohol, intravenous drug use, lack of sleep, poor nutrition, and acute or chronic infection with another agent are conditions that reduce host resistance. For example, infection with the human immunodeficiency

virus (HIV) predisposes a patient to infections from microorganisms that are not pathogens in uninfected individuals. HIV causes acquired immunodeficiency (AIDS) by destroying one type of immune cell, the CD4 T lymphocytes, involved in the immune response. The reduction in CD4 T cells reduces immunity, and an opportunistic pathogen, one that does not cause disease in a healthy, uninfected host, can then cause serious disease or even death (➡ Sections 28.9 and 29.14).

Finally, certain genetic conditions compromise the host. For example, genetic diseases that eliminate important parts of the immune system predispose individuals to infections. Individuals with such conditions frequently die at an early age, not from the genetic condition itself, but from microbial infection.

BIG IDEAS

23.1 • The animal body is a favorable environment for the growth of microorganisms, most of which are beneficial. The number of microorganisms on and in our body is greater than the number of body cells.

23.2 • The skin has at least three different microenvironments, sebaceous, moist, and dry, that harbor distinctly different populations of microorganisms. Environmental and host factors influence the quantity and makeup of the normal skin microflora.

23.3 • The microflora in the oral cavity is extremely complex, with no predominant taxa. The microflora develops in the variable microenvironments associated with the teeth and gums.

23.4 • The gastrointestinal tract supports a diverse population of microorganisms in a variety of nutritional and environmental conditions. The populations of microorganisms are influenced by the diet of the individual and by the unique physical conditions in each distinct site along the gastrointestinal tract.

23.5 • A robust population of normal nonpathogenic microorganisms in the respiratory and urogenital tracts is essential for optimal organ function in normal individuals. The normal microflora help prevent the colonization of pathogens by competing for nutrients and sites for attachment.

23.6 • Virulence is a quantitative measure of pathogenicity. Pathogens use a wide variety of mechanisms and virulence factors to establish an infection.

23.7 • Pathogens gain access to host tissues by adherence at mucosal surfaces through interactions between pathogen and host macromolecules on tissue surfaces.

23.8 • Pathogen invasion starts at the site of adherence and may spread throughout the host via the circulatory or lymphatic systems. A pathogen must gain access to nutrients and appropriate growth conditions before it can infect host tissue. Virulence factors such as various enzymes or cell capsules aid in establishing infection.

23.9 • Exotoxins contribute to the virulence of pathogens. Cytotoxins such as hemolysins, and AB toxins such as diphtheria and cholera toxins are potent exotoxins. Each exotoxin affects a specific host cell function. Enterotoxins are exotoxins that affect the small intestine. Bacterial exotoxins such as botulinum and tetanus toxins are some of the most poisonous substances known.

23.10 • Endotoxins are lipopolysaccharides derived from the outer membrane of gram-negative bacteria such as *Salmonella*. Both the lipid and the polysaccharide components of endotoxin are necessary for toxicity.

23.11 • Innate resistance factors, as well as physical, anatomical, and chemical barriers, prevent colonization of the host by most pathogens. Breakdown of these passive defenses may result in susceptibility to infection and disease.

23.12 • Age, general health, genetic makeup, lifestyle factors such as stress and diet, and chronic diseases can all contribute to susceptibility of the host to infectious disease.

REVIEW OF KEY TERMS

Adherence the enhanced ability of a microorganism to attach to a cell or surface

Attenuation a decrease or loss of virulence

Bacteremia the presence of microorganisms in the blood

Capsule a dense, well-defined polysaccharide or protein layer closely surrounding a cell

Colonization the growth of a microorganism after it has gained access to host tissues

Dental caries tooth decay resulting from bacterial infection

Dental plaque bacterial cells encased in a matrix of extracellular polymers and salivary products, found on the teeth

Disease an injury to a host organism, caused by a pathogen or other factor, that affects host function

Endotoxin the lipopolysaccharide portion of the cell envelope of most gram-negative *Bacteria*, which is a toxin when solubilized

Enterotoxin a protein released extracellularly by a microorganism as it grows that produces immediate damage to the small intestine of the host

Exotoxin a protein released extracellularly by a microorganism as it grows that produces immediate host cell damage

Glycocalyx polymer secreted by a microorganism that coats the surface of the microorganism

Host an organism that can harbor a pathogen

Infection a microorganism not a member of the local flora is established and grows in a host, whether or not the host is harmed

Invasion the ability of a pathogen to enter into host cells or tissues, spread, and cause infection

Lower respiratory tract the trachea, bronchi, and lungs

Mucous membrane layer of mucus-covered epithelial cells that interact with the external environment

Mucus a liquid secretion that contains water-soluble glycoproteins and proteins that retain moisture and aid in resistance to microbial invasion on mucosal surfaces

Normal microflora microorganisms that are usually found associated with healthy body tissue

Opportunistic pathogen an organism that causes disease in the absence of normal host resistance

Pathogen an organism, usually a microorganism, that grows in or on a host and causes disease

Pathogenicity the ability of a pathogen to cause disease

Probiotic a live microorganism that, when administered to a host, may confer a health benefit

Septicemia a bloodborne systemic infection

Slime layer a diffuse layer of polymer fibers, typically polysaccharides, that forms an outer surface layer on the cell

Toxicity the ability of an organism to cause disease by means of a preformed toxin that inhibits host cell function or kills host cells

Upper respiratory tract the nasopharynx, oral cavity, and throat

Virulence the relative ability of a pathogen to cause disease

APPLICATION QUESTIONS

1. Mucous membranes are barriers against colonization and growth of microorganisms. However, mucous membranes, for example in the mouth and gut, are colonized with a variety of different microorganisms, some of which are potential pathogens. Explain how these potential pathogens are controlled under normal circumstances. Then describe at least one set of circumstances that might encourage pathogenicity.
 2. Coagulase is a virulence factor for *Staphylococcus aureus* that acts by causing clot formation at the site of *S. aureus* growth.
- Streptokinase is a virulence factor for *Streptococcus pyogenes* that acts by dissolving clots at the site of *S. pyogenes* growth. Reconcile these opposing strategies for enhancing pathogenicity.
3. Although mutants incapable of producing exotoxins are relatively easy to isolate, mutants incapable of producing endotoxins are much harder to isolate. From what you know of the structure and function of these types of toxins, explain the differences in mutant recovery.

A Cure for Peanut Allergies?

Can allergies be cured? Some allergies are curable by *desensitization*, a process where the foreign substance, the *allergen*, is injected into the patient. This works well for allergens such as ragweed pollen, but not for food allergens such as peanuts. Allergies to peanuts and tree nuts are the most common causes of severe and sometimes fatal food-induced allergic reactions, shown in the photo of the child. These serious reactions, called *anaphylaxis*, are becoming more common, especially in developed countries. Now, however, one research team has developed a method to desensitize peanut-allergic patients.

The researchers reasoned that if desensitization techniques using injected allergens did not work for peanut allergies, then perhaps the route of desensitization would change the outcome. Maybe a small dose of the allergen given to the immune cells in the oral cavity would induce tolerance (nonresponsiveness) to the allergen. To test this, they delivered the allergen *sublingually*—under the tongue—and measured the response.

The results from “feeding” peanut allergens were astonishing. When given very small sublingual doses of allergen over long periods of time, almost all patients could then eat peanuts. And the longer that patients took the sublingual desensitizing doses, the more peanuts they could eat without developing anaphylaxis. The key was to administer the desensitizing dose by the same route that the allergen would normally contact the immune system—in this case, by mouth. When administered in this way, the immune system became tolerant of peanut allergens and no longer responded to the high doses from actually eating peanuts.

It is hoped that this approach will work for other food allergies such as those to shellfish and certain fruits. If so, this would be a major benefit to those that suffer from these harmful immune responses.

- III **Immune Diseases 747**

We discussed passive protection against pathogen invasion, infection, and disease in Chapter 23. In the next three chapters, we focus on active mechanisms evolved by vertebrates to resist pathogens and their diseases. In this chapter we present an overview of **immunity**, the active ability to resist disease. Multicellular organisms have a built-in, or innate, immune system that targets common pathogens regardless of their identity. A second

tier of immunity, the adaptive immune system, targets specific pathogens to minimize their harmful effects.

We first consider the basic features of the immune response to pathogens. We then discuss vaccinations, a practical tool used to recruit the adaptive immune response for protection against future pathogen challenges. We conclude by describing immune system reactions such as allergies that cause disease.

I • Immunity

Innate immunity, the body's built-in ability to recognize and destroy pathogens or their products, is largely a function of **phagocytes**, cells that can ingest, kill, and digest most microbial pathogens. Innate immune responses develop within hours after contact and infection with a pathogen. Structural features such as the cell wall constituents shared by many pathogens interact with universal receptors on the phagocytes. The interactive phagocytes then activate genes that lead to pathogen destruction.

Some pathogens are, however, so virulent that innate responses are not completely effective. When this happens, the innate response phagocytes activate **adaptive immunity** to deal with these infections. Adaptive immunity is the acquired ability to recognize and destroy a specific pathogen or its products. Adaptive responses are directed at unique pathogen molecules called **antigens**. Phagocytes present antigen molecules to lymphocytes, key cells in the adaptive response. The antigens bind specific receptors on the lymphocyte, triggering genes that promote lymphocyte multiplication and production of pathogen-specific proteins that interact with the pathogen, marking it for destruction. A protective adaptive response usually takes several days to develop; the strength of the adaptive response increases as the numbers of antigen-reactive lymphocytes increase.

We begin with the cells and organs common to the entire immune system and then consider the cells and mechanisms active in innate and adaptive immunity.

24.1 Cells and Organs of the Immune System

The cells active in innate and adaptive immunity develop from common precursors called **stem cells**. Immunity results from the actions of cells that circulate throughout the body, primarily through the blood and **lymph**, a fluid similar to blood that contains nucleated cells and proteins but lacks red blood cells. Blood and lymph interact directly or indirectly with every major organ system.

Stem Cells, Blood, and Lymph

Multipotent stem cells are precursor cells that can differentiate into any blood cell (Figure 24.1). Stem cells grow in the bone marrow where they differentiate into a variety of mature cells under the influence of soluble **cytokines** and **chemokines**, proteins that influence many aspects of immune cell differentiation. The differentiated cells travel through the blood and lymph to other parts of the body.

Blood consists of cellular and noncellular components, including many cells and molecules active in the immune response. The most numerous cells in human blood are **erythrocytes** (red blood cells), nonnucleated cells that function to carry oxygen from the lungs to the tissues (Table 24.1). About 0.1% of the cells in blood, however, are nucleated cells called **leukocytes** or *white blood cells*. Leukocytes include the phagocytes of the innate immune system and **lymphocytes**, the cells active in the adaptive response.

Whole blood is composed of suspended cells and **plasma**, a liquid containing proteins and other solutes. Outside the body, whole blood or plasma quickly forms an insoluble fibrin clot, remaining liquid only when an anticoagulant such as potassium citrate or heparin is added. When blood clots, the insoluble proteins trap the cells in a large, insoluble mass. The remaining fluid, called **serum**, contains no cells or clotting proteins. Serum does, however, contain a high concentration of other proteins, including soluble immune proteins called *antibodies* that bind pathogen antigens.

Blood and Lymph Circulation

Blood is pumped by the heart through arteries and capillaries throughout the body and is returned through the veins (Figure 24.2a, b). In the capillary beds, leukocytes and solutes pass to and from the blood into the lymphatic system, a separate circulatory system containing lymph (Figure 24.2a–c).

Lymph drains from extravascular tissues into lymphatic capillaries, lymph ducts, and then into lymph nodes throughout the lymphatic system (Figure 24.2d). **Lymph nodes** are organs that contain lymphocytes and phagocytes arranged to encounter microorganisms and antigens as they travel through the lymphatic circulation. The **mucosa-associated lymphoid tissue** (MALT), another part of the lymphatic system, interacts with antigens and microorganisms that enter the body through mucous membranes, including those of the gut, the genitourinary tract, and bronchial tissues. The MALT also contains phagocytes and lymphocytes. Lymph fluid with antibodies and immune cells empties into the blood circulatory system via the thoracic lymph duct.

The spleen consists of red pulp, which is rich in red blood cells, and white pulp, which consists of organized lymphocytes and phagocytes arranged to filter the blood, analogous to lymph nodes and MALT in the lymphatic system. Collectively, the lymph nodes, MALT, and spleen are called **secondary lymphoid organs**. The secondary lymphoid organs are the sites where antigens interact with antigen-presenting phagocytes and lymphocytes to generate an adaptive immune response (Figure 24.2a).

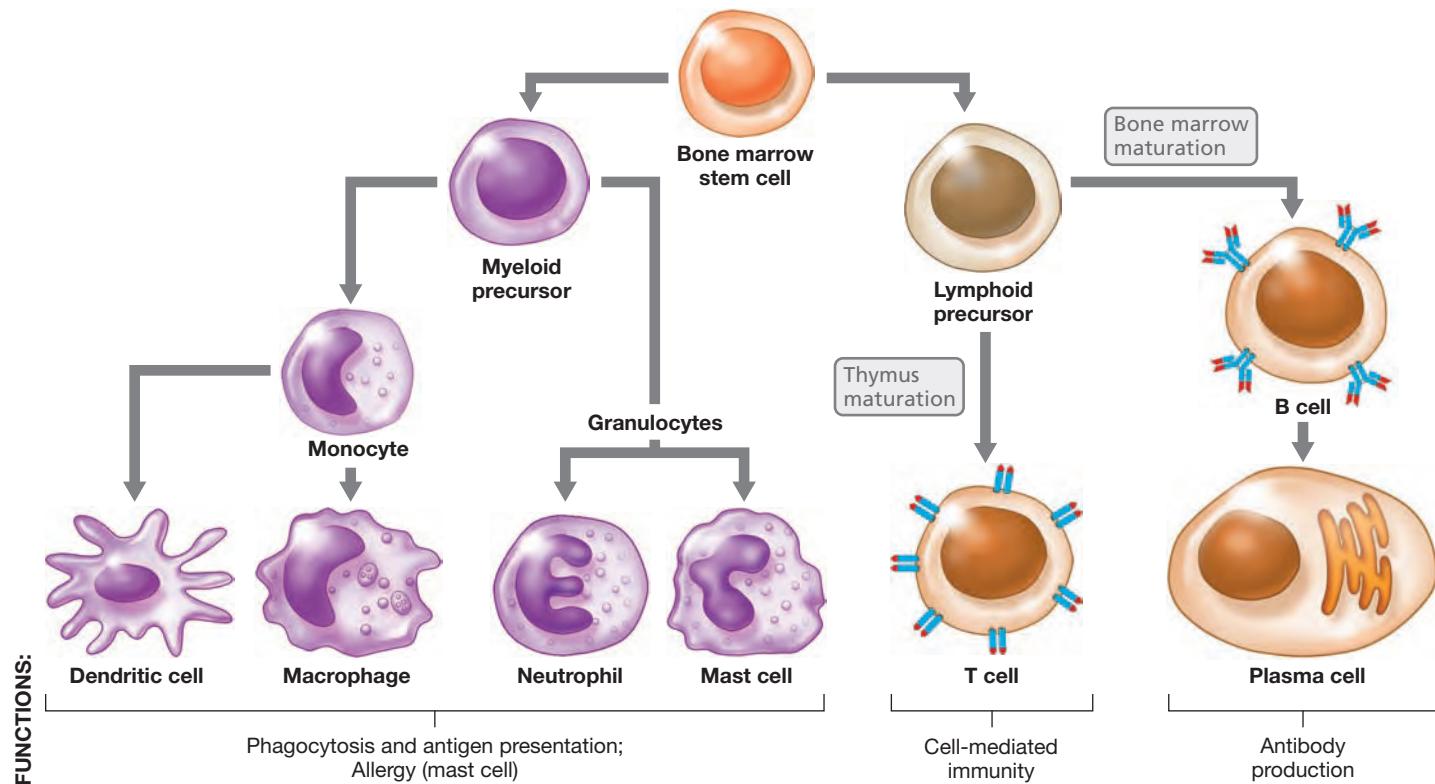

Figure 24.1 Immune response cells. Immune cells develop from multipotent stem cells in the bone marrow into either myeloid precursors or lymphoid precursors. These precursors, in turn, differentiate into end cells that have various immune functions.

Leukocytes

Leukocytes are nucleated white blood cells found in the blood and the lymph. Several distinct leukocytes (Table 24.1 and Figure 24.1) participate in innate and adaptive immunity.

Myeloid cells, active in innate immunity, are derived from myeloid precursor cells. Mature myeloid cells can be divided into two lineages, the monocytes and the granulocytes (Figure 24.1). The monocyte lineage develops into specialized phagocytic cells, the **antigen-presenting cells (APCs)**. These cells, in addition to the B cells we discuss below, engulf, process, and present antigens to lymphocytes. APCs include **macrophages** and **dendritic cells**. Immature cells called monocytes are circulating precursors of macrophages and dendritic cells. **Macrophages** are generally the first defense cells that interact with a pathogen. They are abundant in many tissues, especially spleen, lymph nodes, and MALT. **Dendritic cells** are phagocytes that specialize in presenting antigen to lymphocytes.

Granulocytes are the second lineage of cells derived from myeloid precursors. Granulocytes contain cytoplasmic inclusions, or granules, that can be visualized by staining. These granules contain toxins or enzymes that are released to kill target cells. The phagocytic activity of one granulocyte, the **neutrophil**, also called a *polymorphonuclear leukocyte (PMN)*, is central to innate immunity. Release of granules, a process called *degranulation*, from a granulocyte called a mast cell can cause allergy symptoms and inflammation.

Lymphocytes are specialized leukocytes involved exclusively in the adaptive immune response. Mature lymphocytes circulate

^aLeukocytes include all nucleated blood cells. They include lymphocytes and cells derived from myeloid stem cells, the monocytes and granulocytes, such as neutrophils.

The primary lymphoid organs are the bone marrow and thymus. The secondary lymphoid organs are the lymph nodes, spleen, and MALT. (b) Connections between the lymphatic and blood systems. Blood flows from the veins

to the heart, to the lungs, and then through the arteries to capillaries in tissues. Exchange of solutes and cells occurs between blood and lymphatic capillaries. Lymph drains from the thoracic duct into the left subclavian vein of the blood circulatory system. (c) The exchange of cells between the blood and lymphatic systems is shown in detail. Both blood and lymphatic capillaries are closed vessels, but cells pass from blood capillaries to

lymphatic capillaries and back by a process known as extravasation. (d) A secondary lymphoid organ, the lymph node, showing the major anatomical areas and the immune cells concentrated in each area. The anatomy of the MALT and the spleen is analogous to that of the lymph nodes.

through the blood and lymph system, but are concentrated in the lymph nodes and spleen where they interact with antigens. There are two types of lymphocytes, B cells (B lymphocytes) and T cells (T lymphocytes) (Figure 24.1). **B cells** originate and mature in the **bone marrow**. They are specialized APCs and the precursors of antibody-producing **plasma cells**. **Antibodies**, also called **immunoglobulins (Igs)**, are soluble proteins produced by B cells and plasma cells. Antibodies interact with particular antigens. **T cells**,

which interact with antigen, begin their development in the bone marrow but travel to the **thymus** to mature. The bone marrow and thymus in mammals are called **primary lymphoid organs** because they are the sites where the lymphoid stem cells develop into functional antigen-reactive lymphocytes (Figure 24.2a).

All leukocytes move throughout the body and pass from blood to interstitial spaces, then to lymphatic vessels, and back to the blood circulatory system, a process called *extravasation* (Figure 24.2c).

24.2 Innate Immunity

Innate immunity is the noninducible, preexisting ability to recognize and destroy a pathogen or its products. Innate immunity does not require previous exposure to a pathogen or its products and is mediated by phagocytes. Eukaryotes from the lowest plants through the most evolved vertebrates have functionally similar phagocytic recognition mechanisms that lead to rapid and effective host defense. We know that the innate system receptors present in vertebrates, for example, have structural and evolutionary homologs in phylogenetic groups as distant as the insect *Drosophila* (fruit fly).

Pathogen-Associated Molecular Patterns

The macromolecules inside and on the surface of pathogens display **pathogen-associated molecular patterns (PAMPs)**, consisting of repeating subunits. An example of a PAMP is the lipopolysaccharide (LPS) common to all gram-negative bacterial outer membranes (☞ Section 2.11). Other PAMPs include bacterial flagellin, the double-stranded RNA (dsRNA) of certain viruses, and the lipoteichoic acids of gram-positive bacteria (☞ Section 2.10). These macromolecules consist of repeating structural elements shared among broadly related pathogens.

Pattern Recognition Receptors

Phagocytes such as macrophages and neutrophils are the first line of defense against pathogens that the body has never before encountered. Phagocytes can interact quickly and effectively with pathogens because they have evolved specialized molecules that interact directly with PAMPs. These specialized molecules are called **pattern recognition receptors (PRRs)** (Figure 24.3). Each PRR interacts with a particular PAMP to activate the phagocyte. One PRR found on all phagocytes, for example, interacts with the LPS on gram-negative bacteria, including all pathogenic strains of *Salmonella* spp., *Escherichia coli*, and *Shigella* spp. Another phagocyte PRR interacts with the peptidoglycan on gram-positive cells. Still other PRRs interact with conserved pathogen features such as the dsRNA found in some viruses and flagellin on certain motile bacteria. The interaction of a PAMP with a PRR activates the phagocyte to ingest and destroy the targeted pathogen by phagocytosis. All phagocytes have PRRs that are instantly available to interact with invasive pathogens.

MINIQUIZ

- Identify a pathogen-associated molecular pattern shared by a group of microorganisms.
- Identify the cell types that use pattern recognition receptors to provide innate immunity to pathogens.

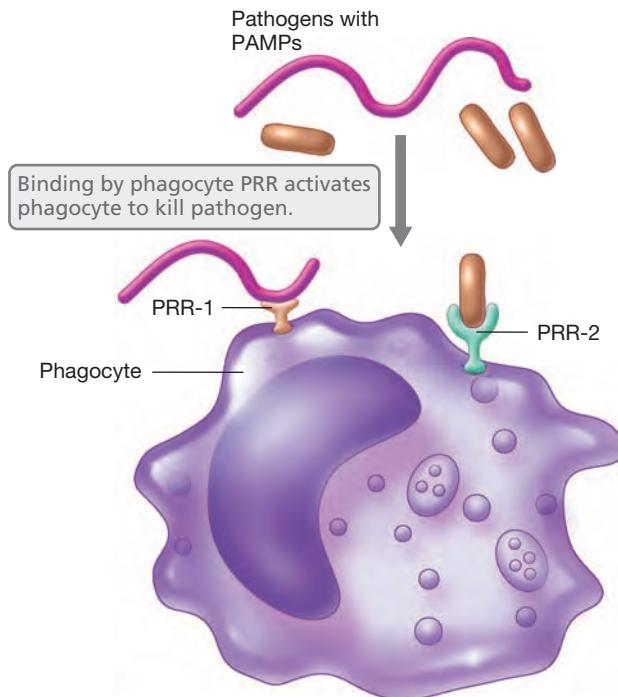

Figure 24.3 Innate immunity. Phagocytes interact with pathogens by recognizing pathogen-associated molecular patterns (PAMPs) with preformed pattern recognition receptors (PRRs). Binding of a PAMP by a phagocyte PRR stimulates the phagocyte to destroy the pathogen and activate other phagocytes.

24.3 Adaptive Immunity

The phagocytes responsible for innate immunity often trigger *adaptive* immunity in vertebrate animals. As compared with the common targets that trigger innate immunity, adaptive immunity is directed toward a molecular component of the pathogen called an antigen. In adaptive immunity, pathogen-specific receptors are produced in large numbers only after exposure to the pathogen or its products.

The first exposure to an antigen generates a **primary adaptive immune response**: The antigen contact stimulates growth and multiplication of antigen-reactive cells, creating **clones**, large numbers of identical antigen-reactive cells. These clones persist for years and confer long-term specific immunity.

Antigen-reactive lymphocytes are divided into T cells and B cells. Each cell type produces a unique protein that interacts with a single antigen. These proteins thus have **specificity** for that antigen. The antigen-binding proteins of T cells are the **T cell receptors (TCRs)**; cell-surface antibodies on a B cell are the **B cell receptors (BCRs)**.

As compared to innate immunity, the adaptive response is inducible only when triggered by a unique antigen on a pathogen. For example, polysaccharide antigen from the LPS of a particular gram-negative bacterium is unique for a genus and sometimes even for a species within the genus. For example, an individual lymphocyte clone that interacts with an LPS polysaccharide on *Salmonella* will not interact with the LPS on other bacteria. The terminal sugars that constitute the polysaccharides of *Salmonella* spp. are unique identifying antigens for the genus and are not

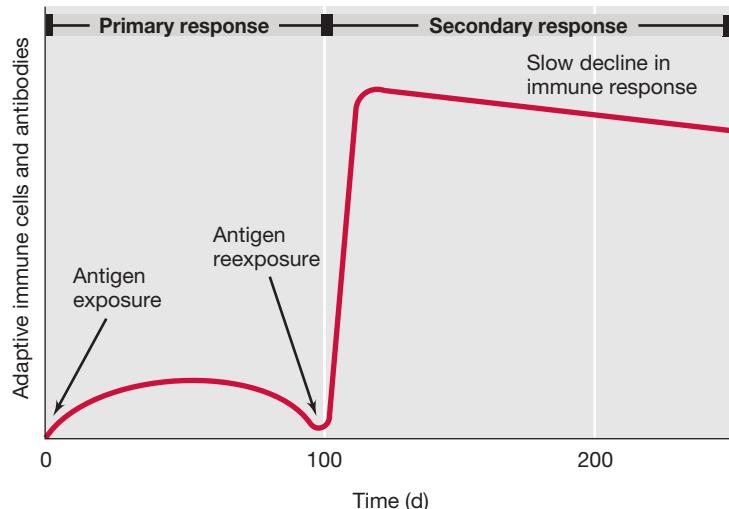

Figure 24.4 Primary and secondary adaptive immune responses. The primary response induces both immune cells and antibodies. The antigens given at day 0 and day 100 must be identical to induce a secondary response. The secondary response may generate more than 10-fold increases in immune cells and antibody concentrations.

shared by other bacteria, even other gram-negative enteric bacteria such as *Escherichia coli* or *Shigella* spp.

A second exposure to the same antigen activates the clones of antigen-reactive cells and generates a faster, stronger **secondary adaptive immune response** that peaks within several days (Figure 24.4). The products of this secondary immune response quickly target the pathogen for destruction. This rapid increase in adaptive immunity after a second antigen exposure is called **memory**. Finally, the adaptive immune system exhibits **tolerance**, the acquired *inability* to generate an immune response against self antigens. Tolerance ensures that adaptive immunity is directed to outside agents that pose genuine threats to the host, and not to host proteins.

T Cells and Antigen Presentation

Adaptive immunity begins with the interactions of immune T lymphocytes with peptide antigens on infected cells. The infected cells that are first recognized by T cells may include the same phagocytes that participate in the innate immune response. The T cell, with its TCR, can recognize peptide only when the peptides are complexed with self proteins called **major histocompatibility complex (MHC)** proteins, found on host cell surfaces (Figure 24.5). All host cells display MHC I proteins that present peptides from viruses and other intracellular pathogens for immune recognition; APCs (macrophages, dendritic cells, and B cells) also display an additional antigen-presenting protein, MHC II. Macrophages are found in all organs of the body, but the other APCs are localized in the secondary lymphoid organs—spleen, lymph nodes, and MALT. These secondary lymphoid organs are the sites where the adaptive immune response begins. APCs ingest bacteria, viruses, and other antigenic material by phagocytosis (in macrophages and dendritic cells) or through internalization of molecular antigen bound to a BCR. After ingestion, the APCs degrade the antigens to small peptides. The MHC proteins inside

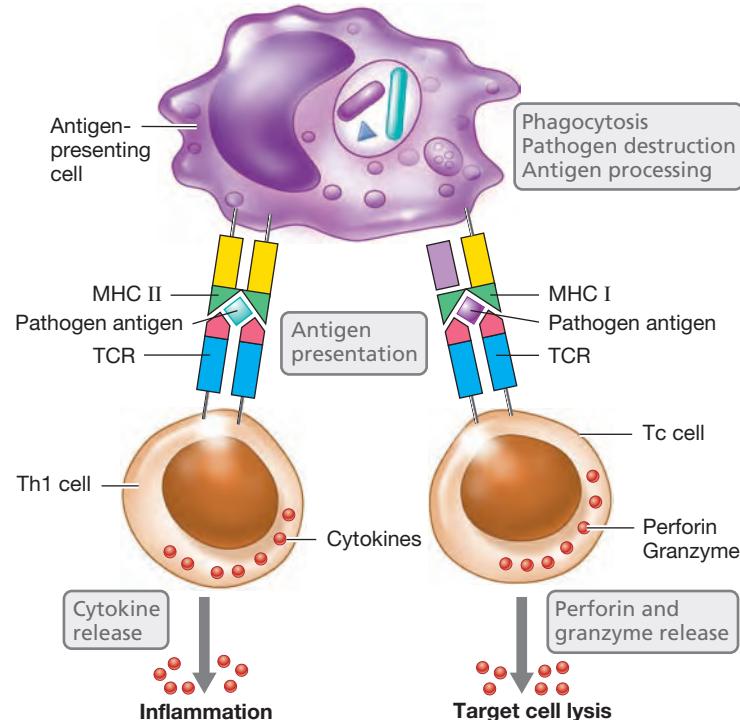

Figure 24.5 T cell immunity. Antigen-presenting cells such as the phagocytes in innate immunity ingest, degrade, and process antigens. They then present antigens to T cells that secrete protein cytokines that activate the adaptive immune response. Antigen-reactive T cells include inflammatory T-helper (Th1) cells that make cytokines that activate other cells, causing inflammation. T-cytotoxic (Tc) cells produce perforins and granzymes, proteins that enter and lyse nearby target cells.

the APC bind the peptides derived from the digested pathogens. The MHC-embedded peptides are then transported to the phagocyte surface where the complex is displayed, a process called *antigen presentation*. For example, a phagocyte infected with influenza virus will display MHC I and II proteins embedded with influenza peptides. These influenza peptide–MHC complexes are the targets for T cells.

T Lymphocyte Subsets

T cells interact with the peptide–MHC complex using the TCR. Each T cell expresses a TCR that is specific for a single peptide–MHC complex. Antigen-specific T cells are found closely associated with the APCs in the spleen, lymph nodes, and MALT. T cells constantly sample surrounding APCs for peptide–MHC complexes; peptide–MHC complexes that interact with the TCR signal the T cell to grow and divide, producing antigen-reactive clones that interact directly to kill cells displaying the same foreign peptide or help other cells to eliminate cells with the same peptide.

Antigen-reactive T cells consist of three basic T cell subsets, based on their functional properties. These T cell subsets interact with other cells to initiate immune reactions. *T-helper (Th) cells* interact with peptide–MHC II complexes on the surface of APCs. This interaction causes the Th cells to differentiate into one of two subsets that indirectly mediate immune reactions. Antigen-activated T cell subsets, termed Th1 and Th2, respond by proliferating and producing soluble cytokines. The cytokines interact

with receptors on other cells, activating them to initiate an immune response. Antigen-specific Th1 cells that interact with peptide–MHC II complexes on the surface of macrophages stimulate the Th1 cell to produce cytokines that activate the macrophages, enhancing phagocytosis of cells displaying the target peptide and causing inflammatory reactions that limit the spread of infections (Figure 24.5, **Figure 24.6**). For example, *Mycobacterium tuberculosis* infects macrophages and other cells in the lung, causing tuberculosis. Activated macrophages kill *M. tuberculosis* inside the cell, stopping the spread of infection to other cells. An inflammatory reaction associated with *M. tuberculosis* is termed the *tuberculin reaction* and is used as a diagnostic test for

M. tuberculosis exposure. This test uses *tuberculin*, an extract from *M. tuberculosis*, to attract immune Th1 cells that then produce cytokines, activating macrophages and causing a localized red, hot, hardened, and swollen area that typifies inflammation and effective immunity. Differentiated Th2 cells, the other T-helper subset, use cytokines to stimulate (“help”) antigen-reactive B cells to produce antibodies, as we discuss below. *T-cytotoxic (Tc) cells* recognize the peptide–MHC I complex on an infected cell. When Tc cells interact with the infected cell, they secrete proteins that kill the peptide-bearing infected cell (Figure 24.5).

MINIQUIZ

- Explain the process of antigen presentation to T cells.
- Define the role of Tc and Th1 cells in adaptive immunity.

24.4 Antibodies

Antibodies are soluble proteins made by B cells and plasma cells (Figure 24.1) in response to exposure to antigens. Each antibody binds specifically to a single antigen. Antibody-mediated immunity controls the spread of infection by recognizing pathogens and their products in extracellular environments such as blood and mucus secretions.

B Cell Functions

B cells are specialized lymphocytes that have antibodies on their surface; each B cell displays multiple copies of a single antibody that is specific for a single antigen. To make antibodies, B cells must first bind antigens through interactions with the BCR (Figure 24.7). The surface antibody–antigen interaction induces the B cell

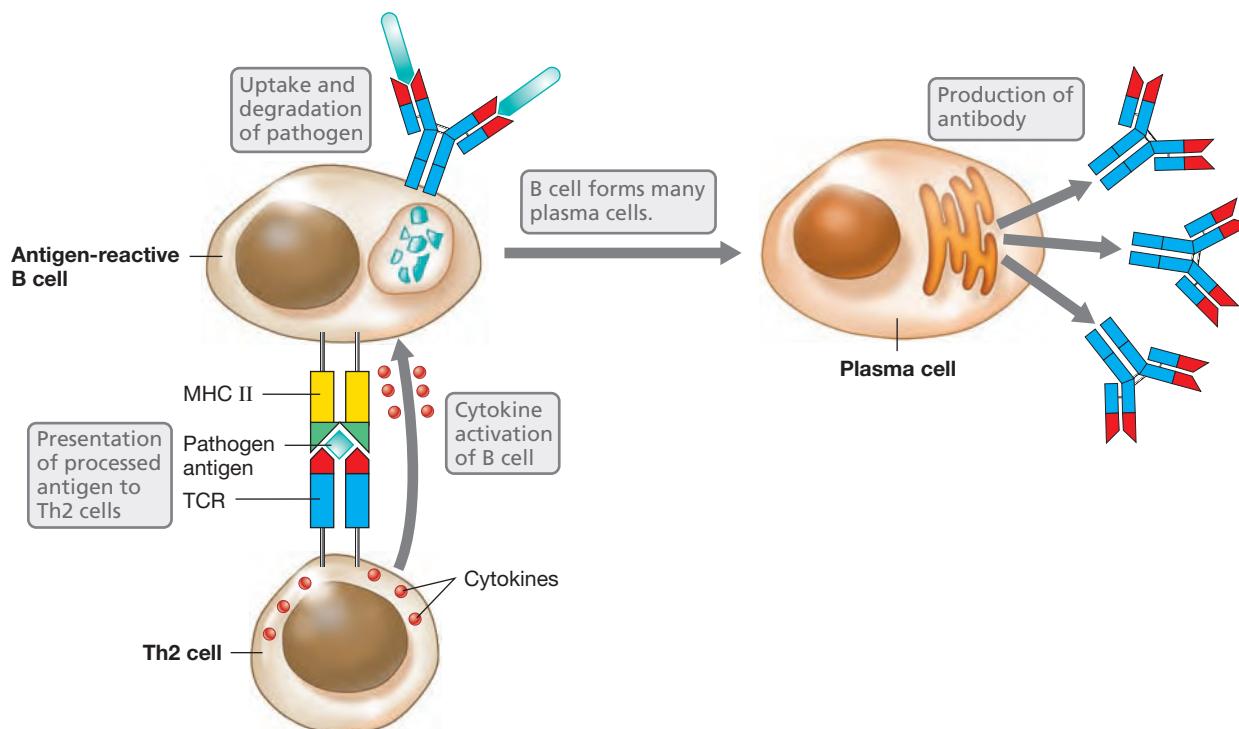

Figure 24.7 Antibody-mediated immunity. Antibody on a B cell binds antigen and, through collaboration with a Th2 cell, the B cell forms clones which can then differentiate into antibody-producing plasma cells.

to ingest the antigen-containing pathogen by phagocytosis. The B cell then kills and digests the pathogen, producing a battery of pathogen-derived peptide antigens. These peptides are then complexed with MHC II and displayed, or *presented*, on the surface of the B cell to the antigen-specific Th2 cell.

The Th2 cell does not interact directly with the pathogen but stimulates (“helps”) other cells, in this case, the antigen-presenting B cell on which it recognized the MHC-peptide. Th2 cells produce cytokines that stimulate antigen-reactive B cells, which in turn respond by growing and dividing, establishing clones of the original antigen-reactive B cell. Many of these activated B cells then differentiate into plasma cells that produce soluble antibodies (Figure 24.7). This primary antibody response is detectable within about five days after antigen exposure, and antibodies reach peak quantities within several weeks. Some of the activated B cells from the clone remain in circulation in the immune system as memory B cells. Subsequent exposure to the same antigen, for example, by reinfection with the same pathogen, stimulates the antigen-reactive memory B cells, producing a secondary antibody response, characterized by a faster development of higher quantities of antibodies (Figure 24.4). The secondary response, also called *immune memory*, is the basis for vaccination, as we discuss later. The antibody response is highly specific for the eliciting antigen; antigen binding by antibodies can trigger neutralization or destruction of pathogens or their products through several mechanisms (Figures 24.8 and 24.9).

Antibody Classes and Functions

Several different classes of antibodies are distinguished from one another by their primary amino acid sequence. Each antibody class has a defined general function (Table 24.2). IgM and IgG are found in blood. The primary antibody response consists mostly of IgM antibodies, whereas the secondary antibody response is characterized by large amounts of IgG (Figure 24.4). IgA is found in blood and in high concentrations in mucous membrane secretions, such as in the lungs and gut. IgE is found attached to the mast cells involved in parasite immunity and allergies. IgD is found primarily as a surface immunoglobulin on B cells.

Antibodies released from plasma cells interact with antigen on the pathogens. The antibody may have one or more effects on the pathogen, but most antibody interactions do not directly kill the pathogen. Many antibodies block interactions between pathogens or their products and host cells. For example, IgA antibodies present in mucosal secretions and directed against influenza virus may interact with influenza virus antigens that bind to host cells, blocking attachment of the influenza virus to the host cell.

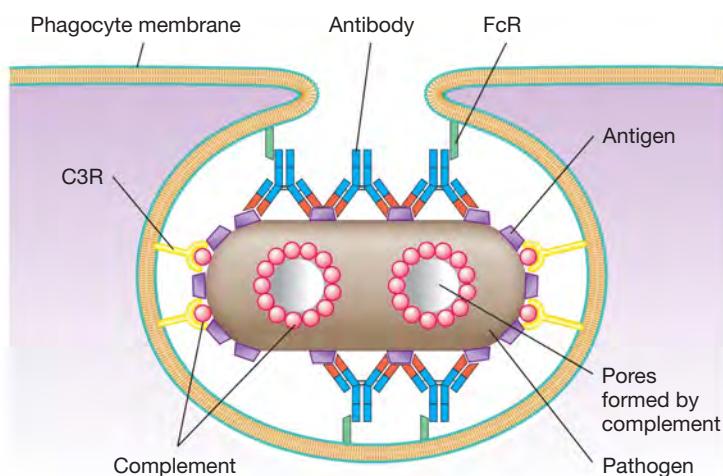

Figure 24.9 Antibodies, complement, and opsonization. Phagocytes have receptors that bind antibodies (FcR; green). Complement proteins (red) bind to antigen-antibody complexes and attach to the cell via complement receptors (C3R; yellow). Interaction with FcR and C3R enhances phagocytosis, a phenomenon called opsonization. Complement may also form pores and directly lyse the cell.

Table 24.2 Major classes of antibodies

Antibody class	Location	Serum Concentration	Functions
IgA	Serum and mucus secretions	2.1 mg/ml in serum and high local amounts at mucosal surfaces	Secondary response and mucosal immunity for extracellular pathogens
IgE	Mast cells	Low amounts in serum; all bound to mast cells	Parasite immunity, allergies
IgG	Serum	13.5 mg/ml (highest in serum)	Secondary response for extracellular pathogens
IgM	Serum	1.5 mg/ml	Primary response for extracellular pathogens

Specific serum antibodies can also bind toxins such as tetanus toxin, again blocking the binding of toxin to host cell receptors. This process is called *neutralization* (Figure 24.8). In many cases, antibodies mark the pathogen for destruction by phagocytosis. Phagocytes have general antibody receptors called *Fc receptors* (*FcR*) that bind to any antibody attached to an antigen. This interaction results in enhanced phagocytosis of the antibody-coated cells, a process known as *opsonization* (Figure 24.9).

Complement

Antibody-mediated destruction of pathogens may also involve a group of proteins known collectively as *complement* (Figure 24.9). The complement proteins attach to pathogen surfaces, attracted by IgM or IgG antibodies bound to the pathogen. The complement proteins bound to the cell surface by the antibody have two possible effects on the pathogen. First, complement proteins can form a pore in the pathogen cytoplasmic membrane, directly lysing the pathogen cell. This complement–antibody interaction affects only those pathogen cells with bound antibodies. For example, antibodies specific for cell surface proteins of *Salmonella* interact only with *Salmonella*. Complement causes

ysis of only the antibody-coated *Salmonella* cell, but not of a nearby *Escherichia coli* cell that is not coated with antibodies. Many pathogens, such as the thick-walled gram-positive *Streptococcus* species, are relatively resistant to complement-mediated lysis because the cell wall makes the cytoplasmic membrane less accessible to complement proteins. Antibodies to the external cell wall components, however, still attract complement proteins to the pathogen surface. The second effect of complement binding is the stimulation of phagocytosis. Pathogen-bound complement proteins are recognized by complement receptors called *C3 receptors* (*C3R*) found on the surface of phagocytes such as neutrophils and macrophages. This interaction results in opsonization and phagocytosis of the cells sensitized by antibody and complement (Figure 24.9).

II • Host Defense

The immune system protects the host through several mechanisms, including inflammation and active and passive adaptive immune responses that rid the body of pathogens. We can also generate protective immunity without infection through vaccination with antigens derived from pathogens.

24.5 Inflammation

Inflammation is a general, nonspecific reaction to noxious stimuli such as toxins and pathogens. Inflammation is characterized by redness (erythema), swelling (edema), pain, and heat, usually localized at the site of infection (Figure 24.6 and Figure 24.10). The

molecular activators of inflammation are a group of cell activators and chemoattractants, including cytokines and chemokines. These activators are produced by various cells. The most important chemokines and cytokines are termed *proinflammatory* because of their inflammation-inducing abilities; they are produced in high concentrations by phagocytes and lymphocytes.

Both innate and adaptive immune responses to infection can cause inflammation; both immune recognition systems induce the activators that recruit and activate effector cells such as neutrophils. An immune response normally activates inflammation to isolate and limit tissue damage by destroying pathogen invaders and removing damaged cells. In some cases, however, inflammation results in considerable damage to healthy host tissue.

Inflammatory Cells and Local Inflammation

Immune-mediated inflammation is an acute condition that begins at the site of pathogen entry into the body. The innate PRRs on macrophages and other tissue cells at the site of infection engage the pathogen PAMPs (Figure 24.3). This action activates the local cells to produce and release mediators including cytokines and chemokines that interact with cytokine and chemokine receptors on other cells such as neutrophils. For example, local tissue macrophages that are activated by PAMP–PRR interaction secrete a chemokine called CXCL8. The CXCL8, through a CXCL8 receptor, activates neutrophils that then migrate along the chemokine gradient toward the source of the CXCL8, where they begin to ingest and kill the pathogen. The neutrophils, in turn, secrete even more CXCL8, attracting more neutrophils and amplifying the response, eventually destroying the pathogens (Figure 24.10b).

The chemokine and cytokine mediators released by injured cells and phagocytes contribute to inflammation. For example, the macrophage and other cells at the site of infection produce proinflammatory cytokines including interleukin-1 (IL-1), IL-6, and tumor necrosis factor α (TNF- α). These cytokines increase vascular permeability, causing the swelling (edema), reddening (erythema), and local heating associated with inflammation. The edema stimulates local neurons, causing pain (Figure 24.11a).

The usual outcome of the inflammatory response is a rapid localization and destruction of the pathogen by macrophages and recruited neutrophils. As the pathogens are removed, the inflammatory cells are no longer stimulated, their numbers at the site are reduced, cytokine production decreases, attraction of phagocytes toward the cytokine producers stops, and inflammation subsides.

Systemic Inflammation and Septic Shock

In some cases, the inflammatory response fails to localize the pathogens and the reaction spreads throughout the body. An uncontrolled systemic inflammation can be more dangerous than the original infection, with inflammatory cells and mediators contributing to large-scale inflammation. An inflammatory response that spreads inflammatory cells and mediators through the entire circulatory and lymphatic systems can lead to septic shock, a life-threatening condition.

A common cause of septic shock is systemic infection by enteric bacteria such as *Salmonella* or *Escherichia coli* caused by a ruptured or leaking bowel that releases the gram-negative organisms into the intraperitoneal cavity or the bloodstream. The primary

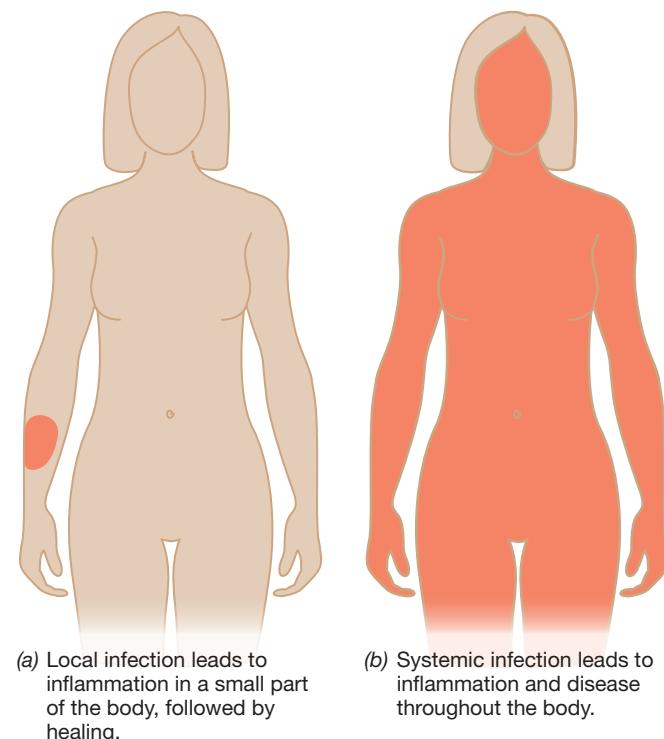

Figure 24.11 Local and systemic inflammation. (a) Local infection, mediated by proinflammatory cytokines from local macrophages, results in inflammation that subsides as the infection is cleared. (b) Systemic infection causes systemic release of proinflammatory cytokines, resulting in widespread systemic inflammatory symptoms including severe edema, fever, and septic shock, even if the infection is controlled.

infection is often cleared by the phagocytes or is treated successfully with antibiotics. However, the endotoxic outer membrane LPS from these organisms interacts with a PRR on phagocytes, stimulating production of proinflammatory cytokines, which are released into the systemic circulation. The cytokines then induce systemic responses that parallel the localized inflammatory response, but on a larger scale involving many organ systems, ultimately leading to an extensive whole-body inflammatory event with potentially life-threatening consequences (Figure 24.11b).

The proinflammatory cytokines IL-1, IL-6, and TNF- α , for example, are *endogenous pyrogens*. They stimulate the brain to produce prostaglandins, chemical signals that raise body temperature, causing a fever. By contrast, the same cytokines released in small amounts at local sites of infection produce local heating; this increases blood flow and promotes healing. The large quantities of endogenous pyrogens released into the general circulation as a result of a systemic infection induce organism-wide heating characterized by uncontrollable high fever. In addition, the large amounts of inflammatory mediators released systemically, instead of causing local edema due to vasodilation and increased vascular permeability, cause the same reactions on a system-wide scale. The result is a massive efflux of fluids from the central vascular tissue with loss of systemic blood pressure due to reduced blood volume, and severe edema due to influx of fluids from vascular tissues into extravascular spaces.

In short, the proinflammatory cytokines, produced in high quantities to combat systemic infections, induce high fever, extremely

low blood pressure, and severe edema. This condition, termed septic shock, causes death in up to 30% of affected individuals.

24.6 Immunity and Immunization

Both the innate and adaptive immune responses protect the host from infections by pathogens, and both innate and adaptive immunity are essential for survival (Figure 24.12). For example, individuals that lack innate immunity because they fail to produce phagocytes develop recurrent infections from bacteria, viruses, and fungi and die at an early age without extraordinary intervention. Individuals who lack adaptive immunity have the same outcome, but may survive longer if the innate immune system is functional.

Immunity may be naturally occurring or artificially induced by exposure to antigens (vaccination). We acquire immunity either *actively*, for example when we generate an immune response through exposure to antigen, or *passively*, for example when we receive antibodies or immune cells from an immune individual. Active and passive immunity are illustrated in Figure 24.13 and contrasted in Table 24.3.

Natural Immunity

Animals normally develop *natural active immunity* by acquiring a natural infection that initiates an adaptive immune response (Figure 24.13). Natural active immunity is the outcome of exposure to antigens through infection and usually results in protective immunity from antibodies and T cells. For example, virtually all adults have acquired natural active immunity to many strains of influenza and cold viruses through immune responses to infections. Natural

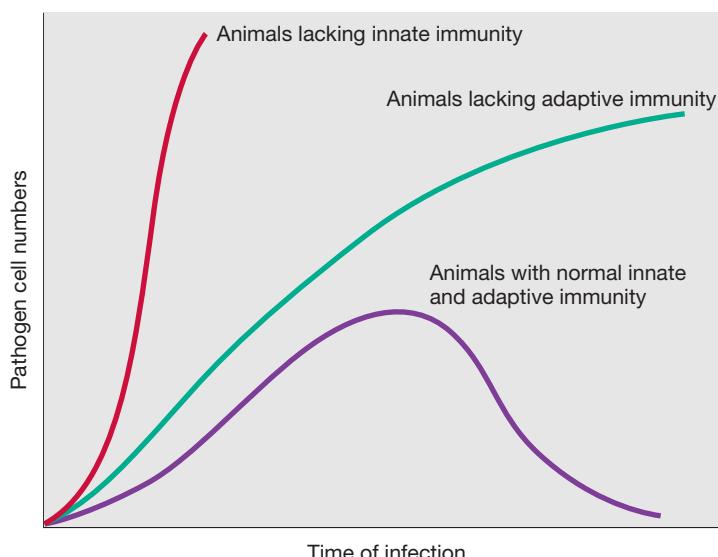

Figure 24.12 Infection and pathogen clearance in normal and immune-deficient animals. Animals with genetic defects that prevent development of the phagocytes critical for innate immunity have recurrent, incurable, lethal infections. Genetic defects that prevent development of mature, antigen-reactive B and T cells critical for adaptive immunity also allow recurrent infections, but the innate response controls these infections for a longer time and these animals live longer than the animals lacking innate immunity. Animals with normal innate and adaptive immunity rapidly clear most infections.

immunity, however, requires that an infection has occurred, which in some cases could involve potentially dangerous pathogens.

Active immunity is critical for infectious disease resistance. We know this because of problems caused by genetic defects and diseases that affect the immune system. For example, patients who cannot produce antibodies because of genetic defects in their B cells acquire serious infections from extracellular pathogens, especially bacteria. Individuals with genetic defects that prevent

Natural active immunity requires infection with a pathogen to activate the adaptive immune response. (2) A 1934 United States government poster promoting breast-feeding. Natural passive immunity occurs when immunity is transferred from one individual to another by natural means, such as the transfer of antibodies in breast milk. (3) Vaccination by nasal inhalation of antigen. Artificial active immunity occurs from exposure to particular antigens in a vaccine. (4) Timber rattlesnakes produce highly poisonous venom. An antivenom consisting of purified timber rattlesnake antivenom antibodies can be prepared in horses and artificial passive immunity conferred on a snakebite victim by injecting the victim with the antivenom.

development of T cells suffer from recurrent infections with viruses and other intracellular pathogens. Individuals with *severe combined immune deficiency syndrome (SCID)* have a genetic defect that prevents proper formation of either B or T cells; they have no effective adaptive immunity and die from multiple recurrent infections (Figure 24.12) unless they receive supportive therapy such as a bone-marrow transplant and antibiotics. Immunodeficiency can also be caused by toxic reactions to drugs, environmental contaminants, or infections. For example, the loss of the adaptive immune response is the defining characteristic of *acquired immunodeficiency syndrome (AIDS)*. In AIDS patients, infection with the human immunodeficiency virus (HIV) causes depletion of Th cells, resulting in a lack of effective immunity (Figure 24.14). In cases of immunodeficiency the result is similar; patients suffer from recurrent life-threatening infections.

Natural passive immunity (Figure 24.13) occurs when a non-immune person acquires preformed immune cells or antibodies through natural transfer of cells or antibodies from an immune

person. For example, for several months after birth, newborns have maternal IgG antibodies in their blood; these protective antibodies were transferred across the placenta before birth. Similarly, IgA antibodies are transferred to newborns in breast milk. In both cases, the antibodies that are protective for the infant were made in the mother and are passively acquired by natural means. These preformed antibodies provide disease protection while the immune system of the newborn matures.

Artificial Passive Immunity

In *artificial passive immunity*, the individual receiving the antibodies played no active part in antibody production; he or she receives preformed antibodies through injection of an *antiserum* (serum containing antibodies from the blood of an immune individual) or purified antibodies (immunoglobulin) derived from an immune individual. These antibodies gradually disappear from the body and a later exposure to the antigen cannot elicit a secondary response.

Artificial passive immunity is used to prevent or treat acute infectious diseases such as tetanus and in the treatment of bites by venomous animals (Figure 24.13). Cells or antibodies from an immune individual are transferred to a nonimmune individual. For example, tetanus antiserum may be administered to passively immunize an individual suspected of being exposed to *Clostridium tetani* due to a traumatic injury such as a car accident. The antibody injection provides immediate immune protection against tetanus toxin. The antibody-containing preparation is known as an *antiserum*, an *antitoxin* if the antibodies are directed against a toxin, or an *antivenom* if the antibodies are directed toward a venom. Antisera are obtained from immunized animals such as horses, or from humans with high levels of antibody. The immunoglobulin from serum pooled from a number of individuals is also used for passive immunization to prevent certain viral diseases since pooled sera contain antibodies to various common pathogens such as hepatitis A.

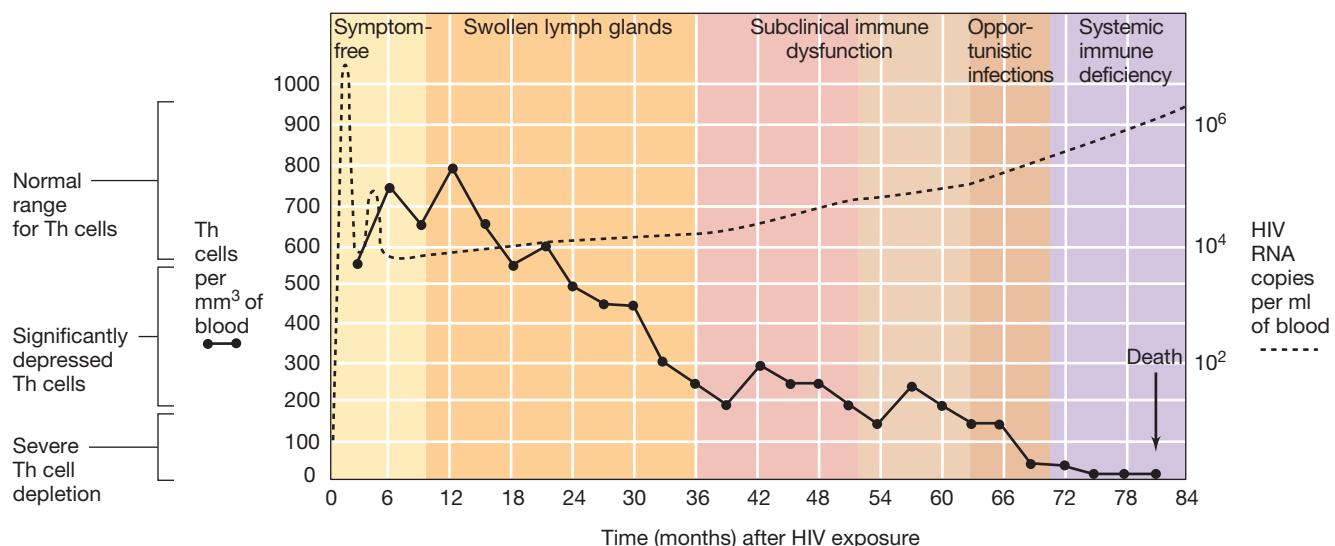

Figure 24.14 Decline of T-helper (Th) lymphocytes and progress of HIV/AIDS. An untreated HIV infection progresses to AIDS. The number and functional ability of the Th cells gradually declines, while the viral load, measured as HIV-specific RNA copies per milliliter of blood, increases after an initial decline. The lack of an effective immune response leads to an increase in life-threatening infections and death.

Artificial Active Immunity: Vaccination

Vaccination or immunization is the purposeful artificial induction of active immunity, and is a major weapon for the prevention and treatment of many infectious diseases. Artificial immunity can be induced actively by injecting an individual with a pathogen or its products (Figure 24.13). The goal is to produce a protective immune response to the pathogen. In active immunity, introduction of antigen induces changes in the host: The immune system produces antibodies in a primary immune response and, more importantly, produces a large number of immune memory cells. A second (“booster”) dose of the same antigen results in a faster response yielding much higher levels of antibodies and immune T cells due to this memory, or secondary, immune response. Active immunity may remain throughout life as a result of immune memory.

Artificial active immunity is used to protect a person against future attack by a pathogen, but takes several days to weeks to induce protective immunity. For example, immunization with tetanus toxoid, a nontoxic version of *C. tetani* (tetanus) exotoxin, protects individuals against future encounters with exotoxin, but it is not an effective therapy for the trauma victim in the car accident above because effective adaptive immunity takes a week or more to develop.

Vaccines

The antigen or antigen mixture used to induce artificial active immunity is known as a **vaccine** or an *immunogen*. A summary of diseases for which vaccines are available for human use is given in **Table 24.4**. Immunization with a vaccine designed to produce artificial active immunity may introduce risks of infection and other adverse reactions. To reduce risks, pathogens or their products are inactivated or otherwise made harmless. For example, many vaccines consist of pathogens killed by chemical agents such as phenol or formaldehyde, or physical agents such as heat. Formaldehyde is also used to inactivate viruses for vaccines, such as in the inactivated (Salk) polio vaccine. Likewise, the active form of an exotoxin cannot be used as an immunogen because of the toxic effects. Many exotoxins, however, can be modified chemically so they retain their antigenicity but are no longer toxic. A modified exotoxin is called a **toxoid**. Toxoids such as the vaccine for *C. tetani* exotoxin can be given safely. The toxoid vaccine induces long-term protective immunity against the exotoxin. In other cases, antigenic components are extracted from pathogens grown in vitro, purified, and injected as a vaccine. Such is the case for some pneumococcal vaccines; they consist of a mixture of pneumococcal polysaccharide capsule antigens derived from the most common pathogenic strains.

Immunization with live cells or virus is usually more effective than immunization with dead or inactivated material. It is often possible to isolate a mutant strain of a pathogen that has lost its virulence but still retains the immunizing antigens; strains of this type are called *attenuated strains* (☞ Section 27.6). However, because attenuated strains of pathogens are still viable, some individuals, especially those who are immunocompromised, may acquire active disease. Serious cases of disease in immunocompromised individuals have occurred, for example, from attenuated poliovirus and smallpox vaccines.

Many effective viral vaccines are live attenuated vaccines. Attenuated vaccines tend to provide long-lasting T cell-mediated immunity, as well as vigorous antibody immunity and a strong secondary response upon reimmunization or infection with the targeted pathogen. However, attenuated vaccine strains are difficult

to select, standardize, and maintain. Live, attenuated vaccines, such as most measles vaccines, have a limited shelf life and require refrigeration for storage. Killed virus vaccines, on the other hand, tend to provide short-lived immune responses with less long-term memory, but they are relatively easy to store and maintain their potency for long periods of time.

Most bacterial vaccines are provided as antigens in an inactivated form, such as the toxoids that protect against tetanus and diphtheria. One current acellular pertussis (whooping cough) vaccine consists of the inactivated pertussis toxin (PT) and filamentous hemagglutinin (FHA) antigens. Inactivated bacterial vaccines induce antibody-mediated protection without exposing recipients to the risk of infection, but primary and secondary responses are somewhat variable with each vaccine and individual, requiring periodic reimmunization to establish and maintain immunity.

Immunization Practices

Infants acquire natural passive immunity from maternal antibodies transferred across the placenta or in breast milk. As a result, infants are immune to many common infectious diseases during the first 6 months of life. However, infants should be immunized to prevent key infectious diseases as soon as possible so that their own active immunity can replace the maternal passive immunity. As discussed in Section 24.3, a single exposure to antigen does not lead to a high antibody *titer*, or antibody quantity. After an initial immunization, a series of secondary or “booster” reimmunizations are given to produce a secondary response and a high antibody titer. A summary of current vaccine recommendations in the United States is shown in Figure 24.15.

The importance of immunization in controlling infectious diseases is well established. For example, introduction of an effective vaccine into a population has reduced the incidence of formerly epidemic childhood diseases such as measles, mumps, and rubella (Section 29.6) and has eliminated smallpox altogether (Section 28.8). The degree of immunity obtained by vaccination, however, varies greatly with the individual as well as with the quality and quantity of the vaccine. Lifelong immunity is rarely achieved by means of a single injection, or even a series of injections, and the immune cells and antibodies induced by immunization gradually disappear from the body. On the other hand, natural infections may stimulate immune memory. In the complete absence of antigenic stimulation, the length of effective immunity varies considerably with different vaccines. For example, protective immunity to tetanus from toxoid immunization may last many years, but it is not lifelong. Current recommendations call for reimmunization in adults every 10 years to maintain protective immunity. Immunity induced by inactivated influenza virus vaccine disappears within a year or two without reimmunization through active infection or reimmunization.

Immunizations benefit individuals by preventing acute disease, and they also benefit the entire population. *Herd immunity* is the

These immunizations are recommended by the U.S. Centers for Disease Control and Prevention, Atlanta, Georgia, as of 2012. concept that infections spread poorly in populations with a large proportion of immune individuals. Immunization is therefore a major tool for infectious disease control programs.

24.7 Immunization Strategies

Historically, many vaccines have been derived from attenuated or inactivated whole pathogens. Today genetic engineering methods

can generate pathogen-derived antigens for use as vaccines, altogether avoiding exposure to whole pathogens either living or dead.

Synthetic and Genetically Engineered Vaccines

In Chapter 11 we discussed how genetic engineering tools can be used to synthesize new genes and proteins. The simplest alternate approach to vaccine development is to make use of these methods to produce *synthetic peptides*. To make a vaccine, a genetic engineer can synthesize a peptide that corresponds to an antigen of an infectious agent. For example, the structure of the toxin from the foot-and-mouth disease virus, an important animal pathogen, is known. Because the whole protein is toxic, it cannot be used as a vaccine. However, a peptide of 20 amino acids is an important antigen in the protein, but the peptide is too small to be an effective vaccine by itself. Genetic engineers attached a synthetic version of the small peptide to a large, innocuous protein that acts as a carrier molecule. The synthetic *conjugate vaccine* produces a protective response to foot-and-mouth disease virus infection. This strategy has great promise for creating vaccines to a number of pathogens, but the entire sequence of the disease-causing protein must be known and a protective antigen recognized by lymphocytes must be identified before an effective vaccine can be engineered. However, the entire genomic sequences of many pathogens are now known, providing the information necessary to identify the most antigenic part of each.

Two widely available conjugate vaccines couple extracted bacterial polysaccharide to a protein toxoid, provoking a more robust immune response with better immune memory than injection of the polysaccharide antigen alone. One pneumococcal vaccine uses pneumococcal polysaccharide coupled to diphtheria toxoid

(**Figure 24.16**). Likewise, the vaccine for *Haemophilus influenzae* type b (Hib) uses Hib polysaccharide coupled to tetanus toxoid. Polysaccharide antigens are not processed efficiently by B cells and generally provide only a primary response with little immune memory, but the conjugated protein toxoids are processed and activate Th2 cells, resulting in a primary response followed by a strong secondary response and immune memory.

Genomic information is particularly useful for making viral vaccines. For example, genes that encode antigens from virtually any virus can be cloned into the vaccinia virus genome and expressed. Inoculation with the antigen-producing vaccinia virus can induce immunity to the product of the cloned gene. Such a preparation is called a *recombinant-vector vaccine*. This method depends on the identification and cloning of the gene that encodes the antigen and also on the ability of the vaccinia virus to express the cloned gene as an antigenic protein. An effective recombinant vaccinia-rabies vaccine has been developed for use in animals. (Recombinant DNA methods for vaccine development were discussed in Section 11.14.)

Another immunization strategy involves the use of proteins made from cloned DNA as immunogens (see Explore the Microbial World: Vaccines and Public Health). First, a pathogen gene must be cloned in a suitable microbial host that expresses the protein encoded by the cloned gene. The pathogen protein can then be harvested and used as a vaccine; such a vaccine is called a *recombinant-antigen vaccine* (► Section 11.14). For example, the current hepatitis B virus vaccine is a major hepatitis surface protein antigen (HbsAg) expressed by genetically modified yeast cells. A vaccine that is effective against human

Conjugate vaccines such as *Streptococcus pneumoniae* (pneumococcus) polysaccharide covalently linked to diphtheria toxoid and *Haemophilus influenzae* type b (Hib) polysaccharide coupled to tetanus toxoid provide effective immunity to polysaccharide antigens. Polysaccharides are poor immunogens in the absence of protein carriers such as toxoids.

Vaccines and Public Health

Various strains of human papillomavirus (HPV) infect up to 75% of sexually active people, causing genital warts and vulvar, vaginal, and cervical cancers in women (**Figure 1**) and genital warts and anal cancers in men. In the United States, about 12,000 women develop cervical cancer each year, and about 4,000 die. Worldwide, nearly half a million women develop cervical cancer annually and about 250,000 die from it. Vaccines directed to HPV antigens are highly protective against viral infection, and prevent genital warts and the cancers caused by the targeted HPVs.

Two HPV vaccines are approved for use. One of these vaccines, *Gardasil*, targets HPV types 6, 11, 16, and 18. Another vaccine, *Cervarix*, is effective against HPV 16 and 18, two strains that account for 70% of cervical cancers and 90% of genital warts (Figure 1). *Gardasil* has been approved for use in females and males 9–26 years of age, and *Cervarix* is approved for use in females ages 9–25. Immunization is recommended for females and males ages 9–26.

The vaccines are a preparation of virus-like particles of the major L1 capsid proteins from the HPV strains. The L1 proteins have been genetically engineered to be expressed by the yeast *Saccharomyces cerevisiae* and are released by disruption of the recombinant yeast cells as self-assembled virus-like particles. After purification, these recombinant-antigen particles are adsorbed onto a chemical adjuvant, an innocuous substance that immobilizes the particles, enhancing their ability to be taken up by phagocytes after injection.

Because HPV is responsible for most cervical cancers, immunization of susceptible individuals with strain-specific HPV vaccines will prevent many cancers in the immunized individuals. Perhaps as important, however, herd immunity resulting from immunization of a large proportion of the population can significantly reduce the spread of these viruses, providing protection even for individuals who are not immunized (☞ Section 28.2). Models suggest that herd immunity can be raised to meaningful levels by immunizing about 80% of young women. The recommended immunization of boys and men might provide the further herd immunity necessary to stop transmission of the targeted HPV strains, and is also effective for prevention of genital warts and anal cancers in men. HPV vaccines are the only ones effective against any sexually transmitted infection in humans.

The HPV vaccine is a recent example of effective vaccine development and implementation, but a number of important infectious diseases still cannot be prevented by vaccination. For example, no vaccines exist for most diarrheal diseases (2.2 million annual deaths worldwide) or respiratory diseases (about 4 million annual deaths worldwide), with the notable exceptions of influenza and pneumococcal vaccines. Effective vaccines still do not exist for three of the world's most lethal infectious diseases: tuberculosis (1.5 million annual deaths worldwide), malaria (about 900,000 annual deaths worldwide), and HIV/AIDS (2 million annual deaths worldwide). Even some effective vaccines have se-

CDC/PHIL

rious limitations. For example, influenza vaccines are only effective for one year; they are reformulated each year to target the strain-specific H and N antigens currently circulating (☞ Sections 28.2 and 28.11). Developments of a universal influenza vaccine that targets a common influenza virus antigen, M1, has been proposed, as it should induce immunity to all influenza strains with a single vaccine. The immunogenicity and protection against influenza provided by M1 and other shared antigens are, however, unproven.

papillomavirus (HPV) is also a recombinant-antigen vaccine made in yeast cells.

DNA Vaccines

A novel method for immunization is based on expression of cloned genes in host cells. *DNA vaccines* are bacterial plasmids that contain cloned DNA with the antigen of interest. Typically, the vaccine is injected intramuscularly into a host animal. Once the plasmid is taken up by host cells, the DNA is transcribed and translated to produce immunogenic proteins, triggering a conventional immune response including Tc cells, Th1 cells, and antibodies directed to the protein encoded by the cloned DNA.

DNA vaccine strategies provide considerable advantages over conventional immunization methods. For instance, because only a single pathogen gene is cloned into the plasmid and injected,

there is no chance of an infection as there might be with an attenuated vaccine. Genes for individual antigens such as a tumor-specific antigen can be cloned, targeting the immune response to a particular cell component. A single bioengineered plasmid encoding an antigen can be used to infect host cells and elicit a complete immune response, inducing both immune T cells and antibodies. In at least one case, an experimental DNA vaccine consisting of an engineered peptide–MHC I complex protected mice from infection with a cancer-producing papillomavirus.

III • Immune Diseases

Immune reactions can cause host cell damage and disease. **Hypersensitivity** is an inappropriate immune response that results in host damage. Hypersensitivity diseases are categorized according to the antigens and the mechanisms that produce disease. Here we discuss these diseases, and ones produced by superantigen proteins produced by certain bacteria and viruses. Superantigens cause host damage by activating massive immune inflammatory responses.

24.8 Allergy, Hypersensitivity, and Autoimmunity

Antibody-mediated **immediate hypersensitivity** is commonly called *allergy*. Cell-mediated hypersensitivities also cause allergy-like diseases but, because of the delayed onset of symptoms, cell-mediated reactions are termed **delayed-type hypersensitivity (DTH)**. **Autoimmunity** is a harmful immune reaction directed against self antigens. These diseases are categorized as type I, II, III, or IV hypersensitivities based on immune effectors, antigens, and symptoms (Table 24.5).

Immediate Hypersensitivity

Immediate hypersensitivity, or type I hypersensitivity, is caused by the release of vasoactive products from mast cells coated with IgE (Figure 24.17). Immediate hypersensitivity reactions occur within minutes after exposure to an *allergen*, the antigen that caused the type I hypersensitivity. Depending on the individual and the allergen, immediate hypersensitivity reactions can be very mild or can cause a life-threatening reaction called *anaphylaxis*.

About 20% of the population suffers from immediate hypersensitivity allergies to pollens, molds, animal dander, certain foods (strawberries, nuts, and shellfish), insect venoms, mites in house dust, and other agents. Most allergens enter the body at the surface of mucous membranes such as the lungs or the gut. Initial exposure to allergens stimulates mucosa-associated Th2 cells to produce cytokines that induce B cells to make IgE antibodies. Rather than circulating like IgG or IgM, the allergen-specific IgE antibodies bind to IgE receptors on mast cells (Figure 24.17). Mast cells are nonmotile granulocytes (Section 24.1) associated with the connective tissue adjacent to capillaries throughout the body. With any subsequent exposure to the immunizing allergen, the mast cell-bound IgE molecules bind the antigen. Cross-linking of IgEs by an antigen triggers the release of soluble allergic mediators from the mast cells, a process called *degranulation*. These mediators cause allergic symptoms within minutes of antigen exposure. After initial sensitization by an allergen, the allergic individual responds to each subsequent reexposure to the allergen.

The principal chemical mediators released from mast cells are histamine and serotonin, modified amino acids that cause rapid dilation of blood vessels and contraction of smooth muscle, initiating symptoms ranging from mild local discomfort to systemic *anaphylactic shock*. Local symptoms typically include mucus production; rash; sneezing; itchy, watery eyes; and hives (Figure 24.18). Anaphylactic shock symptoms may include vasodilation (causing a sharp drop in blood pressure) and asthma due to smooth muscle constriction in the lungs. Severe anaphylaxis is treated immediately with epinephrine to counter smooth muscle contraction, increase blood pressure, and promote breathing. Less serious allergic symptoms can be treated

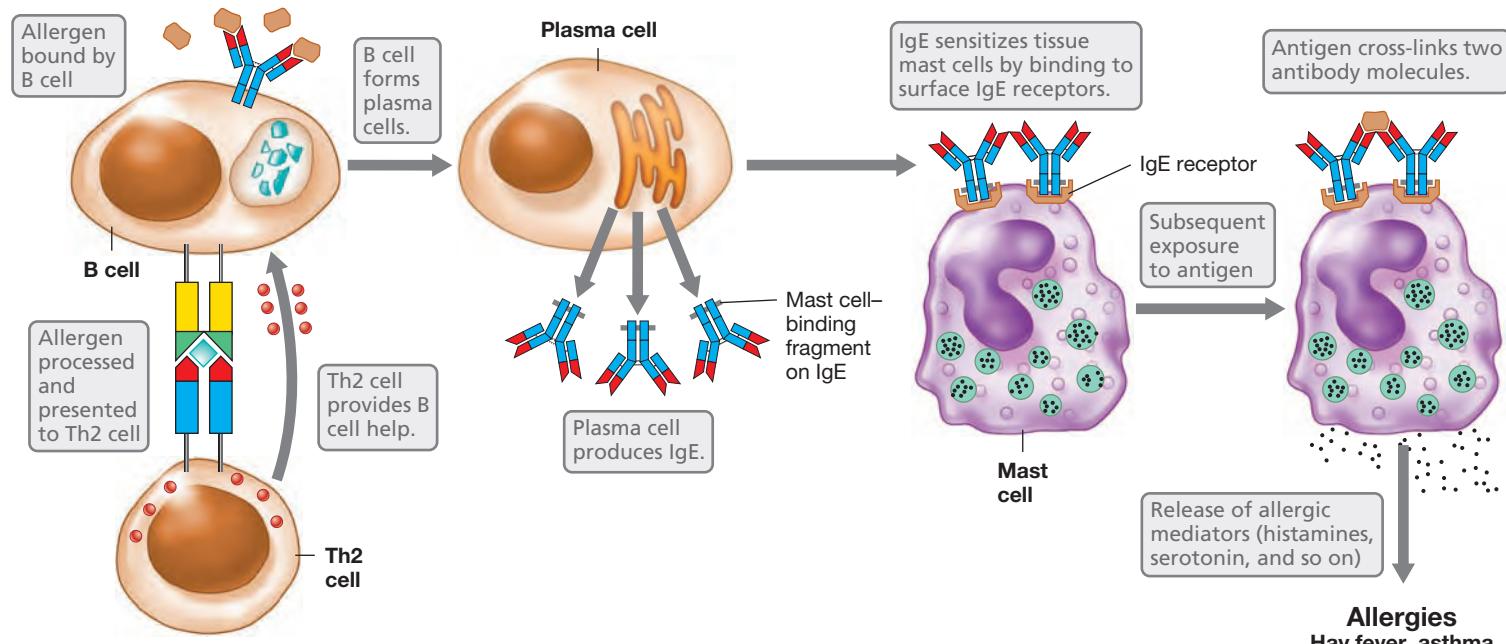

Figure 24.17 **Immediate hypersensitivity.** Certain antigens such as pollens stimulate IgE production. IgE binds to mast cells by means of a high-affinity surface receptor and arms the mast cell. Antigen cross-links surface IgE, causing release of soluble mediators such as histamine. These mediators produce symptoms ranging from mild allergic symptoms to life-threatening anaphylaxis.

with *antihistamines*, drugs that neutralize histamine. Treatment for symptoms may also include anti-inflammatory steroids. Finally, immunization with increasing doses of the allergen may shift antibody production from IgE to IgG and IgA. The IgG and IgA interact with the allergens, blocking binding to the IgE on sensitized mast cells, thus stopping allergic symptoms and inhibiting production of more IgE. This procedure is called *desensitization*.

Delayed-Type Hypersensitivity

Delayed-type hypersensitivity (DTH), or type IV hypersensitivity, is cell-mediated hypersensitivity characterized by tissue damage due to inflammation produced by Th1 cells (Table 24.5). Delayed-type hypersensitivity symptoms appear several hours after secondary exposure to the eliciting antigen, with a maximal response usually occurring in 24 to 48 hours. Typical DTH antigens include chemicals that are not normally antigens but become so when they covalently bind to skin proteins, which can create new antigens and elicit a DTH response. Hypersensitivity to these newly created antigens is known as *contact dermatitis* and results in, for example, skin reactions to poison ivy (Figure 24.19), jewelry, cosmetics, latex, and other chemicals that react with host tissues. Several hours after a second or subsequent exposure to the antigen,

the skin feels itchy at the site of contact. Reddening and swelling appear, often with localized tissue destruction in the form of blistering, and reach a maximum in several days. The delayed onset and the progress of the inflammatory response are the hallmarks of the DTH reaction. As discussed below, certain self antigens may also elicit DTH responses, resulting in autoimmune disease.

Another example of delayed-type hypersensitivity is the development of protective immunity to the causal agent of tuberculosis, *Mycobacterium tuberculosis* (► Section 29.4). This cellular immune response was discovered by Robert Koch during his classic studies on tuberculosis (► Section 1.8). When antigens derived from the bacterium are injected subcutaneously into a person previously infected with *M. tuberculosis*, a skin reaction called the *tuberculin reaction* develops. A positive tuberculin reaction develops fully after 24–48 hours (Figure 24.6), in contrast to IgE-mediated immediate hypersensitivity that develops within minutes after antigen exposure. Th1 cells stimulated by the mycobacterial antigens release cytokines in the region of the introduced antigen that attract and activate large numbers of macrophages, which in turn produce a characteristic local inflammation, including induration, edema, erythema, pain, and heating of the skin. The activated macrophages then ingest and destroy the invading antigen. The DTH-based tuberculin skin test

determines current or previous infection with *M. tuberculosis* or immunization with the BCG-attenuated tuberculosis vaccine.

A number of other infectious diseases due to intracellular pathogens elicit DTH reactions. These include bacterial diseases such as leprosy, brucellosis, psittacosis; viral diseases such as mumps; and fungal diseases such as coccidioidomycosis, histoplasmosis, and blastomycosis. Visible antigen-specific skin responses resembling the tuberculin reaction occur after injection of antigens derived from the pathogens, indicating pathogen exposure and Th1-mediated immunity.

Autoimmunity

As lymphocytes develop, T and B cells that can react with self antigens are normally eliminated. Autoimmune diseases result when these cells are instead activated to produce immune reactions against self proteins (Table 24.6). For example, Th1-mediated DTH can cause autoimmune responses directed against self antigens, as in the case of the Th1-mediated response to brain-derived antigens in allergic encephalitis. In type 1 (juvenile) diabetes mellitus, Th1 cells directed to antigens on pancreatic cells cause reactions that destroy the insulin-producing beta cells in the pancreas. Many autoimmune diseases, however, are caused by **autoantibodies**, antibodies that interact with self antigens.

In many cases, autoantibodies interact with organ-specific antigens. For example, in *Hashimoto's disease*, autoantibodies are made against thyroglobulin, a product of the thyroid gland. In this case, antibodies to thyroglobulin bind complement proteins, leading to local inflammation and destruction of the thyroid cells and function, the hallmarks of a type II hypersensitivity disease (Table 24.6).

Systemic lupus erythematosus (SLE) is an example of a disease caused by type III hypersensitivity. This disease and others like it are caused by autoantibodies directed against soluble, circulating self antigens. In SLE, the antigens include nucleoproteins and DNA. Antibodies bind to soluble proteins, producing insoluble immune complexes. Disease results when circulating antigen–antibody complexes deposit in different body tissues such as the kidney,

lungs, and spleen. Here the antibodies bind complement, resulting in inflammation and local, often severe, cell damage. Thus, type III hypersensitivity is an immune complex disorder (Table 24.5).

Organ-specific autoimmune diseases are sometimes more easily controlled clinically than diseases that affect multiple organs. For example, the product of organ function, such as thyroxine in autoimmune hypothyroidism or insulin in juvenile diabetes, can often be supplied in pure form from another source. SLE, rheumatoid arthritis, and other autoimmune diseases that affect multiple organs and sites can often be controlled only by general immunosuppressive therapy, such as the use of steroid drugs. General immunosuppression, however, significantly increases chances of opportunistic infections.

Heredity influences the incidence, type, and severity of autoimmune diseases. Many autoimmune diseases correlate strongly with the presence of certain MHC proteins (► Section 25.4). Studies of model autoimmune diseases in mice support such a genetic link, but the precise conditions necessary for developing autoimmunity may also depend on factors such as prior infections, gender, age, and health status. Women, for example, are about 20 times more likely to develop SLE than are men.

example, interact directly with many cell types, causing release of endogenous pyrogens and other soluble mediators and producing fever and general inflammation (Section 24.5). Most exotoxins also interact directly with cells to cause cell damage. However, certain exotoxins, the superantigens, act indirectly on host cells, subverting the immune system so that T cells and their cytokine products extensively damage host cells (**Figure 24.20**).

Superantigens are proteins capable of eliciting a very strong response because they activate more T cells than a normal immune response. Superantigens interact directly with TCRs and MHC proteins (**Figure 24.21**). They are produced by many viruses and bacteria. Streptococci and staphylococci, for example, produce several different and very potent superantigens (☞ Sections 29.2 and 29.9).

Superantigen interaction with TCRs differs from the conventional antigen–TCR binding shown in Figure 24.5. Conventional foreign antigens, presented by an MHC protein, bind to a TCR at a defined antigen-binding site. However, superantigens bind to a site on the TCR that is outside the antigen-specific TCR binding site. A superantigen binds to all TCRs with a shared common structure, and many different TCRs share the same structure outside the antigen-binding site. In some cases, superantigens can bind 5–25% of all T cells, whereas less than 0.01% of all available T cells interact with a conventional foreign antigen in a typical immune response. Superantigens also bind MHC II on APCs, again at a

BIG IDEAS

24.1 • Cells involved in innate and adaptive immunity originate from bone-marrow stem cells. The blood and lymph systems circulate cells and proteins that are important components of the immune response. Several different leukocytes participate in immune responses in all parts of the body.

site outside the normal peptide-binding site. These interactions mimic conventional antigen presentation and stimulate large numbers of T cells to grow and divide. As in normal responses, the activated T cells produce cytokines that stimulate other cells, such as macrophages and other phagocytes. The extensive cytokine production by the large proportion of superantigen-activated T cells triggers a widespread cell-mediated response characterized by systemic inflammatory reactions. The resulting fever, diarrhea, vomiting, mucus production, and even systemic shock may be fatal in extreme cases. Clinically, superantigen shock is indistinguishable from septic shock (Section 24.5).

A very common superantigen disease is *Staphylococcus aureus* food poisoning, characterized by fever, vomiting, and diarrhea, and caused by one of several superantigen staphylococcal enterotoxins. *S. aureus* also produces the superantigen responsible for *toxic shock syndrome* (Figure 24.20). *Streptococcus pyogenes* produces erythrogenic toxin, the superantigen responsible for scarlet fever (☞ Section 29.2).

- Identify the binding site for superantigens on T cells and APCs.

24.2 • Innate immunity is a natural protective response to infection characterized by recognition of common pathogen-associated molecular patterns on pathogens. Phagocytes recognize these patterns through preformed pathogen recognition receptors, and the recognition and

interaction process stimulates phagocytes to destroy the pathogens.

24.3 • Adaptive immunity is triggered by the specific interactions of T cells with antigens presented on APCs. Peptide antigens embedded in MHC proteins are presented to T cells. Tc cells kill antigen-bearing target cells directly. Th cells act through cytokines to promote immune reactions. Th1 cells initiate inflammation and immunity by activating macrophages.

24.4 • Th2 cells stimulate B cells that have been exposed to antigen to differentiate into plasma cells, which then produce antibodies. Antibodies are soluble, antigen-specific proteins that interact with antigens. Antibodies provide targets for interaction with proteins of the complement system, resulting in destruction of antigens through lysis or opsonization.

24.5 • Inflammation, characterized by pain, swelling (edema), redness (erythema), and heat, is a normal and generally desirable outcome due to activation of nonspecific immune response effectors. Uncontrolled systemic inflammation, called septic shock, can lead to serious illness and death.

24.6 • Adaptive immunity develops naturally and actively through immune responses to infections, or naturally and

passively through antibody transfer from the placenta or breast milk. The inability to generate an innate or adaptive immune response results in recurrent, uncontrollable infections. Artificial passive immunity occurs when antibodies or immune cells are transferred from an immune individual to a nonimmune individual. Immunization induces artificial active immunity and is widely used to prevent infectious diseases. Vaccines are either attenuated or inactivated pathogens or pathogen products or are genetically engineered antigens.

24.7 • Immunization strategies using bioengineered molecules eliminate exposure to microorganisms and, in some cases, even to protein antigen. Application of these strategies is providing safer vaccines targeted to individual pathogen antigens.

24.8 • Hypersensitivity is the induction by foreign antigens of antibody-mediated or cell-mediated immune responses that damage host tissue. In autoimmunity, the immune response is directed against self antigens. Damage to host tissue is caused by the inflammation produced by immune mechanisms.

24.9 • Superantigens are components of certain bacterial and viral pathogens that bind and activate large numbers of T cells. Superantigen-activated T cells may produce diseases characterized by systemic inflammatory reactions.

REVIEW OF KEY TERMS

Adaptive immunity the acquired ability to recognize and destroy a particular pathogen or its products, dependent on previous exposure to the pathogen or its products; also called specific immunity and antigen-specific immunity

Antibody a soluble protein produced by B cells and plasma cells that interacts with antigen; also called immunoglobulin

Antigen a molecule that interacts with specific components of the immune system

Antigen-presenting cell (APC) a macrophage, dendritic cell, or B cell that takes up and processes antigen and presents it to T-helper cells

Autoantibody an antibody that reacts to self antigens

Autoimmunity a harmful immune reaction directed against self antigens

B cell a lymphocyte that has immunoglobulin surface receptors, produces immunoglobulin, and may present antigens to T cells

B cell receptor (BCR) a cell-surface antibody that acts as an antigen receptor on a B cell

Bone marrow the primary lymphoid organ containing the pluripotent precursor cells for all blood and immune cells

Chemokine a soluble protein that modulates an immune response

Clone a copy of an antigen-reactive lymphocyte

Cytokine a soluble protein produced by a leukocyte that modulates an immune response

Delayed-type hypersensitivity (DTH) an inflammatory allergic response mediated by Th1 lymphocytes

Dendritic cell a phagocytic antigen-presenting cell found in various body tissues; transports antigen to secondary lymphoid organs

Hypersensitivity an immune response leading to damage to host tissues

Immediate hypersensitivity an allergic response mediated by vasoactive products released from IgE-sensitized mast cells

Immunity the ability of an organism to resist infection

Immunoglobulin (Ig) a soluble protein produced by B cells and plasma cells that interacts with antigen; also called antibody

Inflammation a nonspecific reaction to noxious stimuli such as toxins and pathogens, characterized by redness (erythema), swelling (edema), pain, and heat (fever), usually localized at the site of infection

Innate immunity the noninducible ability to recognize and destroy an individual pathogen or its products that does not rely on previous exposure to a pathogen or its products; also called nonspecific immunity

Leukocyte a nucleated cell in blood; also called a white blood cell

Lymph a fluid that circulates through the lymphatic system; like blood but lacking red blood cells

Lymph nodes organs that contain lymphocytes and phagocytes arranged to encounter microorganisms and antigens as they travel through the lymphatic circulation

Lymphocytes a subset of nucleated cells in blood involved in the adaptive immune response

Macrophage a large leukocyte found in tissues that has phagocytic and antigen-presenting capabilities

Major histocompatibility complex (MHC) a genetic region that encodes several proteins important for antigen processing and presentation. MHC I proteins are expressed on all cells. MHC II proteins are expressed only on antigen-presenting cells

Memory (immune memory) the ability to rapidly produce large quantities of specific immune cells or antibodies after subsequent exposure to a previously encountered antigen

Mucosa-associated lymphoid tissue (MALT) a part of the lymphatic system that interacts with antigens and microorganisms that enter the body through mucous membranes, including those of the gut, the genitourinary tract, and bronchial tissues

Neutrophil a leukocyte exhibiting phagocytic properties, a granular cytoplasm (granulocyte), and a multilobed nucleus; also called polymorphonuclear leukocyte or PMN

Pathogen-associated molecular pattern (PAMP) a repeating structural component of a microorganism or virus recognized by a pattern recognition receptor (PRR)

Pattern recognition receptor (PRR) a protein in a phagocyte membrane that recognizes

a pathogen-associated molecular pattern (PAMP)

Phagocyte a cell that engulfs foreign particles, and can ingest, kill, and digest most pathogens

Plasma the liquid portion of the blood containing proteins and other solutes

Plasma cell a differentiated B cell that produces soluble antibodies

Primary adaptive immune response the production of antibodies or immune T cells on first exposure to antigen; the antibodies are mostly of the IgM class

Primary lymphoid organ an organ in which antigen-reactive lymphocytes develop and become functional; the bone marrow is the primary lymphoid organ for B cells; the thymus is the primary lymphoid organ for T cells

Secondary adaptive immune response the enhanced production of antibodies or immune T cells on second and subsequent exposures to antigen; the antibodies are mostly of the IgG class

Secondary lymphoid organ an organ at which antigens interact with antigen-presenting phagocytes and lymphocytes to generate an adaptive immune response; these include lymph nodes, spleen, and mucosa-associated lymphoid tissue

Serum the liquid portion of the blood with clotting proteins removed

Specificity the ability of the immune response to interact with particular antigens

Stem cell a progenitor cell that can develop into other cell types

Superantigen a pathogen product capable of eliciting an inappropriately strong inflammatory immune response by stimulating greater than normal numbers of T cells

T cell a lymphocyte that interacts with antigens through a T cell receptor for antigen; T cells are divided into functional subsets including Tc (T-cytotoxic) cells and Th (T-helper) cells. Th cells are further subdivided into Th1 (inflammatory) cells and Th2 cells, which aid B cells in antibody formation

T cell receptor (TCR) an antigen-specific receptor protein on the surface of T cells

Thymus the primary lymphoid organ in which T cells develop

Tolerance the acquired inability to produce an immune response to particular antigens

Toxoid a form of a toxin that retains antigenicity but has lost toxicity

Vaccination (immunization) the inoculation of a host with inactive or weakened pathogens or pathogen products to stimulate protective active immunity

Vaccine an inactivated or attenuated pathogen, or a harmless pathogen product used to induce artificial active immunity

REVIEW QUESTIONS

- What is the origin of the phagocytes and lymphocytes active in the immune response? Track the maturation of B cells and T cells. (Section 24.1)
- Identify the cells that express pattern recognition receptors (PRRs). How do PRRs associate with pathogen-associated molecular patterns (PAMPs) to promote innate immunity? (Section 24.2)
- Identify the lymphocytes and the antigen-specific receptors involved in cell-mediated adaptive immunity. (Section 24.3)
- Identify the lymphocytes and the antigen-specific receptors involved in antibody-mediated adaptive immunity. (Section 24.4)
- Identify the cells that initiate inflammation and the cells that are activated by inflammatory signals. (Section 24.5)
- List the immunizations recommended for adults in the United States. (Section 24.6)
- List the diseases for which you have been immunized. List the diseases for which you may have acquired immunity naturally. (Sections 24.6 and 24.7)
- The acellular pertussis vaccine uses a biotechnology-based immunization strategy that has been adapted for this approved vaccine. What advantages does the biotechnology-based vaccine have over a conventional vaccine? What disadvantages, if any? (Section 24.7)
- Define the differences between immediate and delayed-type hypersensitivity in terms of immune effectors, target tissues, antigens, and clinical outcome. (Section 24.8)
- Describe the general mechanism used by superantigens to activate T cells. How does superantigen activation differ from T cell activation by conventional antigens? (Section 24.9)

APPLICATION QUESTIONS

- Describe the relative importance of innate immunity compared to adaptive immunity. Is one more important than the other? Can we survive in a normal environment without immunity?
- Inflammation is the hallmark of an active immune response. Explain how inflammation is triggered by both innate and adaptive immune mechanisms. Are the inflammatory cells the same for both methods of activation? Why does inflammation subside as an infection is controlled?
- Many infectious diseases have no effective vaccines. Pick several of these diseases (for example, AIDS, malaria, the common cold) and explain why current vaccine strategies have not been effective. Prepare some alternate strategies for immunization against the diseases you have chosen.
- Are superantigen reactions desirable for the host? Do they confer protection for the host or do they benefit the pathogen?

Why Is Alum in Your Vaccine?

Alum is an insoluble aluminum salt that has been used for over 80 years in human vaccines. Alum is an *adjuvant*, a substance that enhances the immune response nonspecifically when administered with a vaccine. Alum is the only adjuvant that is approved for use in vaccines for humans. For example, the diphtheria–tetanus–acellular pertussis (DTaP) vaccine contains an alum adjuvant. How does alum work?

It is well known that vaccines administered without alum are ineffective and that vaccine proteins (antigens) adsorb to the surface of alum particles. It is also known that without alum, few antigen-specific T helper cells are induced and the immune response is poor. The explanation was that alum increases the half-life of antigen in the body, thus extending exposure of the antigen to immune cells. But is this the whole story?

When a vaccine is injected intramuscularly (see photo), monocytes migrate to the injection site, causing inflammation. A research study¹ found that alum accumulates into nodules that are held together by host chromatin (including DNA) acquired from the inflammatory monocytes. Chromatin DNA and the adsorbed vaccine proteins move into the cytosol of antigen-presenting dendritic cells. From there, the host DNA activates pathways that increase the ability of dendritic cells to interact with antigen-specific T helper cells.

Alum thus works as an adjuvant not simply by prolonging the time antigen stays in the body, but also by enhancing DNA signaling. This in turn promotes more vigorous antigen presentation by dendritic cells and better stimulation of T helper cells. The final result is a stronger and more effective immune response.

We discussed the key features of innate and adaptive immunity in terms of protection against pathogen infection and disease in Chapter 24. Here we focus on the *mechanisms* by which

I • Basic Immune Mechanisms

Innate immunity is primarily a function of *phagocytes*. Innate responses recognize common structural features found on and in pathogens. Interactions with pathogens activate genes in the phagocytes that control the transcription, translation, and expression of proteins that destroy the pathogens. Innate immunity develops immediately when a phagocyte contacts a pathogen, but it is not always effective enough to prevent dangerous infections. However, certain phagocytes also activate adaptive immunity by passing antigens to receptors on lymphocytes. The lymphocytes are the effectors in *adaptive immunity*, the acquired ability to recognize and destroy a particular pathogen or its products. The antigen–receptor interaction activates the lymphocytes that produce pathogen-specific proteins—antibodies and T cell receptors—that are the agents of adaptive immunity. An adaptive response takes several days to develop because only a few pathogen-reactive lymphocytes are initially available; the strength of the adaptive response increases as the pathogen-reactive lymphocytes multiply. Cells that function in the innate and adaptive immune responses were described in Section 24.1.

25.1 Innate Response Mechanisms

Successful pathogens sometimes breach physical and chemical host barriers, leading to host infection. The immune system is then mobilized to protect the host from further damage. Innate immunity is the first line of defense when infection starts and is critical for host protection for about four days after an infection begins. Phagocytes engulf and destroy pathogens, often initiating complex host-mediated inflammatory reactions (Figure 24.5).

Phagocytes

The first cell type active in the innate response is typically a *phagocyte* (literally, a cell that eats). The primary function of a phagocyte is to engulf and destroy pathogens. A secondary function is to process the pathogen for antigens that initiate the adaptive immune response.

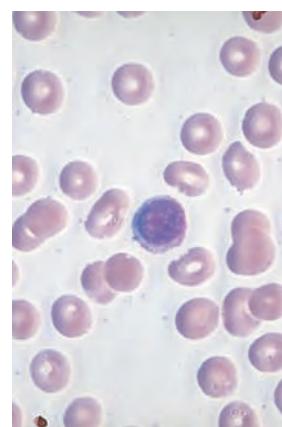

Phagocytes include monocytes, neutrophils, macrophages, and dendritic cells (Figure 25.1). Found in tissues and fluids throughout the body, most have inclusions called *lysosomes*, intracellular vacuoles containing bacteriocidal substances such as hydrogen peroxide, lysozyme, proteases, phosphatases, nucleases, and lipases. Phagocytes trap pathogens on surfaces such as blood vessel walls or fibrin clots. The membrane surrounding the pathogen pinches off and forms a *phagosome*. The phagosome, a vacuole containing the engulfed pathogen, then moves into the cytoplasm and fuses with a lysosome to form a *phagolysosome*. The toxic substances and enzymes inside the phagolysosome usually kill and digest the engulfed microbial cell (Figure 25.2).

The *neutrophil* is an actively motile phagocyte that contains lysosomes (Figure 25.1a). Derived from myeloid stem cells (Figure 24.1), neutrophils are found predominantly in the bloodstream and bone marrow, from where they migrate to sites of active infection in tissues. Neutrophils present in higher than normal numbers in the blood, a condition called *neutrophilia*, or at a site of inflammation indicate an active response to a current infection.

Monocytes are circulating precursors of *macrophages*, a major phagocytic cell type (Figure 25.1a). Macrophages are large noncirculating phagocytic cells found in almost all tissues (Figure 25.1b),

where they may constitute up to 10–15% of the total cells. Because they ingest and destroy most pathogens and foreign molecules that invade the body, macrophages are essential to the innate response. They are also critically important for initiating adaptive immunity by presenting antigens to T lymphocytes.

Dendritic cells (Figure 25.1c) also have the dual function of phagocytosis and antigen presentation. Derived from the same monocyte progenitors as macrophages, immature dendritic cells are found throughout the body tissues, where they function as active phagocytes. When the dendritic cells ingest antigen, they migrate to the lymph nodes, where they present antigen to T lymphocytes. The specialized antigen-presenting properties of macrophages and dendritic cells are examined in Section 25.4.

Pathogen Recognition by Phagocytes

Phagocytes have a pathogen-recognition system that triggers a timely and appropriate response, generally leading to recognition, containment, and destruction of the pathogen. This system employs evolutionarily conserved *pattern recognition receptors* (PRRs). PRRs are membrane-bound phagocyte proteins that recognize a *pathogen-associated molecular pattern* (PAMP), a structural component on a microbial cell or virus (► Figure 24.3). PRRs were first observed in phagocytes in *Drosophila*, the fruit fly, where they are called *Toll receptors*. Each **Toll-like receptor** (TLR) on a human phagocyte recognizes a specific PAMP. For example, TLR-2, a PRR on human phagocytes, interacts with peptidoglycan, a PAMP present in the cell wall of nearly all bacteria (► Section 2.10); the interaction activates the phagocytes, targeting gram-positive pathogens with exposed peptidoglycan (Figure 25.3). Access to the peptidoglycan of gram-negative

cell walls is blocked by the surface lipopolysaccharides. Other TLRs recognize PAMPs such as the unmethylated CpG oligonucleotides, the lipopolysaccharide of gram-negative bacteria, or the double-stranded RNA of certain viruses. Several soluble host molecules function similarly to these phagocyte-associated PRRs. Later in this chapter we discuss the soluble PRRs in the

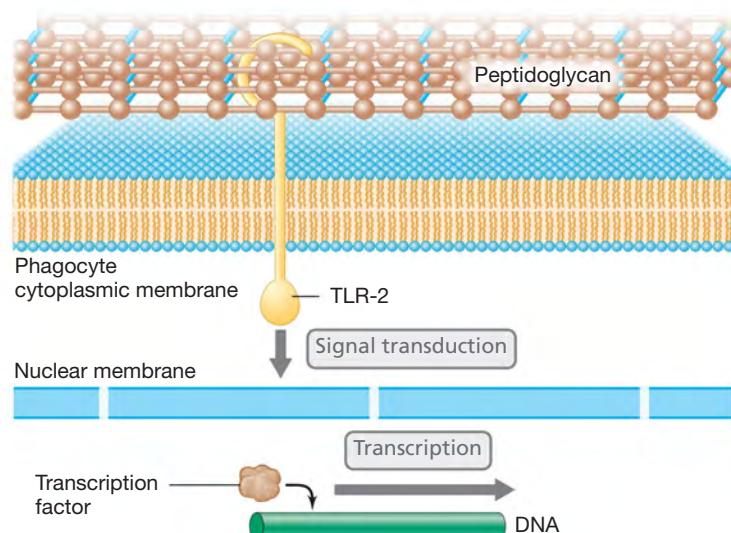

Figure 25.3 A Toll-like receptor. Membrane-spanning TLR-2 interacts with peptidoglycan from gram-positive pathogens. This interaction stimulates signal transduction, activating transcription factors in the nucleus. The result is translation of proteins that induce inflammation and other phagocyte activities. All Toll-like receptors have analogous mechanisms for activating innate immunity.

context of their ability to activate proteins that enhance phagocytosis and destruction of pathogens (Section 25.9). The PAMP-PRR interaction triggers a transmembrane signal that results in production of important defense proteins, including some that produce toxic oxygen compounds that can cause pathogen death.

Oxygen-Dependent Killing in Phagocytes

Genes that control the production of oxygen compounds toxic to pathogens are highly transcribed in activated phagocytes. These toxic compounds include hydrogen peroxide (H_2O_2), superoxide anions (O_2^-), hydroxyl radicals ($OH \cdot$), singlet oxygen (1O_2), hypochlorous acid (HOCl), and nitric oxide (NO) (Figure 25.4) (Section 5.16). The acidic conditions in the phagolysosome favor the production of these highly reactive compounds. Phagocytic cells use toxic oxygen compounds to kill ingested bacterial cells by oxidizing key cellular constituents. The reactions occur within the phagocyte, which is not damaged by the toxic oxygen products.

Inhibiting Phagocytes

Some pathogens have developed mechanisms for neutralizing toxic phagocyte products, for killing the phagocytes, or for avoiding phagocytosis. For example, *Staphylococcus aureus* produces pigmented compounds called carotenoids that neutralize singlet oxygen and prevent killing (Section 29.9). Intracellular pathogens such as *Mycobacterium tuberculosis* (the cause of tuberculosis) grow and persist within phagocytic cells (Section 29.4). *M. tuberculosis* uses its cell wall glycolipids to absorb hydroxyl

radicals and superoxide anions, the most lethal toxic oxygen species produced by phagocytes.

Some intracellular pathogens produce phagocyte-killing proteins called *leukocidins*. In such cases, the pathogen is ingested as usual, but the leukocidin kills the phagocyte, releasing the pathogen. Dead phagocytes make up much of the material of *pus*; organisms such as *Streptococcus pyogenes* and *S. aureus*, major leukocidin producers, are called *pyogenic* (pus-forming) pathogens. Localized infections by pyogenic bacteria can form boils or abscesses.

Another important pathogen defense against phagocytosis is the bacterial capsule (Section 2.13). Encapsulated bacteria are often highly resistant to phagocytosis because the capsule prevents adherence of the phagocyte to the bacterial cell. For example, fewer than ten cells of an encapsulated strain of *Streptococcus pneumoniae* can kill a mouse within a few days after exposure (Figure 23.10). Nonencapsulated strains are completely avirulent. Surface components other than capsules can also inhibit phagocytosis. For instance, pathogenic *S. pyogenes* produces M protein, a substance that alters the surface of the pathogen and inhibits phagocytosis.

Antibodies or soluble PRRs that interact with capsules or other cell surface molecules can reverse the protective effect of bacterial defense mechanisms and enhance phagocytosis, the process of opsonization. As an example, the effective vaccine directed against *Streptococcus pneumoniae*, an organism that causes serious bacterial pneumonia, uses capsule polysaccharides to induce protective antibodies (Section 24.7).

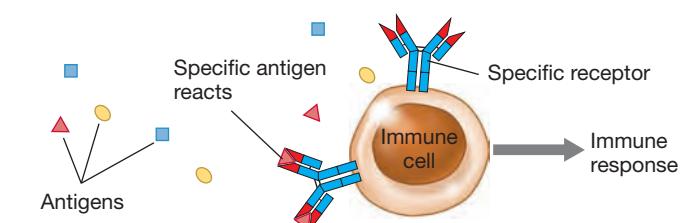

Figure 25.4 These compounds include hydrogen peroxide (H_2O_2), the hydroxyl radical ($OH \cdot$), hypochlorous acid (HOCl), the superoxide anion (O_2^-), singlet oxygen (1O_2), and nitric oxide (NO). Formation of these toxic compounds requires a substantial increase in the uptake and utilization of molecular oxygen, O_2 . This increase in oxygen uptake and consumption by activated phagocytes is known as the respiratory burst.

25.2 Adaptive Response Properties

Adaptive immunity is the acquired ability to recognize and destroy a particular pathogen or its products. In contrast to innate immunity, effective adaptive immunity requires activation by pathogen exposure. B lymphocytes produce antibodies, which protect against extracellular antigens. T lymphocytes, through their antigen-specific T cell receptor (TCR), protect against intracellular pathogens such as viruses and certain bacteria. Adaptive immunity is characterized by the properties of *specificity*, *memory*, and *tolerance*. None of these properties is found in the innate response.

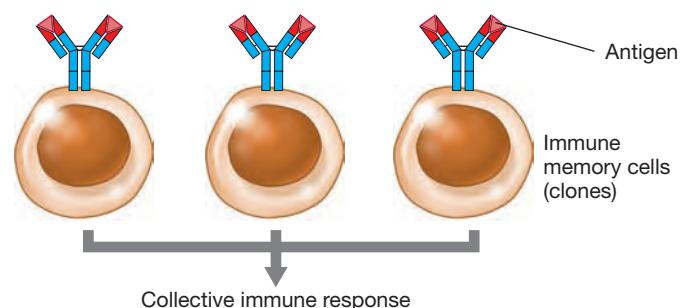

Specificity

The immune response is incredibly specific, but the innate and the adaptive systems differ in this regard. Innate immunity is directed against features common to pathogens such as the peptidoglycan of all gram-positive bacteria or the lipopolysaccharide of all gram-negative bacteria. By contrast, adaptive immunity is directed to interactions with particular pathogen-specific macromolecules such as the M-protein antigen on a

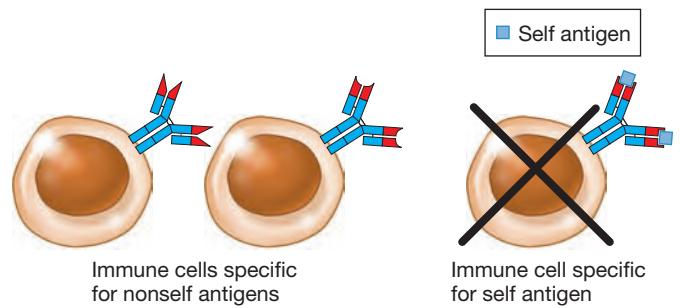

Specificity: Immune cells have surface receptors that interact with individual antigens.

(a)

Memory: The first antigen exposure induces multiplication of antigen-reactive cells, resulting in multiple copies, or *clones*. After a subsequent exposure to the same antigen, the immune response is faster and stronger due to the large number of responding cells.

(b)

Tolerance: Immune cells are not able to react with self antigen. Self-reactive cells are destroyed during development of the immune response.

(c)

Figure 25.5 The adaptive immune response. Key features of antibody-mediated and cell-mediated immunity are (a) specificity, (b) memory, and (c) tolerance.

II • Antigens and Antigen Presentation

The adaptive immune response recognizes a broad range of pathogen-derived macromolecules. The macromolecules are degraded and processed in host cells to produce antigens that are in turn presented to T cells. We first discuss antigens and then focus on the mechanisms of antigen processing and presentation to T cells.

25.3 Immunogens and Antigens

Antigens are substances that react with antibodies or TCRs. Most, but not all, antigens are **immunogens**, substances that induce an immune response. Here we examine the features of

single strain of *Streptococcus pyogenes* (► Section 29.2). The *specificity* of the antigen–antibody or antigen–TCR interaction is dependent on the capacity of the lymphocyte cell receptor to interact with particular antigens. Thus, in contrast to the innate system, the adaptive immune response, triggered by antigen contact, is exclusively and specifically directed to the unique antigen (Figure 25.5a).

Memory and Tolerance

The immune system must encounter antigen to stimulate production of detectable and effective antigen-activated antibodies or TCRs. A subsequent exposure to the same antigen stimulates rapid production of large quantities of the same T cells or antibodies. This capacity to respond more quickly and vigorously to subsequent exposures to the eliciting antigen is *immune memory* (Figure 25.5b). Immune memory provides the host with immediate resistance to previously encountered pathogens. Clinical medicine takes advantage of immune memory by vaccinating susceptible individuals with dead or weakened pathogens or their products to artificially stimulate and enhance immunity for a number of dangerous pathogens (► Section 24.7).

Besides the important aspects of specificity and memory, *tolerance* is important to the immune system and is defined as the acquired *inability* to make an adaptive immune response directed to *self* antigens. Because macromolecules in the host are also antigens, the host immune system must avoid recognizing host macromolecules as they could be damaged if they were recognized as antigens by antibodies or T cells. Thus, the adaptive immune response must develop the capacity to discriminate between *foreign* (nonself and dangerous) antigens and *host* (self and not dangerous) antigens (Figure 25.5c).

effective immunogens and then define the features of antigens that promote interactions with antibodies and TCRs.

Intrinsic Properties of Immunogens

Immunogens share several intrinsic properties that enable them to induce an adaptive immune response. First, *molecular size* is an important property of immunogenicity; for a molecule to be immunogenic, it must be sufficiently large. For example, low-molecular-weight compounds called *hapto*ns cannot induce an immune response but can be bound by antibodies. However, because hapto ns are bound by antibodies, they are antigens even though they are

Table 25.1 Properties of immunogens

not immunogens. Haptens such as sugars, amino acids, and other low-molecular-weight organic compounds become effective immunogens only when they are coupled to a larger protein, generally with a molecular weight of 10,000 or greater. Thus, sufficient molecular size is a prerequisite for immunogenicity; this property and the other key properties discussed next are summarized in **Table 25.1**.

Complex, nonrepeating polymers such as proteins are effective immunogens. Complex carbohydrates can also be very good immunogens. In contrast, nucleic acids, simple polysaccharides with repeating subunits, and lipids, because they are composed of chains of identical or nearly identical monomers, tend to be poor immunogens. Thus, *sufficient molecular complexity* is another property of immunogenicity.

Large, complex macromolecules in insoluble or aggregated form (for example, proteins precipitated by heating) are usually excellent immunogens. The insoluble material is readily taken up by a phagocyte, leading to an adaptive immune response. By contrast, the soluble form of the same molecule may be a very poor immunogen because the soluble molecule is not ingested efficiently by phagocytes. Thus, *appropriate physical form* is another property of immunogenicity.

Extrinsic Properties of Immunogens

Although many substances are intrinsically immunogenic, extrinsic factors also influence immunogenicity. Three extrinsic factors important for immunogens include the *dose*, the *route* of administration, and the *foreign nature* of the immunogen to the host.

The dose of an immunogen administered to a host can be important for an effective immune response, but a broad range of doses ordinarily provides satisfactory immunity. In general, doses of 10 µg to 1 g are effective in most mammals. Doses of immunogen higher than 1 g or lower than 10 µg may not stimulate an immune response but may actually suppress a specific immune response and instead induce tolerance.

The route of administration of an immunogen is also important. Immunizations given by parenteral (outside of the gastrointestinal tract) routes, usually by injection, are normally more effective than those given topically or orally. When given by oral or topical routes, antigens may be significantly degraded before contacting a phagocyte.

Finally, an effective immunogen must be foreign with respect to the host. The adaptive immune system recognizes and eliminates only foreign antigens. Self antigens are not recognized because individuals are tolerant of their own molecules (Section 25.2).

Antigen Binding by Antibodies and T Cell Receptors

The antibody or TCR does not interact with the antigenic macromolecule as a whole but only with a distinct portion of the molecule called an antigenic **epitope** (Figure 25.6). Epitopes include sugars, short peptides, and other organic molecules.

Antibodies interact with a sequence of four to six amino acids, the optimal size for an epitope. Thus proteins, many of which consist of hundreds or even thousands of amino acids, are arrays of overlapping epitopes. The surface of a bacterial cell or virus consists of a mosaic of proteins, polysaccharides, and other macromolecules, all with individual epitopes. In many cases, antibodies recognize *conformational epitopes* composed of, for example, amino acids from two portions of the molecule that are distant in terms of their primary structure but are brought together by folding into the secondary, tertiary, or quaternary structures of a macromolecule.

TCRs recognize protein epitopes only after the immunogens have been partially degraded, or *processed*. Antigen processing destroys the conformational structure of a macromolecule, breaking proteins into peptides less than 20 amino acids long. As a result, TCRs recognize only *linear epitopes* in the primary protein structure. Processed antigens are presented to T cells on the surface of specialized APCs or target cells, as we will discuss in Section 25.4.

Antibodies, on the other hand, can recognize conformational epitopes on proteins or polysaccharides expressed in native conformations on macromolecular surfaces. In addition, antibodies recognize linear epitopes.

Antibodies and TCRs can distinguish between closely related epitopes. For example, antibodies can distinguish between glucose and galactose sugars, which differ only in the orientation of a single hydroxyl group. However, specificity is not absolute, and an individual antibody or TCR may react to some extent with several different but structurally similar epitopes. The antigen that induced the antibody or TCR is called the *homologous antigen*, and any noninducing antigens that react with the antibody are called *heterologous antigens*. An interaction between an antibody or TCR and a heterologous antigen is called a *cross-reaction*.

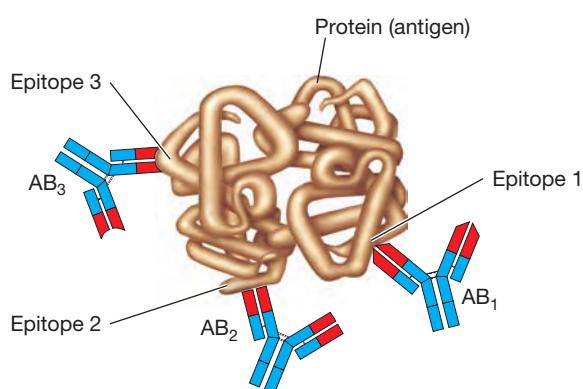

Figure 25.6 Antigens and epitopes for antibodies. Antigens may contain several different epitopes, each capable of reacting with a different antibody (AB). The epitope 1 recognized by AB₁ is a conformational epitope. Epitope 1 consists of two nonlinear parts of the folded polypeptide; the folding brings two distant portions of the polypeptide together to make a single epitope.

25.4 Antigen Presentation to T Cells

T cells are thymus-derived lymphocytes that interact with antigens and activate the adaptive immune response through TCRs (☞ Section 24.3). Here we examine how the TCR interacts with antigens on an antigen-presenting phagocytic cell or on an infected target cell.

The T Cell Receptor

The TCR is a membrane-spanning protein that extends from the T cell surface into the extracellular environment. Each T cell has thousands of copies of the same TCR on its surface. A functional TCR consists of two polypeptides, an α chain and a β chain. Each polypeptide consists of several **domains**, regions of the protein that have defined structural and functional properties. Each chain has a variable (V) domain and a constant (C) domain (Figure 25.7). The V_α and V_β domains interact cooperatively to form an antigen-binding site. As we will see in Section 26.7, the adaptive immune response can generate TCRs that will bind nearly every known peptide antigen. TCRs recognize only MHC-peptide; other antigens, such as complex polysaccharides, are not recognized by TCRs, but these may be bound by the immunoglobulin receptors on B cells. TCRs recognize and bind a peptide antigen only when it is bound to a *self* protein, the major histocompatibility complex protein.

Major Histocompatibility Complex Proteins

A linked set of genes called the *major histocompatibility complex* (MHC) is found in all vertebrates. The MHC encodes a group of proteins important in antigen presentation. The MHC proteins in humans, called *human leukocyte antigens* or *HLAs*, were first identified as the major antigens responsible for immune-mediated organ transplant rejection. We now know that MHC proteins function primarily as

antigen-presenting molecules, binding pathogen-derived peptides and displaying these peptides for interaction with TCRs.

There are two classes of MHC proteins called class I and class II. **MHC class I proteins** are found on the surfaces of all nucleated cells. **MHC class II proteins** are found only on the surface of B lymphocytes, macrophages, and dendritic cells, all of which are APCs. This differential cellular distribution relates to the functions of the class I and class II proteins.

An MHC class I protein consists of two polypeptides, a membrane-embedded alpha chain encoded in the MHC gene region and a smaller protein called *beta-2 microglobulin* (β_2m) encoded by a non-MHC gene (Figure 25.8a). An MHC class II protein consists of two noncovalently linked polypeptides called α and β . Like MHC class I α chains, these polypeptides are embedded in the cytoplasmic membrane and project outward from the cell surface (Figure 25.8b).

In different individuals of the same species, MHC proteins are not structurally identical. Different individuals usually have subtle differences in the amino acid sequence of homologous MHC proteins. These genetically encoded MHC variants, of which there are over 3500 in humans, are called *polymorphisms*. Polymorphisms in MHC proteins are the major antigenic barriers for tissue transplantation from one individual to another; tissue transplants not matched for MHC identity are recognized as nonself by the immune system and are rejected. We present the detailed molecular structure and genetic organization of the MHC genes and proteins in Chapter 26.

Antigen Processing and Presentation

The MHC proteins cannot be expressed on the cell surface unless they are complexed with peptide. These MHC–peptide complexes reflect the composition of the proteins inside the cell. For example, a cell that contains no pathogens or foreign antigens displays MHC proteins complexed with self peptides derived from the normal degradation of self proteins during cell growth. On the other hand, host cells that have ingested foreign proteins or pathogens, and cells infected with viruses, produce peptides that also interact with MHC proteins. The host cells then degrade (process) the antigens to form small peptides. In this case, the MHC proteins expressed on the cell surface are complexed with foreign peptides. These MHC proteins with embedded peptides provide the foreign-antigen targets for T cells. T cells, through their TCRs, continually sample the surface of other cells to identify cells carrying foreign antigens; the TCR

interacts with the foreign antigen presented on an MHC protein. No T cells can react with the MHC–peptide complexes on uninfected cells because self-reactive T cells have been eliminated during the development of tolerance in the immune system. Two distinct antigen-processing schemes are at work, one for MHC I antigen presentation and one for MHC II antigen presentation (Figure 25.9).

MHC I proteins present peptide epitopes derived from pathogen proteins in the cytoplasm of cells that have been infected by viruses and other intracellular pathogens; such infected cells are called *target cells* (Figure 25.9a). Proteins derived from infecting viruses, for example, are taken up and digested in the cytoplasm in a structure called the *proteasome*. Peptides about ten amino acids long are transported into the endoplasmic reticulum through a pore formed by two proteins, called the *transporters associated with antigen processing (TAP)*. Once the peptides have entered the ER, they are bound by the MHC I protein, which has been assembled in the ER and held in place near the TAP site by a group of *chaperone proteins* until a peptide is bound. The MHC I–peptide complex is then released from the chaperones and moves to the

cell surface, where it integrates into the membrane and can be recognized by T cells. Thus, the MHC proteins are a platform to which the foreign peptide is bound. Next, the TCR on the surface of a T cell interacts with both peptide (nonself) and MHC protein (self) on the surface of the target cell. This T cell–target cell interaction induces specialized T-cytotoxic (Tc) cells to produce cytotoxic proteins called perforins that kill the virus-infected target cell (Section 25.5). Any nucleated cell can act as a target cell for T cells recognizing peptide–MHC I complexes.

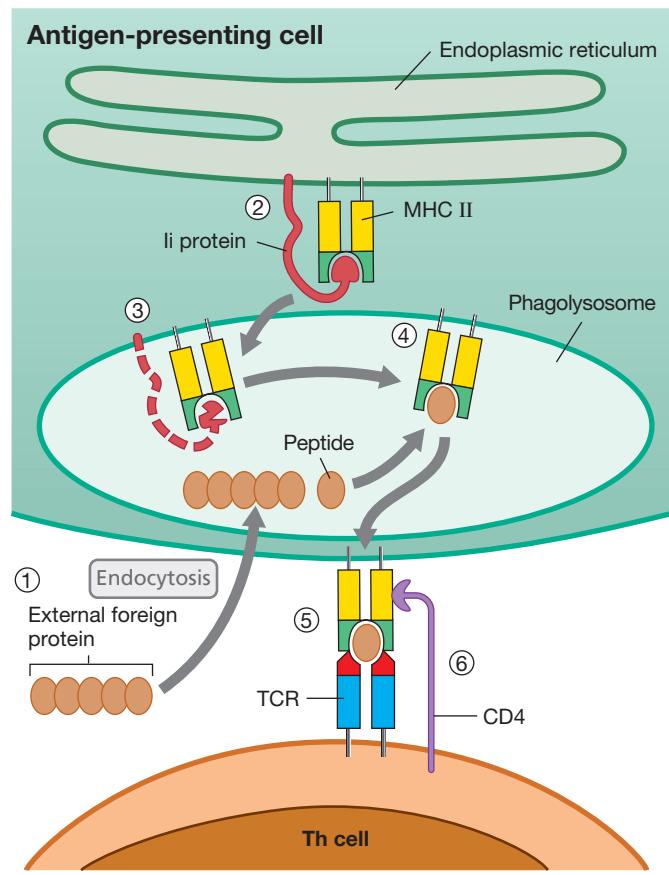

MHC II proteins are the antigen-presenting proteins in a second pathway (Figure 25.9b). MHC II proteins are expressed exclusively on the phagocytic APCs, where they function to present peptides from engulfed pathogens such as bacteria. MHC class II proteins are initially assembled in the endoplasmic reticulum much as MHC I proteins are assembled. However, a difference from the assembly pathway of MHC I proteins is that a chaperone protein called *Ii*, or invariant chain, binds to the MHC II protein, blocking peptide loading inside the endoplasmic reticulum. These MHC II–Ii complexes are transported from the endoplasmic

MHC I–peptide complex interacts with T cell receptors (TCRs) on the surface of Tc cells. ⑤ The CD8 coreceptor on the Tc cell engages MHC I, resulting in a stronger complex. II from binding with peptides in the ER. ③ The MHC II–Ii assembly is transported to the lysosome, where it remains until the lysosome fuses with the phagosome, forming a phagolysosome where Ii is degraded, ④ freeing the MHC II protein to bind the foreign peptide fragments. ⑤ The MHC II–peptide complex is transported to the cell surface, where it interacts with TCRs and ⑥ the CD4 coreceptor on Th cells. The Th cells then release cytokines that interact with other cells to promote an immune response.

reticulum to lysosomes. After phagocytosis of a pathogen, the phagosome containing the foreign antigen fuses with the lysosome to form a phagolysosome. In the latter, the foreign antigens and the Ii peptide are digested by lysosomal enzymes. The foreign peptides, generally about 11–15 amino acids long (slightly larger than MHC I-binding peptides), bind to the newly opened MHC II antigen-binding site. The complex is transported to the cytoplasmic membrane, where it is displayed on the cell surface to specialized **T-helper (Th) cells**. The Th cells, through the TCR, recognize the MHC II-peptide complex. This interaction activates the Th cells to secrete cytokines, stimulating antibody production by B cells or causing inflammation.

CD4 and CD8 Coreceptors

In addition to the TCR, each T cell expresses a unique cell surface protein that functions as a coreceptor. Th cells express a **CD4 coreceptor** protein, and Tc cells express a **CD8 coreceptor**

protein (Figure 25.9). When the TCR binds to the peptide–MHC complex, the coreceptor on the T cell also binds to the MHC protein on the antigen-presenting cell, strengthening the molecular interactions between the cells and enhancing activation of the T cell. CD4 binds only to the MHC II protein, strengthening Th cell interaction with APCs that express MHC II protein. Likewise, CD8 binds only to the MHC I protein, enhancing the binding of Tc cells to MHC I-bearing target cells. The CD4 and CD8 proteins are also used for in vitro tests as T cell markers to differentiate Th (CD4) cells from Tc (CD8) cells.

III • T Lymphocytes and Immunity

Antigen presentation activates precursor T lymphocytes to differentiate into T cells that carry out antigen-specific cell-mediated immunity. These functions include cell-mediated killing, inflammatory responses, and “help” for antibody-producing B cells. In the absence of antigen-activated T cells, there is little antigen-specific immunity and no immune memory.

25.5 T-Cytotoxic Cells and Natural Killer Cells

In the previous section we introduced two subsets of T cells, the T-cytotoxic cells and the T-helper cells. Here we examine the antigen-specific cell-killing function of the T-cytotoxic cells in detail. We also introduce the natural killer (NK) cell, a lymphocyte-like cell that uses another mechanism to recognize and kill cells infected with intracellular pathogens.

T-Cytotoxic Cells

T-cytotoxic (Tc) cells, also called cytotoxic T lymphocytes (CTLs), are CD8 T cells that directly kill cells that display foreign surface antigens. As we discussed in Section 25.4, Tc cells recognize foreign peptides embedded in MHC I proteins. Cells displaying the foreign antigen are killed by the Tc cells. For example, a viral peptide embedded in MHC I, displayed on a virus-infected cell, marks the cell for interaction and killing by a Tc cell.

Contact between a Tc cell and the target cell is required for cell death (Figure 25.10). The point of initial contact is between the TCR and the peptide–MHC I complex. The CD8 protein on the Tc cell then binds the MHC I protein, strengthening the interaction. On contact with the target cell, granules in the Tc cell migrate to the contact site, where the contents of the granules are released (degranulation). The granules contain perforin and proteases called *granzymes*. Perforin enters the membrane of the target cell and forms a pore, through which granzymes enter the target cell. Granzymes are cytotoxins that cause *apoptosis*, or

programmed cell death, characterized by death and degradation of the cell from within. The Tc cells, however, remain unaffected; their membranes are not damaged by perforin. Tc cells kill only those cells displaying the foreign antigen because the granules are released only at the contact surface between the Tc and the target cell bearing peptide–MHC I. Cells lacking the peptide recognized by the Tc cells do not make contact and are not killed.

Natural Killer Cells

Natural killer cells (NK cells) are cytotoxic lymphocytes that are distinct from T cells and B cells. Nevertheless, NK cells resemble Tc cells in their ability to destroy cancer cells and cells infected with intracellular pathogens. NK cells also use perforin and granzymes to kill their targets, destroying cancer cells and virus-infected cells without prior exposure or contact with the foreign

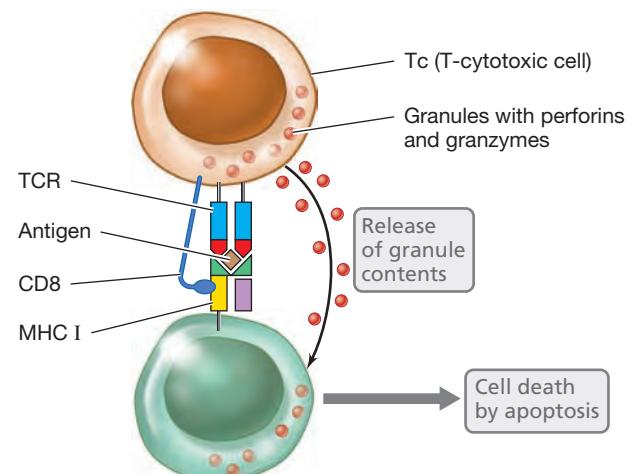

Figure 25.10 T-cytotoxic cells. When the TCR on a Tc cell binds MHC I-peptide complexes on any cell, the Tc cell releases granules that contain perforin and granzymes, cytotoxins that perforate the target cell and cause apoptosis, respectively.

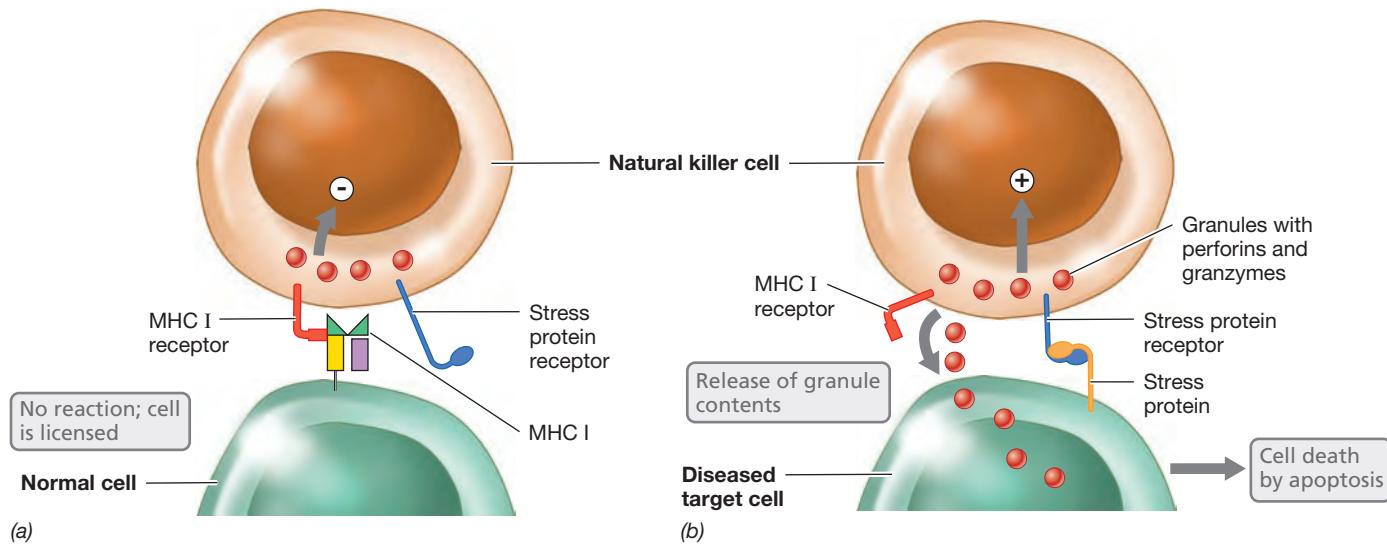

Figure 25.11 **Natural killer cells.** Natural killer (NK) cells have two receptors: one interacts with MHC I on healthy cells; the second one interacts with cell stress proteins, found only on tumor cells or pathogen-infected cells. (a) MHC I recognition licenses the healthy cells, preventing the NK cell from releasing its contents. (b) Pathogen-infected cells or tumor cells express stress proteins and often reduce MHC I expression. In the absence of MHC I recognition, the NK cell interacts with the stress protein and releases perforins and granzymes, killing the diseased cell.

cells (Figure 25.11). This is important because many tumor cells and virus-infected cells reduce or eliminate normal MHC I expression to evade the antigen-specific Tc response. In this process, the number of NK cells does not increase, nor do they exhibit memory after interaction with target cells.

NK cells recognize and destroy tumor cells or pathogen-infected cells using a two-receptor system. The molecular targets of NK cells are proteins on the surface of other cells (Figure 25.11a). As NK cells circulate and interact with the cells in the body, they use special MHC I receptors to recognize MHC I proteins on normal, healthy cells. Binding of the NK receptors to MHC I deactivates the NK cell, turning off the perforin and granzyme killing mechanisms, a process called *licensing*. Tumor cells or pathogen-infected cells, however, may express stress proteins on their surface; NK cells have complementary receptors for many of these stress proteins. Especially in the absence of the MHC licensing interaction, the stress receptors on NK cells engage stress proteins on target cells. The NK cell responds by releasing cytotoxic perforins and granzymes, thus destroying pathogen-infected or tumor cells that express disease-indicating stress proteins and no longer express the MHC proteins of healthy cells (Figure 25.11b).

25.6 T-Helper Cells

Interactions with APCs drive CD4 Th cells to differentiate into several subsets, each producing unique combinations of cytokines that

recruit effector cells such as macrophages, antibody-producing B cells, and neutrophils. Cells of Th1 and Th2 subsets play a role in adaptive immunity, promoting inflammation and antibody production respectively. Th17 cells amplify the innate immune response, and Treg cells suppress immunity when it is not needed (Table 25.2).

Th1 Cells and Macrophage Activation

Macrophages play a central role as APCs in cell-mediated immunity. As illustrated in Figure 25.12, macrophages engulf, process, and present antigen to Th1 cells. Th1 cells produce IL-2 (interleukin-2), a cytokine that promotes growth and activation of other T cells, and activate macrophages through other cytokines. As a general rule, even inactive macrophages phagocytose and kill most bacteria, but a few pathogens survive and multiply within the phagolysosome. These intracellular pathogens include *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and *Listeria monocytogenes*, the bacteria that cause tuberculosis, leprosy, and listeriosis, respectively. Animals inoculated with a moderate dose of *M. tuberculosis* are able to overcome the infection and develop a protective T cell-mediated immune response mediated by T-inflammatoty cells, the Th1 subset. Th1 cells activate the macrophages through the cytokines interferon gamma (IFN- γ), tumor necrosis factor alpha (TNF- α), and granulocyte-monocyte colony-stimulating factor (GM-CSF) (Figure 25.12). The Th1-activated macrophages take up and kill foreign cells more efficiently than resting macrophages. Surprisingly, the activated macrophages also phagocytose and kill cells infected with unrelated intracellular pathogens such as *Listeria*. Specificity is at the level of the Th1 Cells and Macrophage Activation effector macrophages act nonspecifically; activated macrophages kill intracellular bacteria that normally multiply in nonactivated macrophages or other cell types.

Th1-activated macrophages not only kill pathogen-infected cells but also help destroy tumor cells because tumor cells often produce

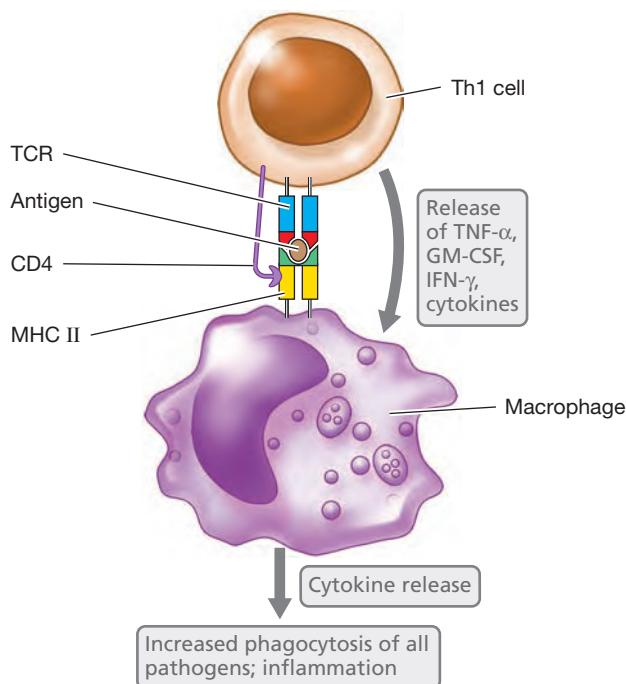

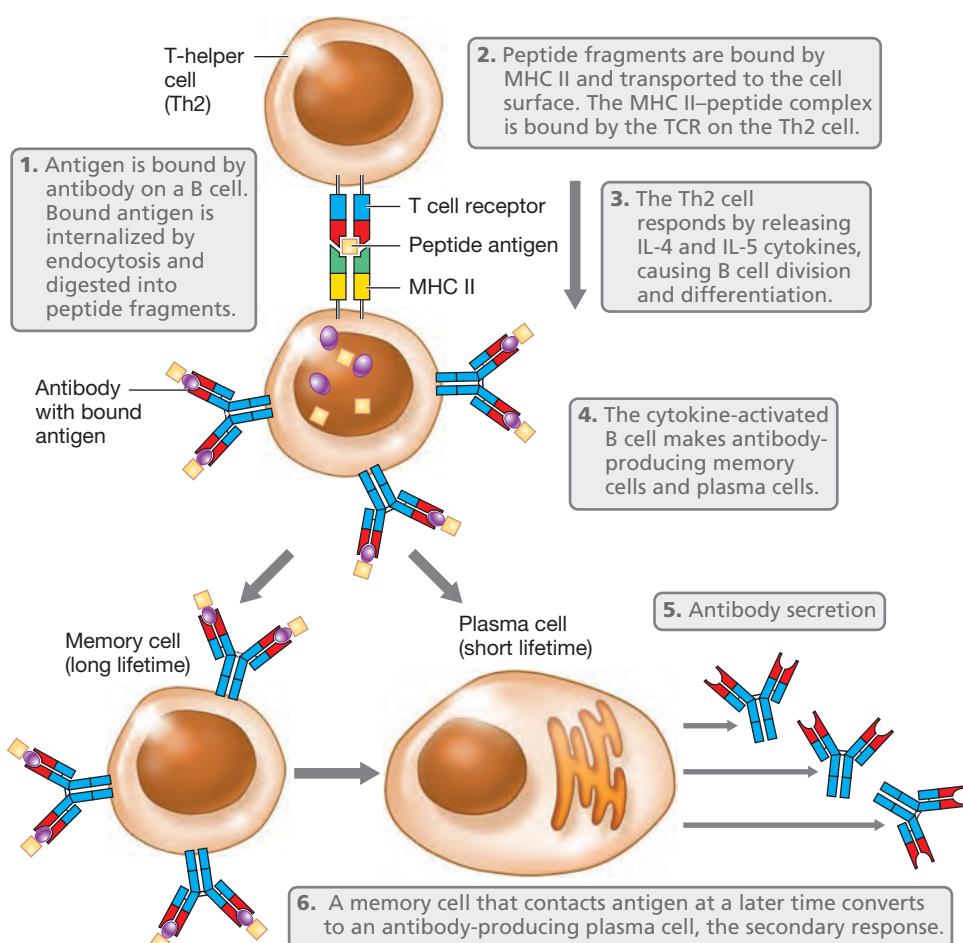

Figure 25.12 Th1 cells. Th1 cells (T-infiltratory cells) are activated by antigens presented on macrophages in the context of MHC II protein. Activated Th1 cells produce cytokines that stimulate the macrophages to increase phagocyte activity and promote inflammation.

tumor-specific antigens not found on normal cells. Tumor cells can be destroyed by macrophages activated by the Th1 cells that react with the tumor-specific antigen. Transplantation rejection, a major problem encountered after organs or tissues are transplanted from one person to another, is also mediated by Th1-activated macrophages. In this case, Th1 cells recognize the nonself MHC proteins of the transplant, triggering macrophage activation and transplant destruction.

Th2 Cells

Th2 cells play a pivotal role in B cell activation and antibody production. As discussed in Section 24.4, B cells make antibodies. Differentiated B cells are coated with antibodies that are antigen receptors. Antigen binds to the B cell antigen receptors but the B cell does not immediately produce soluble antibodies (Figure 25.13). The antibody-bound antigen is first taken into the B cell by endocytosis and degraded. Peptides from the degraded antigen are then presented on the B cell's MHC II protein. In this way the B cell serves a dual role, first as an APC, and second as an antibody producer. As an APC, the B cell takes up and processes antigen into peptides and loads them into MHC II. The B cell then presents the MHC II-peptide to a Th2 cell. The Th2 cell responds by producing IL-4 and IL-5, cytokines that activate the B cell. The activated B cell differentiates into

Figure 25.13 T cell–B cell interaction and antibody production. B cells interact with antigen and Th2 cells to produce antibodies. B cells initially function as antigen-presenting cells using the antigen-specific Ig receptor to trap antigen. Antigen processing by the B cell and presentation to the Th2 cell induces the Th2 cell to make cytokines that activate the B cell to become an antibody-producing plasma cell or a memory cell.

a plasma cell that produces and secretes antibodies, as we will discuss in Section 25.8.

Th17 and Treg Cells

Antigen presentation by dendritic cells plays a critical role in the development of Th17 and Treg cells. **Th17** cells are important in the first stages of the adaptive immune response; triggered by antigen interactions, Th17 cells recruit neutrophils, innate immune cells important in inflammation. Undifferentiated or *naive* Th cells differentiate into Th17 cells through the action of dendritic cells. When dendritic cells encounter pathogens, they present antigen and secrete two cytokines, IL-6 and transforming growth factor- β (TGF- β), which catalyze differentiation of Th to Th17 cells (Figure 25.14a). Th17 cells then produce IL-17, a cytokine that activates other tissue cells to produce cytokines and chemokines that attract neutrophils to the site of infection. Thus, the function of Th17 cells is to produce IL-17, starting a cascade that draws neutrophils to infection sites. By recruiting neutrophils, Th17 cells amplify innate immunity triggered by interaction of a pathogen with the dendritic cell.

Treg cells are important in control of immunity. Undifferentiated Th cells remain so unless they are stimulated to mature by certain cytokines, as is the case for IL-6 stimulation to produce Th17 cells. However, in the absence of a pathogen, Th cells can still interact with dendritic cells through MHC II-peptide-TCR (Figure 25.14b). In this case, the peptide is usually a self peptide; immunity to it could cause an autoimmune disease. However, because the dendritic cells did not interact with pathogen, they cannot produce IL-6 to promote Th17 differentiation. Instead, the absence of IL-6 pushes differentiation to Treg cells that make IL-10 and TGF- β , two cytokines that suppress immunity and inflammation. In the presence of self antigens and the absence of IL-6, Treg cells shut down the immune response and inhibit inflammation. This is important for controlling immune responses to self antigen and preventing autoimmunity.

IV • Antibodies and Immunity

Antibodies provide antigen-specific immunity that protects against extracellular pathogens and dangerous soluble proteins such as toxins. After considering the structure and genetic

diversity critical to antibody function, we investigate antibody mechanisms that neutralize or destroy antigens.

25.7 Antibody Structure

Antibodies, also called *immunoglobulins* (*Ig*), are proteins that interact specifically with antigenic epitopes. They are found in the serum and other body fluids such as mucosal secretions and milk. Serum containing antigen-specific antibodies is called *anti-serum* (Section 24.6). Immunoglobulins are separated into five major classes based on their physical, chemical, and immunological properties: IgG, IgA, IgM, IgD, and IgE (Table 25.3).

Immunoglobulin G Structure

IgG is the most common circulating antibody, comprising about 80% of the serum immunoglobulins. IgG is composed of four polypeptide chains (Figure 25.15). Disulfide bridges (S—S bonds) connect the individual chains. In each IgG protein, two identical light chains are paired with two identical heavy chains. Each light chain has about 220 amino acids, and each heavy chain has about 440 amino acids. Each heavy chain interacts with a light chain to form a functional antigen-binding site. An IgG antibody, therefore, is *bivalent* because it has two identical sites that bind two identical epitopes.

Heavy and light chains consist of a series of distinct protein domains of about 110 amino acids (Figure 25.15). A heavy-chain variable domain is connected to three constant domains about 110 amino acids long. The amino acid sequence in the variable domain differs in each different antibody. The variable domain binds antigen. The three constant domains of each heavy chain are identical in all Ig molecules of a given class. Each light chain consists of one variable and one constant domain. The variable domain of a light chain interacts with the variable domain of a heavy chain to bind antigen. The amino acid sequence in the constant domain is the same in light chains of the same type.

The Antigen-Binding Site

The antigen-binding site of IgG and all other antibodies form by cooperative interaction between the variable domains of heavy and light

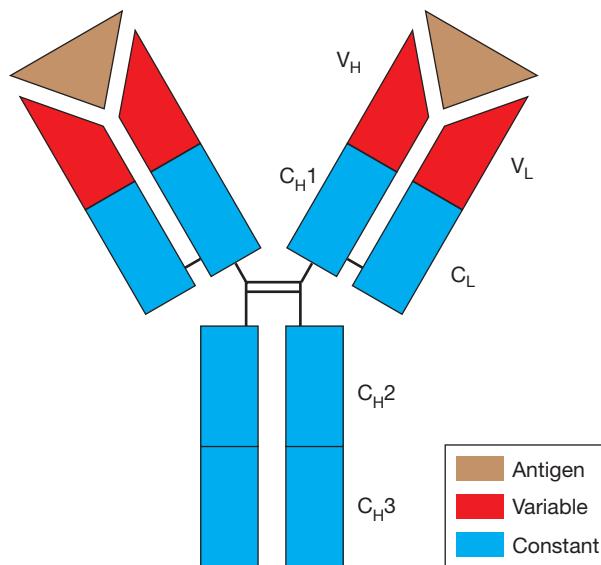

Figure 25.15 **Immunoglobulin G structure.** IgG consists of two heavy chains (50,000 molecular weight) and two light chains (25,000 molecular weight), with a total molecular weight of 150,000. One heavy and one light chain interact to form an antigen-binding unit. The variable domains of the heavy and light chains (V_H and V_L) bind antigen. The constant domains (C_{H1} , C_{H2} , C_{H3} , C_L) are identical in all IgG proteins. The chains are covalently joined with disulfide bonds.

chains (Figure 25.16). The variable domains of the two chains interact, forming a receptor that binds antigen strongly but noncovalently. The measurable strength of binding of antibody to antigen is called *binding affinity*. A high-affinity antibody binds tightly to antigen.

Each individual's immune system has the capacity to recognize, or bind, countless antigens, and each antigen is bound by a unique antigen-binding site. To accommodate all possible antigens, each individual can produce billions of different antigen-binding sites, each encoded by a gene formed through somatic recombination

and mutation events. Antigen interaction with the antibodies on a B cell stimulates the B cell to produce and secrete copies of the preformed antibody.

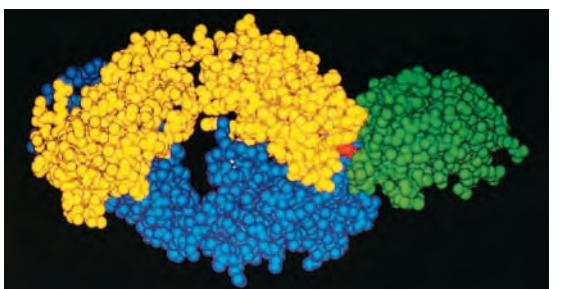

Other Antibody Classes

Antibodies of the other classes differ from IgG. The class of a given antibody molecule is defined by the amino acid sequence of its heavy-chain constant domains. The heavy chain called *gamma* (γ) defines the IgG class; *alpha* (α) defines IgA; *delta* (δ) defines IgD; *mu* (μ) defines IgM; and *epsilon* (ϵ) defines IgE (Table 25.3). The constant domain sequences constitute three-fourths of the heavy chains of IgG, IgA, and IgD and four-fifths of the heavy chains of IgM and IgE (Figure 25.17).

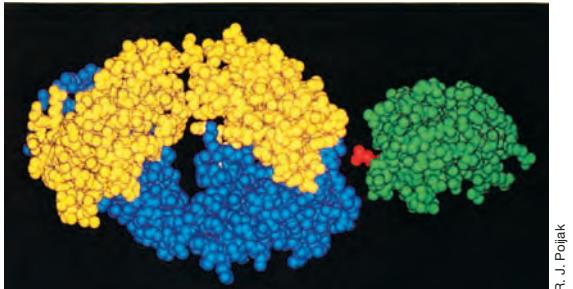

The structure of IgM is shown in **Figure 25.18**. IgM usually forms an aggregate of five immunoglobulin molecules attached by at least

one J (joining) chain. IgM is the first class of Ig made in a typical immune response to a bacterial infection, but IgMs generally have low *affinity* (binding strength) for antigen. Overall antigen-binding strength is enhanced, however, by the high *valence* of the pentameric IgM molecule; ten binding sites are available for interaction with antigen (Table 25.3 and Figure 25.18). The combined strength of antigen binding by the multiple antigen-binding sites on IgM is called *avidity*. Thus, IgM has *low affinity* but *high avidity* for antigen. Up to 10% of serum antibodies are IgM. IgM monomers are the class of antibodies found on the surface of B cells.

Dimers of IgA are present in body fluids such as saliva, tears, breastmilk colostrum, and mucosal secretions from the gastrointestinal, respiratory, and genitourinary tracts. These mucosal surfaces are associated with mucosa-associated lymphoid tissue (MALT) that produces IgA. In an average adult, the mucosal

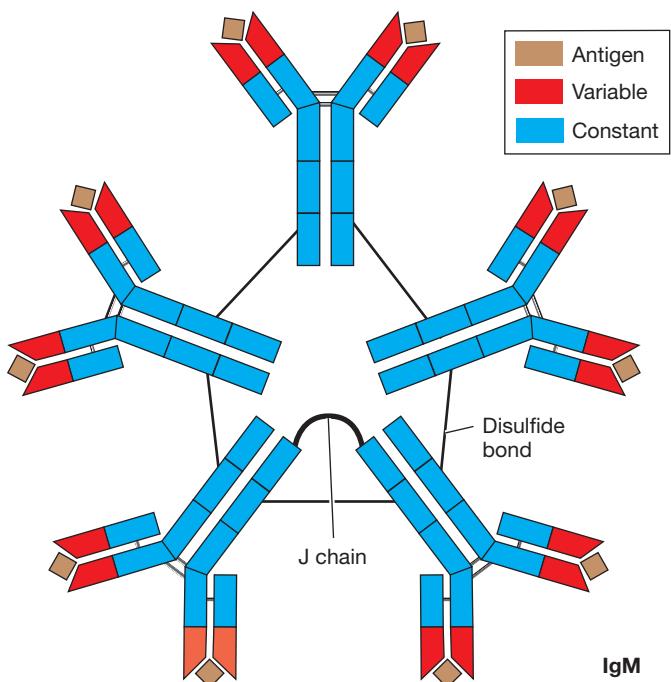

Figure 25.18 Immunoglobulin M. IgM is found in serum as a pentameric protein consisting of five IgM proteins covalently linked to one another via disulfide bonds and a J chain protein. Because it is a pentamer, IgM can bind up to ten antigens, as shown.

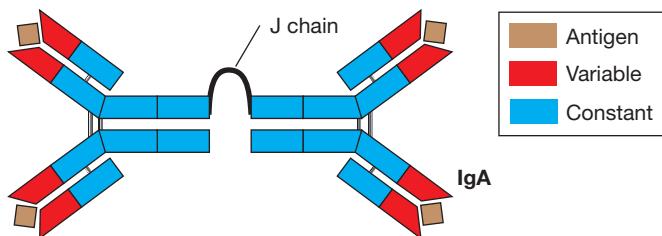

Figure 25.19 Immunoglobulin A. Secretory IgA (sIgA) is often found in body secretions as a dimer consisting of two IgA proteins covalently linked to one another by a joining (J) chain protein. A secretory component, not shown, aids in transport of IgA across mucosal membranes.

surfaces total about 400 m^2 (skin has about 6 m^2), and large amounts of secretory IgA are produced—about 10 g per day. By contrast, the serum IgG produced in an individual is about 5 g per day, only half as much as IgA. Secretory IgA has two IgA molecules covalently linked by a J chain peptide and a protein called the *secretory component* that aids in transport of IgA across membranes (Figure 25.19). IgA is also present in serum as a monomer (Table 25.3).

IgE is found in extremely small amounts in serum (about 1 of every 50,000 serum Ig molecules is IgE). Most IgE is bound to cells. For example, IgE antibody, through its constant region, binds eosinophils, arming these granulocytes to target eukaryotic parasites like schistosomes and other worms. IgE also binds to tissue mast cells. Binding of antigen to the variable antigen-binding portions of IgE on mast cells causes release of the mast cell contents in a process called degranulation. Degranulation of mast cells triggers immediate-type hypersensitivities (allergies, ↗ Section 24.8). The molecular weight of IgE is significantly higher than most other Igs (Table 25.3) because, like IgM, IgE has a fourth constant domain (Figure 25.17). The additional constant domain of IgE binds to eosinophils and mast cells, a critical step for activating the protective and allergic reactions associated with these cell types (↗ Figure 24.17).

IgD (Figure 25.17), present in serum in low concentrations, has no known unique immune protective function. However, IgD, like IgM, is abundant on the surfaces of B cells, especially memory B cells.

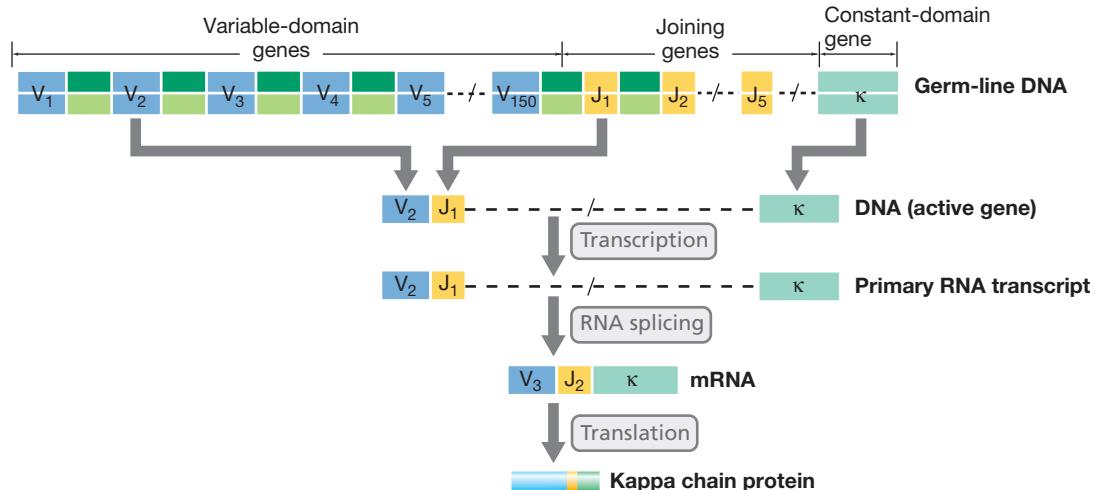

Figure 25.20 Immunoglobulin kappa chain gene rearrangement in human B cells. The gene segments are arranged in tandem in the kappa (κ) light-chain genes on chromosome 2. DNA rearrangements are completed in the maturing B cell. Any one of the 150 V (variable) sequences may combine with any one of the 5 J sequences. Thus, 750 (150×5) recombinations are possible, encoding 750 distinct kappa variable domains, but only one productive rearrangement occurs in each cell.

- Differentiate among antibody classes using structural characteristics, expression patterns, and functional roles.

25.8 Antibody Production

A predictable sequence of events leads to antibody production after antigen exposure. At the genetic level, B cells and T cells use gene recombination and mutation mechanisms to generate rearranged genes encoding a limitless number of unique antigen-binding receptors. At the cellular level, complex interactions between B cells and T cells produce antibodies that provide effective antigen-specific immunity.

Generation of Antigen Receptor Diversity

Each individual is capable of producing billions of different antibodies and TCRs, each aimed to interact with one of the countless antigens in our environment. How does the immune system produce all of these antigen-specific proteins? Immune receptor diversity is generated by a mechanism found only in B and T cells. Antibody production starts with stepwise rearrangements of the Ig-encoding genes. During development of B cells in the bone marrow, both heavy-chain and light-chain genes rearrange. The genes are recombined—individual gene pieces are mixed and matched in various combinations—by gene splicing and rearrangements in the differentiating B cells, a process called *somatic recombination*.

Figure 25.20 shows how rearrangement of a single human light-chain kappa gene results in formation of one light-chain protein. The heavy-chain gene complex has even more gene segments, allowing for more recombinations and potential heavy chains (↗ Figure 26.8). Only one rearrangement, however, is produced in any given B cell. The final result is a single functional heavy-chain gene and a single functional light-chain gene. Each of these rearranged genes is transcribed and translated to make an antibody consisting of two heavy-chain proteins and two light-chain proteins. The unique antibody is then expressed on the surface of the B cell.

Antigen exposure is necessary to stimulate the B cell to produce soluble antibodies and differentiate to plasma cells that will produce more soluble antibody copies. In addition, antigen exposure induces mutations at an accelerated rate in antibody genes, a phenomenon called *somatic hypermutation*. This process further modifies and diversifies the antibodies produced.

The large number of possible gene rearrangements coupled with the somatic hypermutation events after antigen exposure ensure almost unlimited antibody diversity. Similar rearrangements also occur during

T cell development, resulting in the generation of considerable diversity in TCRs. T cells, however, do not use hypermutation to expand diversity.

Antibody Production and Immune Memory

Starting with a B cell, antibody production begins with antigen exposure and culminates with the production and secretion of an antigen-specific antibody according to a defined sequence:

1. Antigens are introduced via the lymphatic and blood circulatory systems to secondary lymphoid organs such as lymph nodes, spleen, and MALT (➡ Section 24.1 and Figure 24.2). The route of antigen exposure influences the class of the antibodies produced. Antigen introduced into the bloodstream by injection or infection travels to the spleen, where IgM, IgG, and serum IgA antibodies are formed. Antigen introduced subcutaneously, intradermally, topically, or intraperitoneally is carried by the lymphatic system to the nearest lymph nodes, again stimulating production of IgM, IgG, and serum IgA. Antigen introduced to mucosal surfaces is delivered to the nearest MALT. For example, antigen delivered orally is delivered to the MALT in the intestinal tract, preferentially stimulating production of secretory IgA in the gut.
2. Following the initial antigen contact, each antigen-stimulated B cell multiplies and differentiates to form antibody-secreting plasma cells and memory cells (Figure 25.13). *Plasma cells* are relatively short-lived (less than 1 week), but they produce and secrete large amounts of mostly IgM antibody in the *primary antibody response* (Figure 25.21). After a short latent period, antibody appears in the blood and a gradual increase in *antibody titer* (antibody quantity) occurs. As antigen disappears, the primary antibody response decreases slowly.
3. The **memory B cells** generated by the initial exposure to antigen may live for years. A reexposure to the same antigen immediately stimulates memory B cells to differentiate to

plasma cells and produce antibody; memory B cells need no T cell help. The second and each subsequent exposure to antigen causes the antibody titer to rise rapidly to a level often 10–100 times greater than the titer following the first exposure. This rise in antibody titer is the *secondary antibody response*. The secondary response illustrates immune memory: a more rapid, more abundant antibody response than the primary response. The secondary response usually switches from IgM production to another antibody class. In serum, the most common antibody class switches are from IgM to IgG and IgA. This phenomenon is called *class switching* (Figure 25.21).

4. The titer slowly decreases over time, but subsequent exposures to the same antigen can cause another memory response. The rapid and strong memory response is the basis for the immunization procedure known as a “booster shot” (for example, the yearly rabies shot given to domestic animals). Periodic reimmunization maintains high levels of memory B cells and circulating antibody specific for a certain antigen, providing long-term active protection against individual infectious diseases.

MINIQUIZ

- Explain how a limited numbers of immunoglobulin genes can be rearranged to form almost limitless numbers of antibody proteins.
- Explain the rationale for periodic revaccination in children and adults.

25.9 Antibodies, Complement, and Pathogen Destruction

Complement is a group of sequentially interacting proteins, many with enzymatic activity, important in both innate and adaptive immunity. Complement activity can be triggered by innate or adaptive mechanisms.

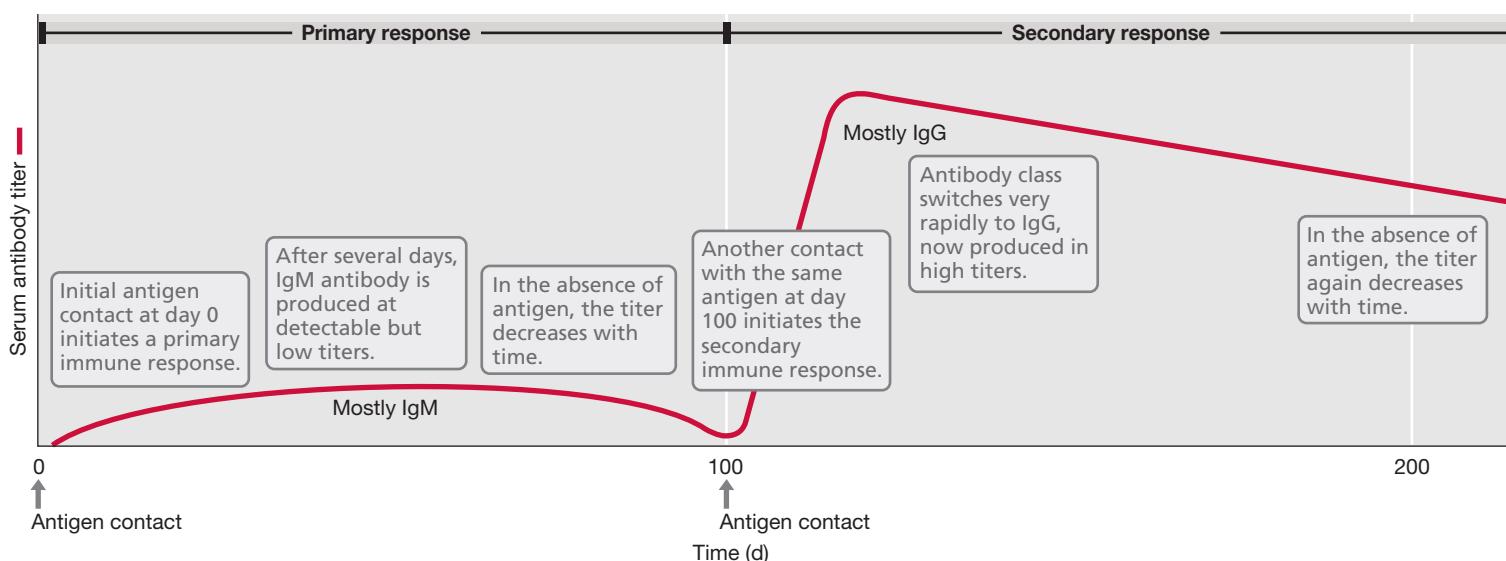

Figure 25.21 Primary and secondary antibody responses in serum. The antigen injected at day 0 and day 100 must be identical to induce a secondary response. The secondary response, also called a booster response, may be more than 10-fold greater than the primary response. Note the class switch from IgM production in the primary response to IgG production in the secondary response.

Classical Complement Activation and Cell Damage

Complement proteins react in a sequence after exposure to antigen–antibody complexes on a target cell. Complement activation may result in membrane damage and lysis of the target cell or enhanced phagocytosis of the target cell, a process called *opsonization*. Serum contains complement, and most antigen-bound IgG or IgM antibodies can bind complement (Table 25.3).

The individual proteins of complement are designated C1, C2, C3, and so on. Classical activation of complement occurs when IgG or IgM antibodies bind antigens, especially on cell surfaces. The antibodies are said to *fix* (bind) the ever-present complement proteins. The complement proteins react in a defined sequence, with activation of one complement protein leading to activation of the next, and so on. The key steps, shown in

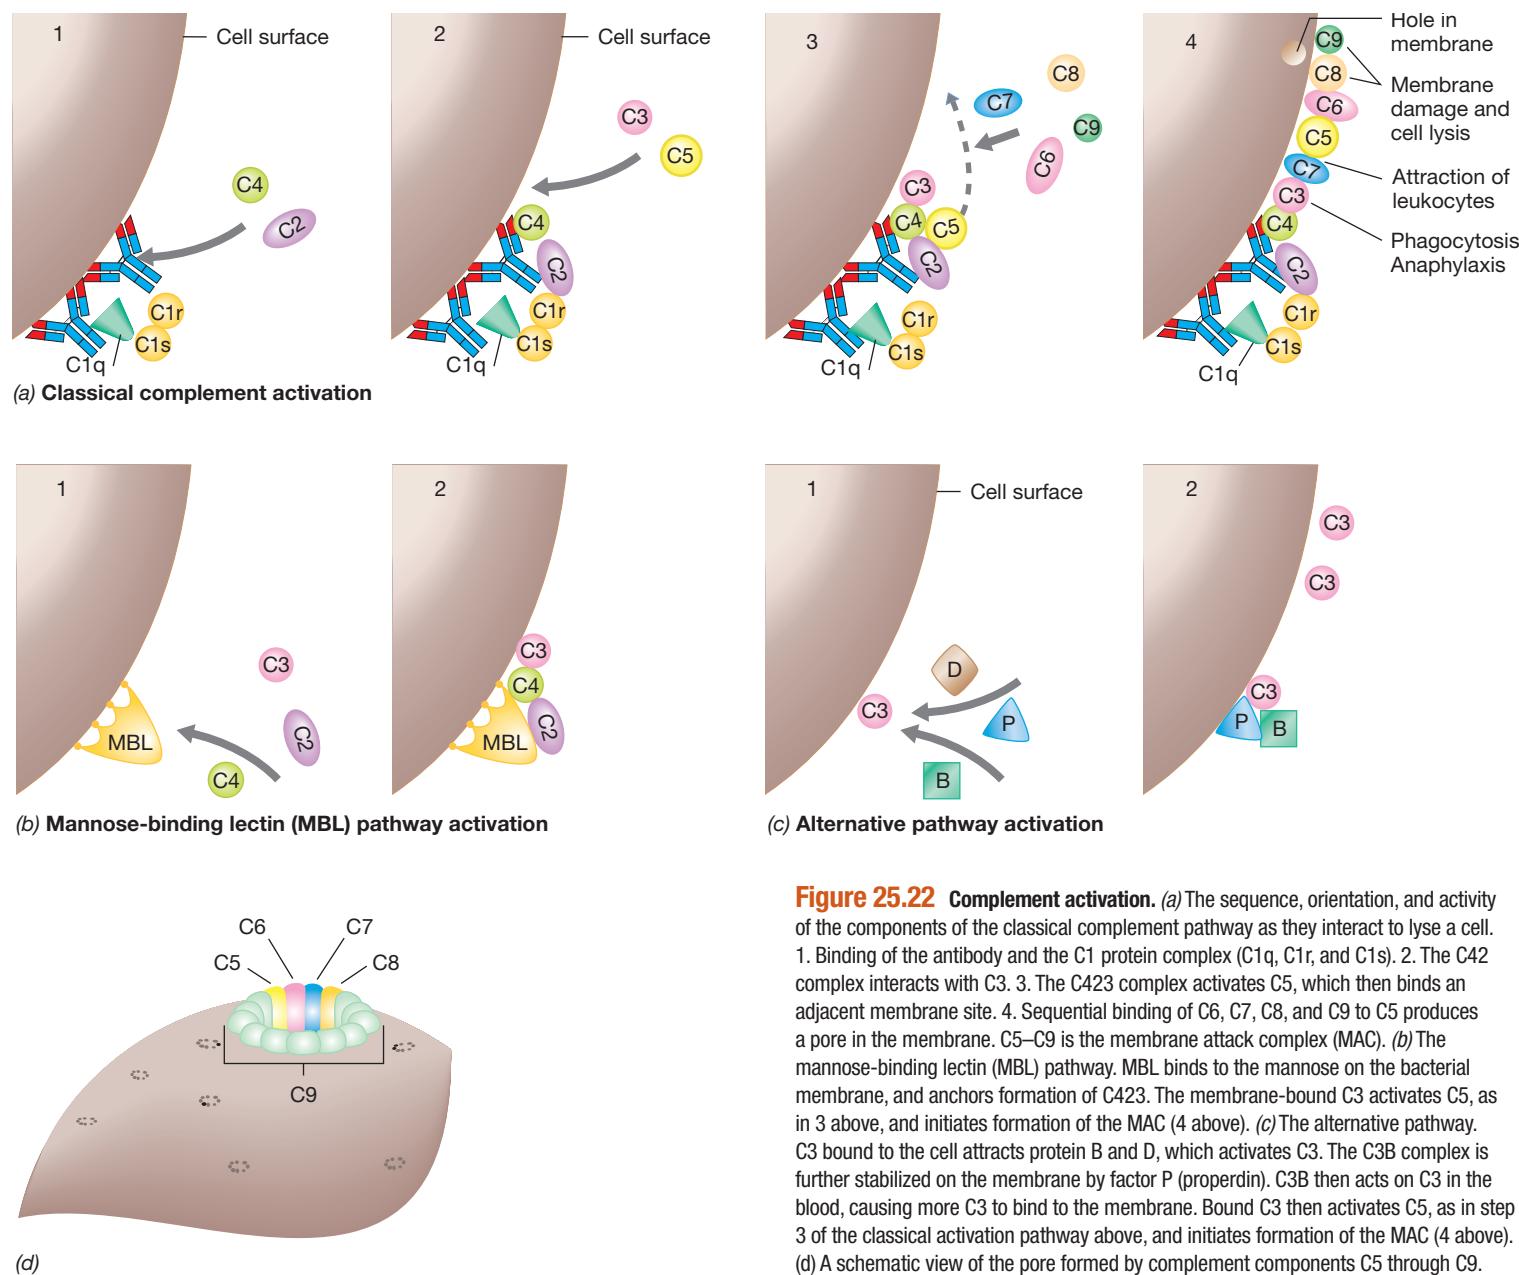

Figure 25.22, start with binding of antibody to antigen (initiation) and binding of C1 components (C1q, C1r, and C1s) to the antibody–antigen complex, leading to C4-C2 deposition at an adjacent membrane site. This complex is called a *C3 convertase*, an enzyme that cleaves C3 to C3a and C3b. C3b then binds to the convertase, forming a complex that initiates a C5-C6-C7 interaction at a second membrane site. C8 and C9 are then deposited with the C5-C6-C7. The membrane-bound C5–9 components, called the *membrane attack complex (MAC)*, insert through the membrane to form a pore and allow the contents to leak out, lysing the cell (**Figure 25.23**).

By-products of complement activation include chemoattractants called *anaphylatoxins*; these molecules cause inflammatory reactions at the site of complement deposition. For example, when C3 is cleaved to C3a and C3b, C3b fixes to the target cell,

Binding of the antibody and the C1 protein complex (C1q, C1r, and C1s). 2. The C42 complex interacts with C3. 3. The C423 complex activates C5, which then binds an adjacent membrane site. 4. Sequential binding of C6, C7, C8, and C9 to C5 produces a pore in the membrane. C5–9 is the membrane attack complex (MAC). (b) The mannose-binding lectin (MBL) pathway. MBL binds to the mannose on the bacterial membrane, and anchors formation of C423. The membrane-bound C3 activates C5, as in 3 above, and initiates formation of the MAC (4 above). (c) The alternative pathway. C3 bound to the cell attracts protein B and D, which activates C3. The C3B complex is further stabilized on the membrane by factor P (properdin). C3B then acts on C3 in the blood, causing more C3 to bind to the membrane. Bound C3 then activates C5, as in step 3 of the classical activation pathway above, and initiates formation of the MAC (4 above). (d) A schematic view of the pore formed by complement components C5 through C9.

as outlined above. Release of soluble C3a attracts and activates phagocytes, increasing phagocytosis. Reactions involving the C5a cleavage product lead to T cell attraction, cytokine release, and inflammation.

When activated by specific antibody, complement lyses many gram-negative bacteria. Gram-positive bacteria, on the other hand, are not lysed by complement and specific antibodies. Gram-positive bacteria can, however, be destroyed through opsonization.

Opsonization

Opsonization is the enhancement of phagocytosis due to the deposition of antibody or complement on the surface of a pathogen or other antigen. For example, a bacterial cell is more likely

to be phagocytosed when antibody binds antigen on its surface. If complement binds to an antibody–antigen complex on the cell surface, the cell is even more likely to be ingested. This is because most phagocytes, including neutrophils, macrophages, and B cells, have antibody receptors (FcR) as well as C3 receptors (C3R). These receptors bind the antibody constant domain and C3 complement protein, respectively. Normal phagocytic processes are enhanced about 10-fold by antibody–FcR interactions and amplified another 10-fold by C3–C3R interactions. Antibodies bound to surface antigens on gram-positive *Bacteria* use the classical complement pathway to promote opsonization, leading to enhanced phagocytosis and pathogen destruction.

Mannose-Binding Lectin and Alternative Pathways

In addition to complement activation by the classical pathway, C3 can be deposited on membranes and the MAC can be activated by the mannose-binding lectin (MBL) pathway and the alternative pathway. These pathways depend on recognition of shared pathogen components and are an important part of the innate immune system (Figure 25.24).

The MBL pathway depends on the activity of a serum MBL protein. MBL is a soluble PRR (Section 25.1) that binds to mannose-containing polysaccharides found only on bacterial cell surfaces (Figure 25.24). The MBL–polysaccharide complex resembles the C1 complexes of the classical complement system and fixes C4 and C2, again producing C3 convertase and binding C3b to C42. As before, this complex catalyzes formation of the C5–9 MAC and leads to lysis or opsonization of the bacterial cell.

The alternative pathway is a nonspecific complement activation mechanism using many of the classical complement pathway components as well as several unique serum proteins. Together they induce opsonization and activate the C5–9 MAC. The first step in alternative pathway activation is the binding of C3b produced by the classical or MBL pathway to the bacterial cell

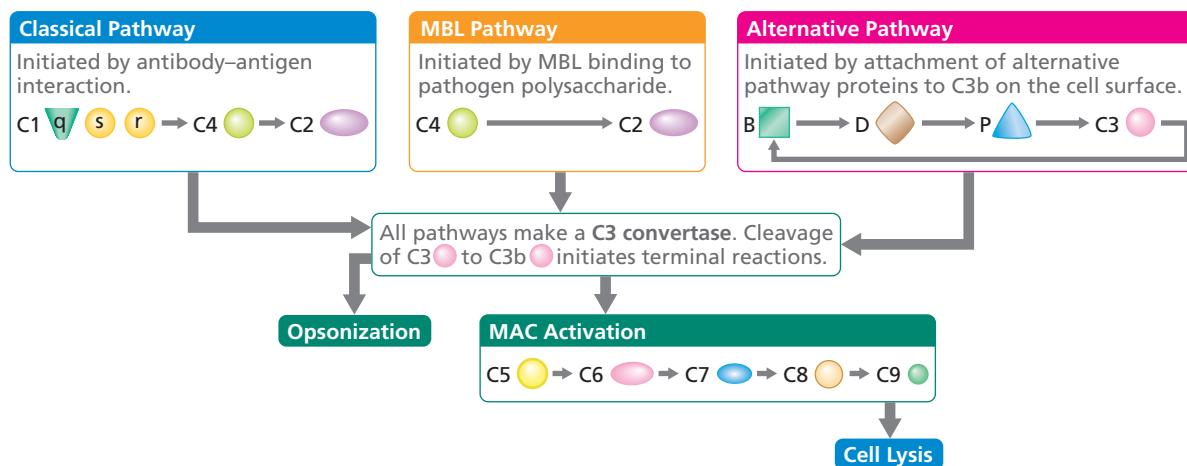

Figure 25.24 Activation of the complement system. Proteins that activate the complement system in the classical, mannose-binding lectin (MBL), and alternative pathways are shown. The proteins interact in an ordered sequence as shown by the arrows, with each pathway independently leading to production of a C3 convertase that cleaves C3 to produce C3b, a protein necessary for initiation of the terminal complement-mediated outcomes of opsonization or cell lysis.

surface. C3b on the membrane can then bind the alternative pathway serum protein factor B, which is cleaved by factor D to give soluble Ba and Bb. The C3bBb complex is another C3 convertase. Factor P, or properdin, also binds to bacterial cell walls. P may join C3bBb to form C3bBbP. This is a very stable C3 convertase because it is fixed on the cell, as are the C3 convertases produced by the classical and MBL pathways (Figure 25.24). C3bBbP then attracts more C3, which is deposited on the membrane, initiating the same reaction as the membrane-bound C423 complex of the classical complement pathway. The result is formation of the C5–9 MAC and cell destruction or enhanced opsonization via phagocyte C3 receptors.

Both the alternative pathway and the MBL pathway nonspecifically target bacterial invaders and lead to activation of the membrane attack complex and enhanced opsonization via formation

of stable C3 convertases. MBL, factors B, D, and P, and classical complement proteins are part of the innate immune response. Neither the alternative pathway nor the MBL pathway requires prior antigen exposure or the presence of antibodies for activation. Through the alternative and MBL pathways, C3 convertase triggers formation of the C5–9 MAC or enhances opsonization via C3 receptors on phagocytes.

BIG IDEAS

25.1 • Phagocytes use their membrane-bound pattern recognition receptors (PRRs) to recognize pathogen-associated molecular patterns (PAMPs). PRR–PAMP interactions activate phagocyte killing of pathogens and cause inflammation. Many pathogens have developed mechanisms to inhibit phagocytes.

25.2 • The adaptive immune response is characterized by *specificity* for the antigen, the ability to respond more vigorously when reexposed to the same antigen (*memory*), and the acquired inability to interact with self antigens (*tolerance*).

25.3 • Immunogens are foreign macromolecules that induce an immune response. Immunogens initiate an immune response when introduced into a host. Antigens are molecules recognized by antibodies or TCRs. Antibodies recognize linear and conformational epitopes; TCRs recognize linear peptide epitopes.

25.4 • T cells interact with antigen-bearing cells including dedicated APCs and pathogen-infected cells. TCRs bind peptide antigens presented by MHC proteins on infected cells or APCs. These interactions activate T cells to kill antigen-bearing cells or to promote inflammation or antibody production.

25.5 • T-cytotoxic (Tc) cells recognize antigens on virus-infected host cells and tumor cells through antigen-specific TCRs. Antigen-specific recognition triggers killing via perforins and granzymes. NK cells do not require antigen, but respond to stress proteins on virus-infected cells and tumor cells, using perforins and granzymes to kill the targets.

25.6 • Through the action of cytokines, Th1 inflammatory cells activate macrophage effector cells; Th2 helper cells activate B cells. Th17 cells are activated by pathogen-activated dendritic cells and recruit neutrophils. Treg cells produce cytokines that suppress adaptive immunity.

25.7 • Each immunoglobulin (antibody) protein consists of two heavy and two light chains. The antigen-binding site is formed by the interaction of the variable regions of one heavy and one light chain. Each antibody class has different structural characteristics, expression patterns, and functional roles.

25.8 • Antibody production is initiated when an antigen contacts an antigen-specific B cell. The antigen-reactive B cell processes the antigen and presents it to an antigen-specific Th2 cell. The Th2 cell becomes activated, producing cytokines that signal the antigen-specific B cell to clonally expand and differentiate to produce antibodies. Activated B cells live for years as memory cells and can rapidly expand and differentiate to produce high titers of antibodies after reexposure to antigen.

25.9 • The complement system catalyzes bacterial opsonization and cell destruction. Complement is triggered by antibody interactions or by interactions with nonspecific activators such as mannose-binding lectin. Complement activation may be a product of either innate or adaptive immunity. Complement may enhance phagocytosis or cause target cell lysis.

Ancient Hominids Helped Shape Modern Immunity

Genes encoding the human immune system class I major histocompatibility proteins (also called the human leukocyte antigens, or HLAs) are highly polymorphic, with several hundred alleles at some loci. HLA gene products are critically important for presenting antigens to T cells in early steps of the immune response. We can trace an individual's ancestry by inspecting that person's spectrum of HLA genes, which is also one method of proving (or disproving) paternity. But in exciting new research on human origins, HLA genes are being used to track the ancestry and migration of ancient humans.¹

The research study suggests that some HLA genes in modern humans were acquired by early human interbreeding with at least two related hominid groups that later became extinct, the Neanderthals and Denisovans. The Denisovans, a lineage recently discovered in Siberia, were a group of hominids closely related to the Neanderthals (photo) that populated large parts of Eurasia.

Denisovan HLA genes are found today in contemporary humans from South Pacific islands and in the Aboriginal peoples of Australia. The implication is that the Denisovans lived in Eurasia and interbred with humans as they migrated out of Africa and eventually populated the South Pacific islands and beyond. However, since other modern Asians do not have Denisovan HLAs, a second migration must have occurred, one that did not interbreed with Denisovans, presumably because they were extinct.

Denisovan HLA genes are not found in African peoples. Thus, our human ancestors that migrated out of Africa must have acquired Denisovan genes only after the migrations had occurred. The Denisovan HLA genes provided modern humans with additional genetic diversity and likely enhanced the overall immune response and improved survival.

In this chapter we examine molecules of the innate immune response and the adaptive response, and the mechanisms that affect cell differentiation and activation in immunity. First we examine the innate immune response proteins that interact with

shared molecular targets on pathogens. We then discuss the structure and development of receptors of the adaptive immune response. We conclude by presenting the mechanisms that activate the adaptive immune response.

I • Receptors and Immunity

26.1 Innate Immunity and Pattern Recognition

An *innate* recognition system for recognizing and controlling pathogens is widely distributed in multicellular organisms from primitive plants to vertebrate animals. Many invertebrates have genes homologous to the pattern recognition receptors found in higher animals.

Pathogen-Associated Molecular Patterns and Pattern Recognition Receptors

Pathogen-associated molecular patterns (PAMPs) are structural components common to a particular group of infectious agents. PAMPs are often macromolecules and include polysaccharides, proteins, nucleic acids, or even lipids. The lipopolysaccharide

(LPS) of the gram-negative bacterial cell wall (☞ Section 2.11) is an excellent example of a PAMP.

Pattern recognition receptors (PRRs) are a group of soluble and membrane-bound host proteins that interact with PAMPs (Table 26.1). An example of a soluble extracellular PRR is mannose-binding lectin (MBL) (☞ Section 25.9). The PAMP recognized by MBL is the sugar mannose, found as a repeating subunit in bacterial and fungal polysaccharides (mannose on mammalian cells is inaccessible to MBL). C-reactive protein, an extracellular soluble PRR, is an *acute phase protein* produced by the liver in response to inflammation. C-reactive protein interacts with the phosphocholine macromolecules of gram-positive bacteria cell walls. Both of these PRRs target pathogen surface PAMPs, and both bind complement proteins, leading to lysis or opsonization of the targeted cell.

EXPLORE THE MICROBIAL WORLD

Multicellular organisms such as invertebrates and plants lack adaptive immunity, but they have a well-developed innate response to a wide variety of pathogens. Virtually all of these respond by recognizing molecules found on the pathogen cell or virus. These molecules contain conserved, repetitive structures called pathogen-associated molecular patterns (PAMPs) that include such things as the LPS and flagellin of gram-negative bacteria, the peptidoglycan of gram-positive bacteria, and the double-stranded RNA molecules unique to certain viruses, among others. By recognizing features shared by many pathogens, the innate immune mechanism has evolved to provide protection against most common pathogens.

Responses to pathogens by the fruit fly, *Drosophila melanogaster* (Figure 1), have provided insight into innate immune mechanisms in many other groups of organisms. Several proteins required for fruit fly development are also important receptors for recognizing invading bacteria, functioning as pattern recognition receptors (PRRs) that interact with PAMPs on the macromolecules produced by the pathogen. The best example of a PRR is *Drosophila* Toll, a transmembrane protein essential for dorsoventral axis formation as well as in the innate immune response of the fly.

Toll immune signaling is initiated by the interaction of a pathogen or its components with the Toll protein displayed on the surface

of phagocytes. *Drosophila* Toll, however, does not interact directly with the pathogen. Signal transduction events start with the binding of a PAMP such as the lipopolysaccharide (LPS) of gram-negative bacteria (► Section 2.11) by one or more accessory proteins (Figure 26.1 shows the analogous TLR-4 system in humans). The LPS-accessory protein complex then binds to Toll. The membrane-integrated Toll protein initiates a signal transduction cascade, activating a nuclear transcription factor and inducing transcription of several genes that encode antimicrobial peptides. Toll-associated transcription factors induce expression of antimicrobial peptides, including drosomycin, active against fungi; diptericin, active against gram-negative bacteria; and defensin, active against gram-positive bacteria. The peptides, produced in the liver-like fat body of *Drosophila*, are released into the fly's circulatory system where they interact with the target organism and cause cell lysis.

Structurally, the Toll proteins are related to lectins, a group of proteins found in all multicellular organisms including invertebrates and plants. Lectins interact specifically with certain oligosaccharide monomers. In humans, Toll-like receptors (TLRs) react with a wide variety of PAMPs. As with *Drosophila* Toll, human TLR-4 provides innate immunity against gram-negative bacteria through indirect interactions with LPS, initiating a kinase signal cascade and activating the nuclear transcription factor

NF κ B. NF κ B activates transcription of cytokines and other phagocyte proteins involved in the host responses (Figure 26.1).

Drosophila Toll is an evolutionary, structural, and functional relative of the Toll-like receptors in higher vertebrates, including humans. Toll and its homologs are evolutionarily ancient, highly conserved components of the innate immune system in animals and have even been found in plants.

PRRs were first recognized as evolutionarily conserved membrane-associated receptors in the invertebrate *Drosophila* (the fruit fly), where they were called Toll receptors (see Explore the Microbial World, “*Drosophila* Toll Receptors—An Ancient Response to Infections”). Structural, functional, and evolutionary homologs of the Toll receptors, called *Toll-like receptors* (TLRs), are widely expressed on mammalian innate immune cells. TLRs are found associated with membranes on the surface or in intracellular vesicles in macrophages, monocytes, dendritic cells, and neutrophils, all of which are phagocytes that have the ability to engulf and destroy pathogens. At least nine TLRs in humans interact with a variety of cell surface and soluble PAMPs from viruses, bacteria, and fungi.

The *NOD-like receptors* (NLRs) are a family of PRRs having a nucleotide-binding oligomerization domain (NOD). NLRs are soluble PRRs found in the cytoplasm. NOD1 and NOD2 interact with peptidoglycan components of gram-negative and gram-positive bacterial cell walls, respectively, stimulating production of antimicro-

bial peptides and inflammatory cytokines (Table 26.1). NOD-like receptor pyrin 3 (NLRP3) interacts with other proteins to form a structure called an *inflammasome*. The cytoplasmic inflammasome senses cellular stress indicators such as the loss of potassium (K^+) ions from damaged cells, triggering the production of proinflammatory cytokines and initiating inflammation.

Several TLRs interact with more than one PAMP. For example, TLR-4 is part of the innate immune response to bacterial LPS and also responds to *heat shock proteins* produced by damaged host cells. Both LPS and heat shock protein interact with TLR-4 via receptor proteins that, in turn, interact with TLR-4. In other cases, the TLR binds directly to the PAMP without the interactions of receptor proteins, as is the case for TLR-5 and its target, flagellin.

Signal Transduction in Phagocytes

Interaction of a PAMP with a PRR triggers transmembrane signal transduction, initiating gene transcription and translation

of host-response proteins similarly to the membrane signal transduction mechanisms in prokaryotes (see Section 7.7). Signal transduction initiated by PAMP–PRR interaction results in enhanced phagocytosis, killing of pathogens, inflammation, and tissue healing (see Section 24.5).

For example, a signal transduction pathway may be activated by the binding of LPS (a PAMP) to TLR-4 (a PRR) (Figure 26.1). TLR-4 then binds proteins in the cytosol, starting a cascade of reactions that activates transcription factors such as NF κ B (nuclear factor kappa B), a protein that binds to specific regulatory sites on DNA, initiating transcription of downstream genes. Many of the NF κ B-regulated genes encode host-response proteins such as the cytokines that activate cells and initiate inflammation.

TLR-4 consists of three distinct protein domains, each with a separate function. The external domain of TLR-4 contains a binding site for LPS complexed with a cell surface protein called CD14 (Figure 26.1). A transmembrane domain in TLR-4 connects the external domain to a cytoplasmic domain. Binding of the CD14–LPS complex by the TLR-4 external domain causes a change in the conformation of a third TLR-4 domain extending into the cytoplasm, exposing a site that interacts with an adaptor protein, MyD88. MyD88, in turn, is conformationally altered and binds a protein tyrosine kinase (PTK), IRAK4. PTKs transfer energy-rich phosphates from ATP to target-protein tyrosines that are exposed when binding alters conformation. In this case, binding of MyD88 by IRAK4 activates the kinase activity of IRAK4, initiating a kinase cascade through ATP-mediated phosphorylation of TRAF6, another kinase. TRAF6 then phosphorylates I κ K (inhibitor of kappa kinase). I κ K then phosphorylates the I κ B (inhibitor of kappa B) protein, causing it to dissociate from NF κ B. The uninhibited NF κ B then diffuses across the nuclear membrane, binds to NF κ B-binding motifs on DNA, and initiates transcription of downstream genes.

As this example shows, signal transduction pathways initiate activation of transcription through ligand–receptor binding on the cell surface. The ligand–receptor interaction outside the cell induces the binding, recruitment, and concentration of the adaptor proteins and kinase enzymes inside the cell. A single kinase can phosphorylate many signal cascade proteins, amplifying the effect of a single ligand–receptor interaction. Signal transduction leading to activation of shared transcription factors and protein production is also the activation mechanism for lymphocytes in adaptive immunity, as we will discuss below.

26.2 Adaptive Immunity and the Immunoglobulin Superfamily

The **immunoglobulin gene superfamily** includes genes and their protein products that share structural, evolutionary, and functional features with immunoglobulin genes and proteins.

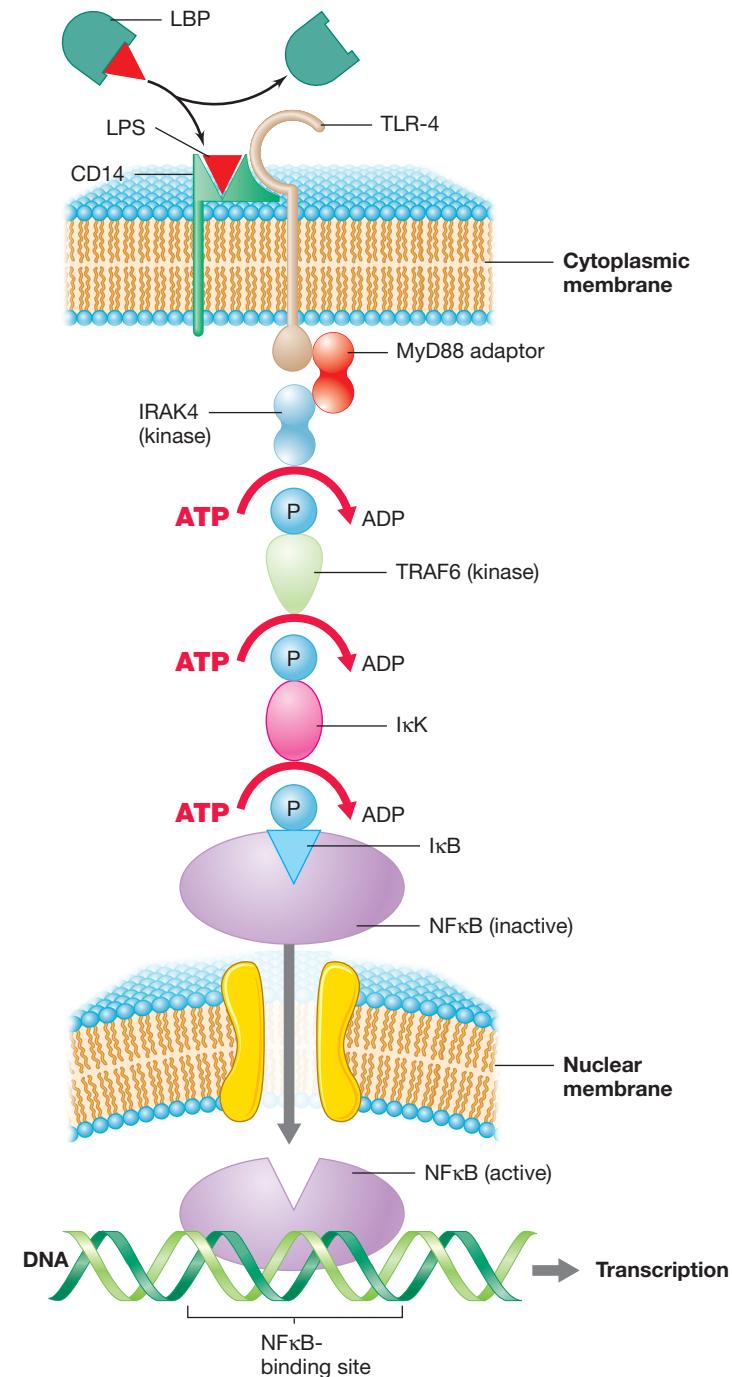

Figure 26.1 Signal transduction in innate immunity. Signal transduction is initiated when LPS, a PAMP, is bound by LBP (lipopolysaccharide-binding protein), which then transfers LPS to CD14 on the surface of a phagocyte. The LPS–CD14 complex then binds to the transmembrane TLR-4 receptor. The binding of TLR-4 initiates a series of reactions involving adaptor proteins and kinases, resulting in activation of the transcription factor NF κ B. NF κ B then diffuses across the nuclear membrane, binds to DNA, and initiates transcription of proteins essential for innate immunity.

The antigen-binding proteins of the adaptive immune response are part of this extended gene family.

As we discussed in Chapters 24 and 25, three different cell surface proteins interact directly with antigens during the adaptive immune response. These are the *immunoglobulins* (*Igs* or

antibodies) produced by B cells that interact with antigens; the antigen-binding *T cell receptors* (TCRs) on the surface of T cells; and the proteins of the *major histocompatibility complex* (MHC) that present processed antigen. Each of these three antigen-binding proteins has a different location, structure, and function. IgS, found on the surface of B lymphocytes and in serum and mucosal secretions, interact directly with extracellular antigens (► Section 25.7). TCRs, found exclusively on T cells, also bind antigen, but only when it is presented by MHC proteins (► Section 25.4).

Structure and Evolution of Antigen-Binding Proteins

Ig, TCR, and MHC proteins share structural features and have evolved by duplication and selection of genes encoding primordial antigen receptors. Some important Ig superfamily proteins are shown in **Figure 26.2**. The proteins consist of a number of discrete domains.

Each protein has at least one domain with a highly conserved amino acid sequence called a *constant (C) domain*. The C domain typically has about 100 amino acids with an intrachain disulfide bond spanning 50–70 amino acids. C domains provide structural integrity for the antigen-binding molecules, attach the antigen-binding V domains to the cytoplasmic membrane, and give each protein its characteristic shape. C domains can also provide recognition sites for accessory molecules. For example, C domains of most IgG and all IgM proteins are bound by the C1q component of complement, a critical first step in initiating the complement activation sequence (► Section 25.9). Likewise, MHC class I C domains bind to the accessory CD8 protein on T-cytotoxic (Tc) lymphocytes, and homologous MHC class II C domains bind CD4 on T-helper (Th) cells. MHC I–CD8 and MHC II–CD4 interactions are critical steps for T cell activation and immune response development (► Section 25.4).

The *variable (V) domains* of TCR and Ig are about the same size as the constant domains, but V-domain structures can be considerably different from one another and from the C domains. Ig and TCR V domains have evolved to interact with a wide variety of antigens. By contrast, the V domains of MHC proteins have evolved independently of Ig and TCR V domains; they interact with nonself peptides, resulting in the MHC–peptide complex recognized by a TCR.

TCR, Ig, and MHC proteins each consist of two nonidentical polypeptides. The TCR consists of an alpha (α) and a beta (β) chain. MHC proteins also consist of two different polypeptide chains, again designated α and β (► Section 25.4). IgS have a separate heavy and light chain (► Section 25.7). These heterodimers are expressed on a cell surface and bind antigens. However, the specific function of each of these molecules is quite different. IgS can be anchored on B cell surfaces where they bind to pathogens and their products such as toxins. IgS are also produced in large quantities as soluble serum and mucosal proteins. TCRs are found exclusively on T lymphocytes and interact with antigenic peptides derived from processed pathogen proteins. These peptides are presented by the MHC proteins on target cells or specialized antigen-presenting cells, or APCs (as we discussed in Section 25.4, APCs include macrophages, dendritic cells, and B lymphocytes).

Signal Transduction in Antigen-Reactive Lymphocytes

B cells and T cells interact with antigen through their Ig and TCR antigen receptors, respectively. As with the membrane-integrated PRRs in the innate immune response, the antigen-specific IgS and TCRs transmit a signal from receptor binding across the cytoplasmic membrane to enhance transcription and activate the cell. B and T lymphocytes use the antigen-binding Ig and TCR proteins to transfer signals across the membrane by connecting

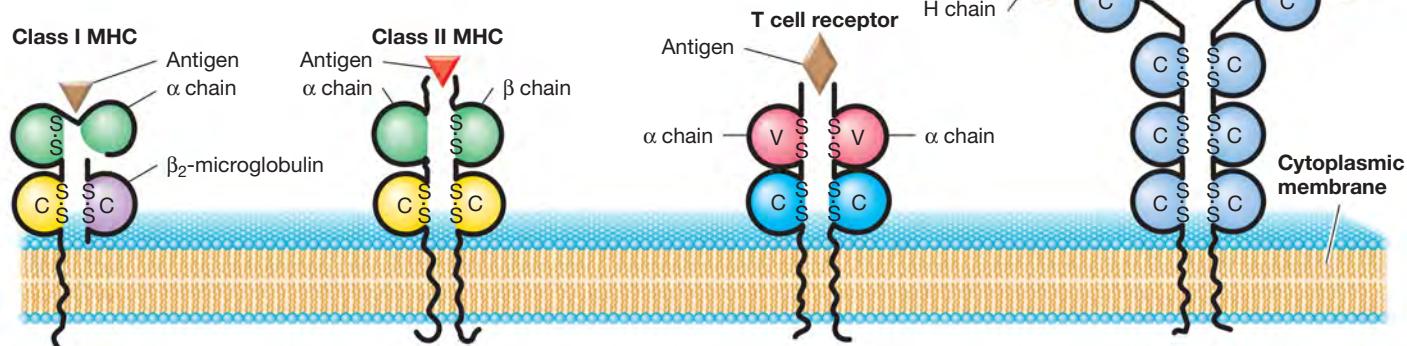

Figure 26.2 Immunoglobulin gene superfamily proteins. Constant domains have homologous amino acid sequences and higher-order structures. The Ig-like C domains in each protein chain indicate evolutionary relationships that identify the proteins as members of the Ig gene superfamily. The V domains of IgS and TCRs are also Ig domains, but the peptide-binding domains of MHC class I and class II proteins are not because their structures vary considerably from the basic features of the Ig domain.

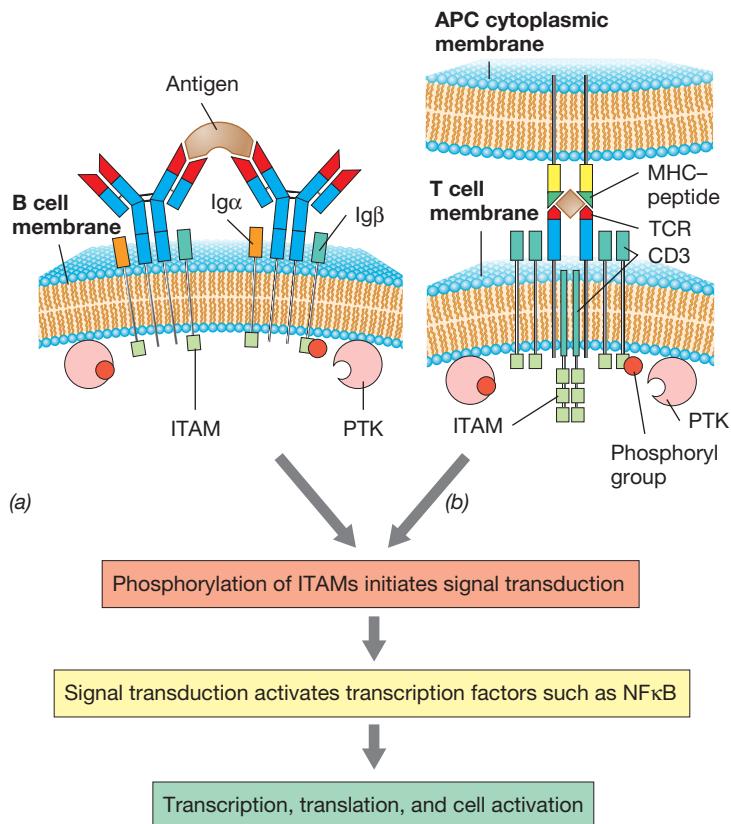

Figure 26.3 Signal transduction in adaptive immunity. (a) The surface Ig on B cells associates with two adaptor proteins, Ig α and Ig β , in the cytoplasmic membrane. The adaptor proteins contain multiple ITAMs (immune-based tyrosine-activation motifs) that are exposed when antigen binds and cross-links Ig. Phosphorylation of the ITAMs by kinases initiates signal cascades and induces activation of transcription factors, including NF κ B, which initiate transcription. (b) The TCR also associates with adaptor proteins, collectively called CD3. TCR interaction with the MHC-peptide complex exposes the ITAMs on the CD3 components, leading to phosphorylation, signal transduction, activation of transcription factors, and translation of T cell-specific proteins.

to the common signal transduction pathways inside the cell. The antigen receptors, however, cannot directly connect to the signal transduction pathways because Iggs and TCRs have very small cytoplasmic domains. These domains do not interact directly with the adaptor proteins common to signal transduction pathways. In addition, the cytoplasmic domains of neither Iggs nor TCRs have cytoplasmic tyrosines that can be phosphorylated (Figure 26.3).

To get around this problem, both receptors associate with adaptor molecules that have *immune-based tyrosine-activation motifs* (ITAMs), possessing tyrosine residues that can be phosphorylated. These adaptor proteins are Ig α and Ig β for immunoglobulins (Figure 26.3a) and the CD3 complex for TCRs (Figure 26.3b). The adaptors associate noncovalently with their respective antigen receptors in the membrane. Antigen binding by the Ig or TCR provokes conformational changes in the adaptor proteins. These changes expose the adaptor proteins' cytoplasmic ITAMs, which are then phosphorylated by a family of protein–tyrosine kinases (PTKs), as shown in Figure 26.3b. As in signal transduction in the innate response, the kinase reaction initiates a cascade, culminating in the activation of NF κ B and other transcription factors, and initiating transcription of downstream genes.

These transcription factors induce the transcription of downstream genes such as the heavy and light chain immunoglobulin genes in B cells, leading to translation and immunoglobulin production. In T cells, transcription factors may cause transcription of TCR genes and also cytokine genes, leading directly to translation and expression of cytokines and activation of more antigen-reactive cells.

II • The Major Histocompatibility Complex (MHC)

The major histocompatibility complex (MHC) genes are found in all vertebrates and encode MHC proteins that are responsible for tissue transplant rejection and, more importantly, present processed peptide antigens to TCRs. The MHC spans about 4 Mbp on human chromosome 6 and is called the **human leukocyte antigen** (HLA) complex (Figure 26.4).

26.3 MHC Proteins

MHC proteins are always expressed on cell surfaces as a complex with an embedded peptide. In normal cells, the embedded peptide is derived from breakdown products of cell metabolism. Thus, the MHC proteins hold embedded *self* peptides. In cells infected with a virus, however, many of the embedded peptides are derived from the virus. These viral peptides complexed with the MHC protein look much like the variant MHC proteins on

a transplant. As a result, the MHC–virus peptide complexes are recognized as *nonself* and are targeted for destruction by Tc cells. The MHC proteins present peptides to T cells for screening and potential targeting (Section 25.4).

MHC proteins consist of two classes. *MHC class I proteins* are found on the surfaces of all nucleated cells. As a rule, the class I proteins present peptide antigens to Tc cells. If class I–embedded peptides are recognized by Tc cells, the antigen-containing cell is targeted and directly destroyed (Section 25.5). *MHC class II proteins* are found only on the surface of B lymphocytes, macrophages, and dendritic cells, the professional APCs (Section 25.4). Through the class II proteins, the APCs present antigens to the Th cells, stimulating cytokine production that leads to antibody-mediated immunity or inflammatory responses (Section 25.6).

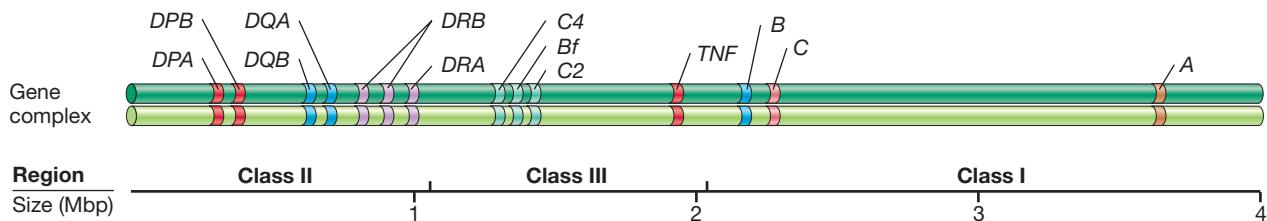

Figure 26.4 The human leukocyte antigen (HLA) gene map. The HLA complex, located on chromosome 6, is more than 4 million bases in length. Class II genes *DPA* and *DPB* encode class II proteins DP α and DP β ; *DQA* and *DQB* encode DQ α and DQ β ; *DRA* and two *DRB* loci encode DR α and DR β proteins. The class I MHC proteins HLA-B, HLA-C, and HLA-A are encoded by genes *B*, *C*, and *A*. The class II and class I loci are highly polymorphic and encode peptide-binding proteins. Class III MHC genes encode proteins associated with immune-related functions such as complement proteins C4 and C2, and the cytokine TNF (tumor necrosis factor).

Class I MHC Proteins

An MHC class I protein consists of two polypeptides (Figure 26.5a). The gene for the membrane-integrated alpha (α) chain is in the MHC gene region on chromosome 6. The other class I polypeptide is the noncovalently associated beta-2 microglobulin ($\beta_2\text{m}$). The three-dimensional structure of class I MHC protein interacts with the antigen peptide and the TCR simultaneously. The class I α chain folds to form a groove that is closed on both ends. The groove lies between two α -helices that straddle a β -sheet. In the endoplasmic reticulum, the MHC I groove is loaded with peptides of about 8 to 11 amino acids in length, derived from degraded *endogenous* proteins (Figure 26.5b). For example, viral proteins produced inside the cell are degraded into peptides and loaded into class I MHC proteins. The MHC-peptide complex then moves to the cell surface to be recognized by TCRs on Tc cells (Section 25.4).

Class II MHC Proteins

An MHC class II protein consists of two noncovalently associated, membrane-integrated polypeptides, α and β , found only on APCs. One α and one β polypeptide, expressed together, form a functional heterodimer (Figure 26.5c). The heterodimers may be arranged in pairs or trimers that enhance their stability. The $\alpha 1$ and $\beta 1$ domains of the class II protein interact to form a binding site for TCR-peptide similar to the class I binding site for TCR-peptide. However, the ends of the groove are open, permitting the class II protein to bind and display peptides that may be significantly longer than 8–11 amino acids. Class II-binding peptides, generally 10 to 20 amino acids long, are proteolytic fragments derived from *exogenous* pathogens internalized and processed by the APCs (Section 25.4). The APCs use the class II-peptide complex to interact with TCRs on Th cells, leading to Th activation (Section 25.6).

26.4 MHC Polymorphism, Polygeny, and Peptide Antigen Binding

The human MHC class I and class II genes encode peptide-binding proteins that bind antigen peptides for presentation to T cells. The many variations of these proteins collectively bind all known peptides.

Polymorphism and Polygeny

Polymorphism is the occurrence in a population of multiple alleles (alternate forms of a gene) at a specific locus (the location of the gene on the chromosome) in frequencies that cannot be explained by recent random mutations. For example, the MHC class I locus *HLA-A* has 2013 known alleles. These genetic variations encode 2013 distinct HLA-A proteins. Each person, however, has only two of the *HLA-A* alleles; one allele is of paternal origin and one is of maternal origin; the polymorphisms reside in the entire human population. The two allelic protein products are expressed *codominantly* (equally) (Figure 26.6a).

In addition, gene duplication events during evolution resulted in two additional genetically, structurally, and functionally related polymorphic loci, *HLA-B* and *HLA-C*. The occurrence of multiple copies of evolutionarily, genetically, structurally, and functionally related genes is called **polygeny**. *HLA-B* has 2605 known allelic variants; *HLA-C* has 1551 known alleles. Thus, an individual usually displays six structurally distinct proteins derived from the three polymorphic class I loci (three products derived from maternal origin and three products derived from paternal origin) (Figure 26.6b). Likewise, highly polymorphic alleles encode MHC class II proteins at the *HLA-DR*, *HLA-DP*,

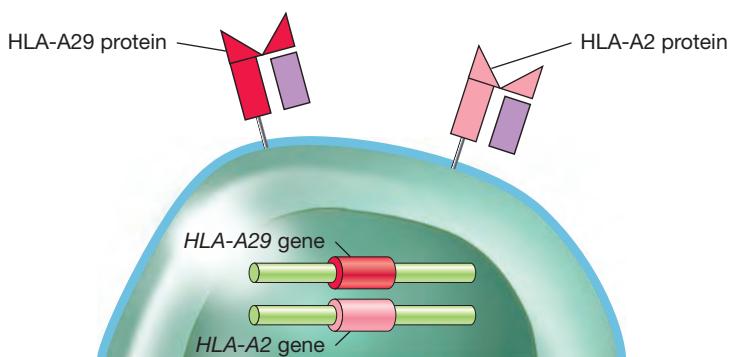

and *HLA-DQ* alpha- and beta-chain loci. Class II gene products are also expressed codominantly, resulting from the 12 alleles that encode distinct class II alpha and beta proteins.

As a result of polygeny, most individuals have unique MHC profiles; only closely related family members are likely to have all of the same MHC genes and proteins. These highly polymorphic variations in MHC proteins are major barriers to successful tissue transplants because the MHC proteins on the donor tissue (graft) are recognized as foreign antigens by the recipient's immune system. An immune response directed against the graft MHC proteins causes graft death and rejection. Tissue graft rejection, however, is minimized by matching MHC alleles between donors and recipients. Control of rejection can also be accomplished through drugs that suppress the immune system.

Peptide Binding

Most of the allelic variations in MHC proteins occur as amino acid changes concentrated in the antigen-binding groove, and each polymorphic variation of the MHC protein binds a different set of peptide antigens. The peptides bound by a single MHC protein share a common structural pattern, or peptide **motif**, and each different MHC protein binds a different motif. For example, for a certain class I protein, the bound peptides contain eight amino acids with a phenylalanine (F) at position 5 and a leucine (L) at position 8. All other positions in the peptide can be occupied by any amino acid (X). Thus, all peptides sharing the sequence X-X-X-X-F-X-X-L would bind that MHC protein. Another MHC class I protein encoded by a different MHC allele binds a different motif, with nine amino acids and invariant amino acids tyrosine (Y) at position 2 and isoleucine (I) at position 9 (X-Y-X-X-X-X-X-I).

The invariant amino acids in each motif are *anchor residues*: They bind directly and specifically within an individual MHC-peptide binding groove. Thus, an individual MHC protein can bind and present many different peptides if the peptides contain the same anchor residues. Since each MHC protein binds a different motif with different anchor residues, the six possible MHC

(a) Polymorphism

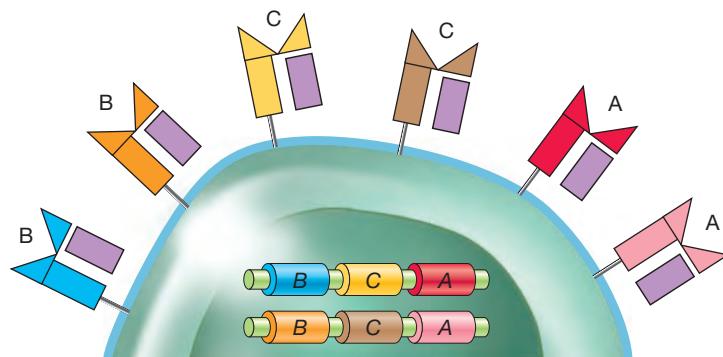

Figure 26.6 Polymorphism and polygeny in MHC genes and proteins. (a) Polymorphism in *HLA-A* loci results in codominant expression of proteins encoded by both alleles. There are over 2000 *HLA-A* alleles in the human population, but only two (one at each locus) are found in each individual. *HLA-B* and *HLA-C* exhibit similar levels of polymorphism. (b) Polygeny in MHC results in duplicated polymorphic *HLA-A*, *HLA-B*, and *HLA-C* genes that potentially encode three pairs of different MHC proteins. The colors represent alternate alleles of each gene and their respective protein.

I proteins in an individual bind six different motifs. In this way, each individual can present a large number of different peptide antigens using the limited number of MHC I molecules available. MHC II proteins bind peptides in an analogous manner. As a result, within the human species, at least a few peptide antigens from each pathogen will display a motif that will be bound and presented by the MHC proteins. This system is very different from the mechanisms employed by IgS and TCRs that also bind antigens. Each Ig or TCR interacts very specifically with only

a *single* antigen. As we shall see, these proteins employ unique genetic mechanisms to generate virtually unlimited diversity (Sections 26.6 and 26.7).

III • Antibodies and T Cell Receptors

Here we look at the structure, antigen-binding function, genetic organization, and generation of diversity in the infinitely variable immunoglobulins and T cell receptors.

26.5 Antibody Proteins and Antigen Binding

Antibodies consist of four polypeptides, two heavy chains (H) and two light chains (L) (Figure 26.2), arranged as a pair of heterodimers. Each heterodimer consists of a light-chain-heavy-chain pair and is a complete antigen-binding unit. The heavy and light chains are further divided into C (constant) and V (variable) domains. The C domains are responsible for common functions such as complement binding (Section 25.9). The V domains of one H and one L chain interact to form an antigen-binding site (Figure 26.7). Here we examine the structural features of the V domains and the antigen-binding site.

Variable Domains

Amino acid sequences are considerably different in the V domains of different IgS (Figure 26.7). Amino acid variability is especially apparent in several **complementarity-determining regions (CDRs)**. The three CDRs in each of the V domains provide most of the molecular contacts with antigen. CDR1 and CDR2 differ somewhat between different immunoglobulins, but the CDR3s differ dramatically from one another. The CDR3 of the heavy chain has a particularly complex structure, encoded within three distinct gene segments, as we shall see shortly. The CDR3 consists of the carboxy-terminal portion of the V domain, followed by a short “diversity” (D) segment of about three amino acids, and a longer “joining” (J) segment about 13–15 amino acids long. The light-chain CDR3 is similar, but lacks the D segment. The heavy- and light-chain CDRs cooperate in antigen binding.

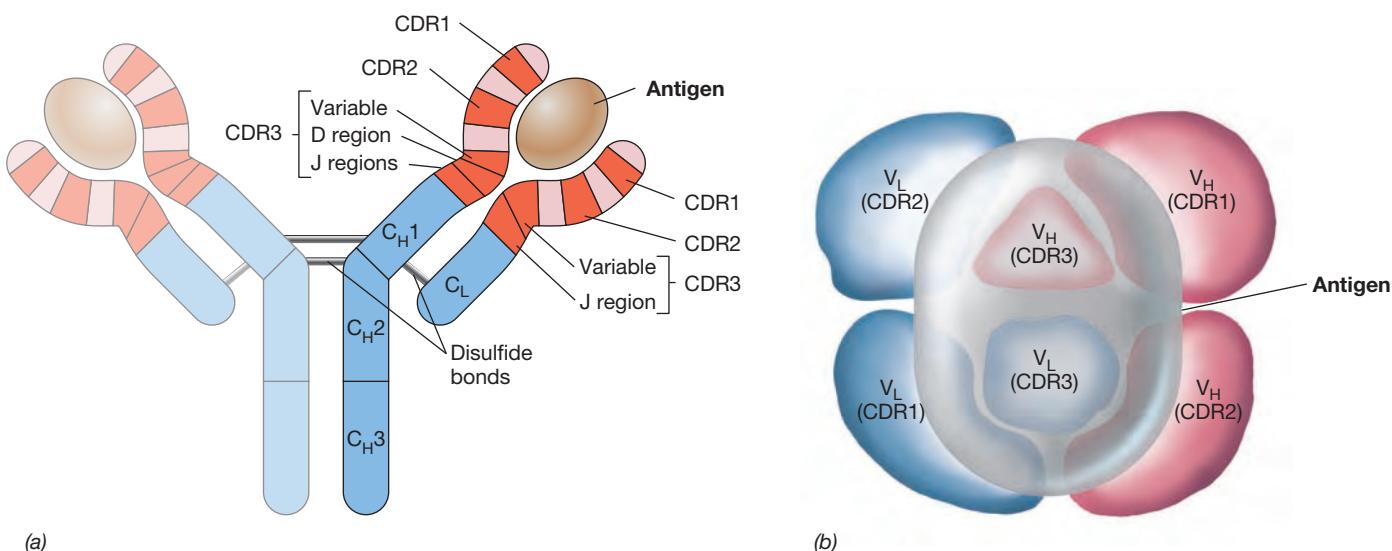

Figure 26.7 Antigen binding by immunoglobulin light and heavy chains. (a) An Ig is shown schematically, with bound antigen. The V domains on the H and L chains are shown in red, with the antigen-binding CDR1, CDR2, and CDR3. C_H1, C_H2, and C_H3 are constant domains in the H chain, and C_L is the constant domain in the L chain. (b) Complementarity-determining regions (CDRs) from both H (red) and L (blue) chains, shown from above, are conformed to make a single antigen-binding site on the Ig. The highly variable CDR3s from both H and L chains cooperate at the center of the site. Antigen, shown in gray, may contact all CDRs. The shape of the site may be a shallow groove or a deep pocket, depending on the antibody–antigen pair involved.

Antigen Binding

The Ig three-dimensional structure was shown in Figure 25.16. Each antigen–antibody reaction requires the specific combination of the antigen with the cooperating variable domains of the heavy and light chains. The antigen-binding site of an antibody molecule measures about 2×3 nm, large enough to accommodate a small portion of the antigen, called an *epitope*, about 10 to 15 amino acids long. Antigen binding is ultimately a function of the Ig folding pattern of the heavy and light polypeptide chains. The Ig folds of the V region bring all six CDRs (CDR1, 2, and 3 from both heavy and light chains) together. The result is a unique and specific antigen-binding site (Figure 25.16 and Figure 26.7). In the next section, we examine the genetic mechanisms that generate the tremendous diversity found in the Ig proteins.

Each antibody binds each antigen with a characteristic affinity (binding strength). The affinity of an antibody is typically highest for the antigen for which it was selected, and antibodies usually do not bind other antigens. However, some antibodies will interact, usually weakly, with antigens other than the selecting antigen. This phenomenon is called a *cross reaction*.

26.6 Antibody Genes and Diversity

For most proteins, one gene encodes one protein. However, this is not the case with the heavy and light chains of immunoglobulins. Because the collection of antibodies in each individual must recognize and bind a wide variety of molecular structures, the immune system must generate almost unlimited antibody variation. Several mechanisms including *somatic recombination*, random heavy- and light-chain *reassortment*, and *hypermutation* all contribute to the almost limitless diversity generated from a relatively small number of Ig genes. **Table 26.2** summarizes these diversity-generating mechanisms.

Table 26.2 Generation of antigen-binding receptor diversity in B cells and T cells

Diversity-generating mechanism	B cell Ig receptors, heavy and light chains	T cell receptors, α and β chains

Somatic hypermutation	Yes	No

Immunoglobulin Genes

The gene encoding each immunoglobulin H or L chain is constructed from several gene segments. In each B cell, Ig gene segments undergo a series of somatic, random rearrangements (recombination followed by deletion of intervening sequences) to produce a single functional antibody gene derived from the pool of antibody genes. Molecular studies have verified this “genes in pieces” hypothesis by demonstrating that the V, D, and J gene segments encoding heavy-chain V domains, as well as the genes encoding C domains, are separated from one another in the genome. As the B cell matures, the gene segments are brought together (somatically recombined) to form a single Ig heavy-chain gene (Figure 26.8). A single V gene encodes CDR1 and CDR2, whereas CDR3 is encoded by a mosaic of the 3' end of the V gene, followed by the D and J genes.

In each B cell, only one protein-producing rearrangement occurs in the heavy- and light-chain genes. Called *allelic exclusion*, this mechanism ensures that *each B cell produces only one Ig*. Finally, the class-defining constant domains of Igs are encoded by separate C genes. Thus, four different gene segments, V, D, J, and C, recombine to form one functional heavy-chain gene. Similarly, light chains are encoded by recombination products of light-chain V, J, and C genes.

The gene segments required for all Igs exist in all cells but undergo recombination only in developing B lymphocytes. As shown in Figure 26.8, each B cell contains multiple kappa (κ) and a corresponding set of lambda (λ) light-chain V and J genes arranged in tandem. Each B cell also contains tandem heavy-chain V genes, D genes, and J genes. In addition, the heavy-chain constant-domain (C_H) genes and the light-chain constant-domain genes (C_L) are present. The V, D, J, and C genes are separated by noncoding sequences (introns) typical of gene arrangements in eukaryotes. Genetic recombination occurs in each B cell during its development. One each of the V, D, and J segments is randomly recombined to form a functional heavy-chain gene. On another chromosome, V and J segments are also randomly recombined to form a complete light-chain gene. The active gene, still containing an intervening sequence between the VDJ or VJ gene segments and the C gene segments, is transcribed, and the resulting primary RNA transcript is spliced to yield the final messenger RNA (mRNA). The mRNA is then translated to make the heavy and light chains of the Ig molecule.

Reassortment and VDJ Joining

Up to this point, all Ig diversity is generated from recombination of existing genes. In humans, for example, based on the numbers of genes at the kappa (κ) light-chain loci, there are about $40 V \times 5 J$ possible rearrangements, or 200 possible κ light chains. For the alternative lambda (λ) light chain, there are about $30 V \times 4 J = 120$ possible chain combinations. About 6000 possible heavy chains can be formed by the rearrangement of about $40 V \times 25 D \times 6 J$ genes. Each heavy and light chain gene has a theoretically equal possibility of being expressed in each B cell, randomly reassorting all heavy and light chains. The final light chain and heavy chain produced by a given B cell result from assembly of the single translated heavy- and light-chain genes (Figure 26.8c). Assuming that each heavy chain and light

chain has an equal chance to be expressed, there are $6000 \times 200 = 1,200,000$ possible immunoglobulins with κ light chains and $6000 \times 120 = 720,000$ possible immunoglobulins with λ chains. Adding these possibilities together, at least 1,920,000 possible antibodies can be expressed!

Additional diversity is generated in the CDR3 of both heavy and light chains by several unique mechanisms. First, the DNA-joining mechanism responsible for construction of V-D or D-J segments in the heavy chain or the V-J gene segments in the light chain is imprecise; the final sequence at these coding joints frequently varies by a few nucleotides from the genomic sequence. Even more diversity is generated at V-D and D-J coding joints in the heavy-chain genes and at V-J coding joints in light-chain genes by nucleotide additions. Either random (N) or template-specific (P) nucleotides may be added. Since these coding joints are contained within the sequences responsible for encoding CDR3

on both heavy and light chains, N and P diversity at V-domain coding joints changes or adds amino acids in the CDR3 of both heavy and light chains.

Hypermutation

Finally, antibody diversity is expanded even more in B cells by **somatic hypermutation**, the mutation of Ig genes at much higher rates than the mutation rates observed in other genes. Somatic hypermutation of Ig genes is typically evident after a second exposure to an immunizing antigen. Somatic hypermutation occurs only in the V regions of rearranged heavy- and light-chain genes, creating B cells with mutated Ig receptors. These mutated B cells then compete for available antigen. This process selects B cells with receptors having higher antigen-binding strength (affinity) than the original B cell receptor. This *affinity maturation* process is one of the factors responsible for a dramatically

stronger secondary immune response (☞ Figure 25.21). The affinity maturation mechanism adds additional possibilities to the generation of Ig diversity, making the potential antibody repertoire almost limitless.

26.7 T Cell Receptors: Proteins, Genes, and Diversity

T cell receptors (TCRs) are cell surface antigen receptors integrated into the cytoplasmic membrane of T cells. TCRs bind foreign peptides in the context of MHC proteins. The TCRs accomplish this dual binding function through a binding site composed of the V domains of the TCR α and β chains. The α -chain and β -chain V domains of TCRs contain CDR1, CDR2, and CDR3 segments that bind directly to the MHC–peptide antigen complex (☞ Section 25.4).

TCR Proteins

The three-dimensional structure of the TCR bound to MHC–peptide is shown in Figure 26.9. Both TCR and MHC proteins bind directly to peptide antigen. The MHC protein binds one face of the peptide—the MHC motif—whereas the TCR binds the other peptide face—the T cell epitope. The CDR regions of the TCR bind directly to the MHC–peptide complex, and each CDR has a specific binding function. The CDR3 regions of the TCR α chain and β chain bind the antigen epitope; the CDR1 and CDR2 regions of the TCR α and β chains bind mainly to the MHC proteins.

TCR Genes and Diversity

T cells generate receptor diversity in ways similar to the generation of Ig diversity in B cells. Table 26.2 summarizes and compares the receptor diversity-generating mechanisms for each cell type. Analogous to the H and L chains of immunoglobulins, the TCR α and β chains are encoded by distinct constant- and variable-domain gene segments. TCR V-region genes are arranged as a series of tandem segments. The α chain has about 80 V and 61 J genes, whereas the β chain has 52 V genes, 2 D genes, and 13 J genes (Figure 26.10). The β -chain V, D, and J genes and the α -chain V and J genes undergo recombination to form functional V-region genes. As in Igs, somatic

This structure was derived from data deposited in the Protein Data Bank. (b) A diagram of the TCR:MHC–peptide structure. Note that the peptide is bound by both MHC and TCR proteins and has a distinct surface structure that interacts with each.

mutations result from N and P diversity at V-D and D-J coding joints in the β chain and at the V-J coding joint in the α chain. Finally, the D region of the β chain can be transcribed in all three reading frames, leading to production of three separate transcripts from each D-region gene and creating greater diversity than would be expected from the D gene segments alone. As for assembly of Ig H and L chains, individual α and β chains are produced by each T cell at random and assembled to form a complete $\alpha:\beta$ heterodimer. The somatic hypermutation mechanisms responsible for increased receptor diversity in Ig genes do

not operate in T cells and do not generate additional TCR diversity. Potential TCR diversity, however, is still enormous, and on the order of 10^{15} different TCRs can be generated.

MINIQUIZ

- Distinguish among the functions of the CDR1, CDR2, and CDR3 segments of the T cell receptor.
- Identify diversity-generating mechanisms unique to TCRs as compared to diversity-generating mechanisms in Igs.

IV • Molecular Switches in Immunity

In addition to antigen interaction, several factors control immune activity. Clonal selection selects antigen-reactive cells that respond to foreign antigens while ignoring self antigens. A set of unique cell-surface molecular signals are required for activating T cells or B cells. Finally, cytokines and chemokines produced by activated cells recruit other cells in the immune response.

26.8 Clonal Selection and Tolerance

T cells must be able to discriminate between the potentially dangerous nonself antigens and the harmless self antigens that compose our body tissues. Thus, T cells acquire *tolerance*, or specific unresponsiveness to self antigens. Mature immune lymphocytes interact only with nonself antigens.

Clonal Selection

The **clonal selection** theory states that each antigen-reactive B cell or T cell has a cell surface receptor for a single antigen epitope.

When stimulated by interaction with that antigen, each cell can replicate, and antigen-stimulated B and T cells grow and differentiate, producing a pool of cells that expresses the same antigen-specific receptors. A *clone* comprises the identical progeny of the initial antigen-reactive cell (Figure 26.11). Cells that have not interacted with antigen do not proliferate.

To respond to the seemingly infinite variety of antigens, a nearly infinite number of antigen-reactive cells are needed in the body. As we have discussed, the immune system generates a nearly limitless number of antigen-specific B and T cell receptors. Inevitably, some of these receptors will have the potential to react with self antigens in the host; the immune system must eliminate or suppress these self-reactive cells while at the same time selecting cells that may be useful against nonself antigens.

T Cell Selection and Tolerance

T cells undergo immune selection *for* potential antigen-reactive cells and selection *against* those cells that react strongly with self

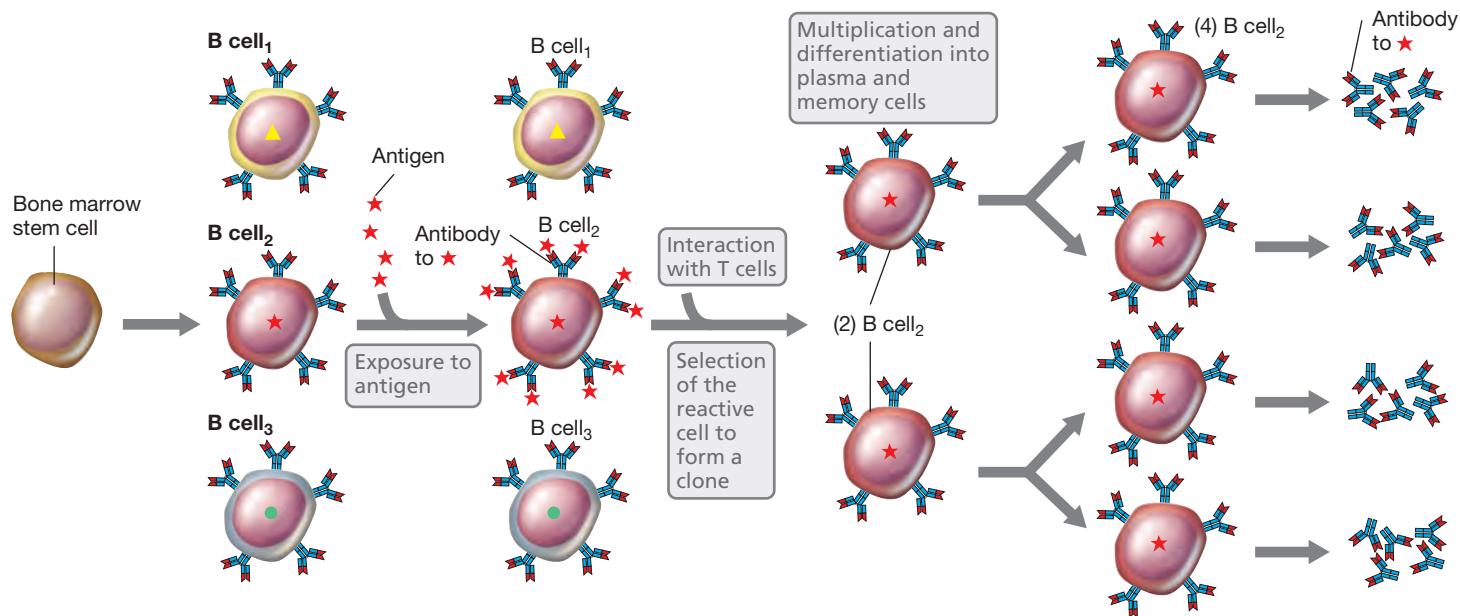

Figure 26.11 Clonal selection. Individual B cells, specific for a single antigen, proliferate and expand to form a clone after interaction with the specific antigen. The antigen drives selection and then proliferation of the individual antigen-specific B cell. Clonal copies of the original antigen-reactive cell have the same antigen-specific surface antibody. Continued exposure to antigen results in continued expansion of the clone.

antigens. Selection against self-reactive cells results in the development of tolerance. The failure to develop tolerance may result in dangerous reactions to self antigens, a condition called *autoimmunity* (➡ Section 24.8).

T lymphocyte precursors leave the bone marrow and enter the thymus, a primary lymphoid organ, via the bloodstream (Figure 26.12). During the process of T cell maturation in the thymus, immature T cells undergo a two-step selection process

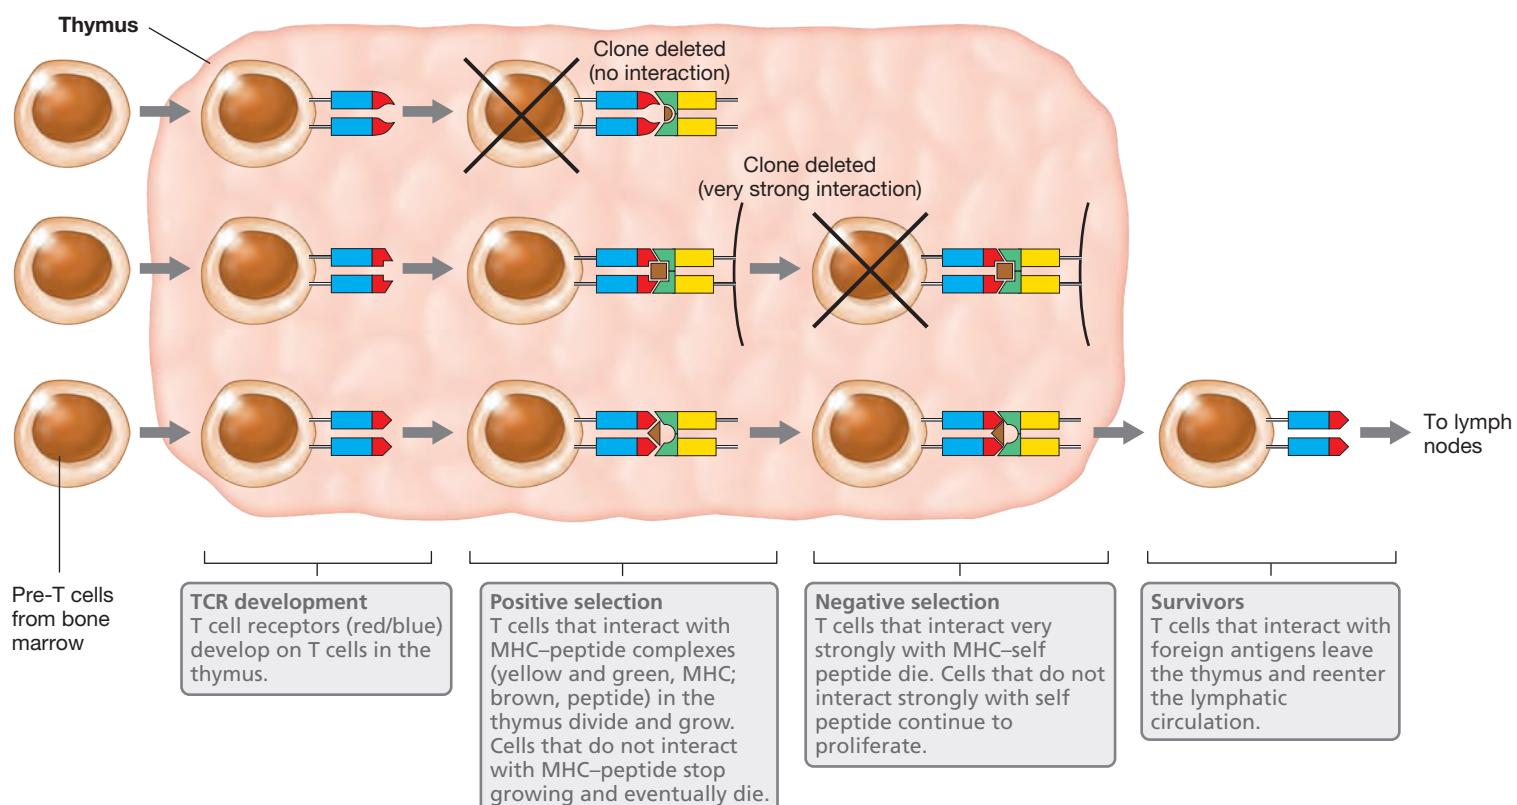

Figure 26.12 T cell selection and clonal deletion. T cells undergo selection for recognition of dangerous nonself antigens in the thymus.

to (1) select potential antigen-reactive cells (positive selection) and (2) eliminate cells that react with self antigens (negative selection). **Positive selection** requires the interaction of new T cells in the thymus with the thymic self antigens; the peptide antigens in the thymus are of self origin. Using their TCRs, some T cells bind to MHC-peptide complexes on the thymic tissue. The T cells that do not bind MHC-peptide complexes undergo *apoptosis*, or programmed cell death, and are permanently eliminated. By contrast, those T cells that bind thymic MHC proteins receive survival signals and continue to divide and grow. Positive selection retains T cells that recognize MHC-peptide and deletes T cells that do not recognize MHC-peptide and would therefore be unable to recognize MHC-peptide outside the thymus.

The second stage of T cell maturation is **negative selection**. Here the positively selected T cells continue to interact with thymic MHC-peptide. T cells that react with thymic self antigens are potentially dangerous if they react very strongly with these antigens (autoimmunity). The very strongly self-reactive T cells bind tightly to thymus cells; these self-reactive T cells cannot divide and eventually die. TCRs that react less strongly with self MHC-peptide survive this selection and live. This two-stage thymic selection process for selecting self-tolerant, antigen-reactive T cells results in **clonal deletion**. Precursors of T cell clones that are either useless (do not bind) or harmful (bind too tightly) die in the thymus; more than 95% of all T cell precursors that enter the thymus do not survive the selection process.

The remaining selected T cells are destined to interact very strongly with nonself antigens. They are not destroyed in the thymus because their weak binding interactions with thymic self antigens signal them to proliferate. The selected and growing T cells leave the thymus and migrate to the spleen, mucosa-associated lymphoid tissue, and lymph nodes, where they can contact foreign antigens presented by B lymphocytes and other APCs.

B Cell Tolerance

The development of tolerance in B cells is also necessary because antibodies produced by self-reactive B cells (autoantibodies) may cause autoimmunity and damage to host tissue (☞ Section 24.8). B cells also undergo a process of clonal deletion. Many self-reactive B cells are eliminated during development in the bone marrow, the primary lymphoid organ responsible for B cell development in mammals.

In addition to clonal deletion, **clonal anergy** (clonal unresponsiveness) also plays a role in final selection of the B cell repertoire. Some immature B cells are reactive to self antigens, but do not become activated even when exposed to high concentrations of self antigens. This is because B cell activation requires a second signal from Th cells, as we shall now see. If no second signal is generated because the available Th cells have been rendered tolerant to the antigen in the thymus, the B cell remains unresponsive.

MINIQUIZ

- Distinguish between positive and negative T cell selection. How do positive and negative selection control the development of tolerance in T cells?
- Distinguish between clonal deletion and clonal anergy in B cells.

26.9 T Cell and B Cell Activation

T and B cells require additional molecular signals for activation in addition to antigen interactions through IgGs or TCRs. Lack of these signals results in unresponsive cells, even if they are exposed to antigen. This mechanism helps to prevent autoimmunity.

T Cell Activation

As we have described, T cells that react strongly with self-antigens are deleted in the thymus. However, many self-antigens are not expressed in the thymus. As a result, many T cell clones responsive to nonthymus antigens avoid clonal deletion in the thymus. These self-reactive T cells become anergic, but may persist as unresponsive T cells. The key to maintaining clonal anergy in these potentially dangerous self-reactive T cells is the signal mechanism used to activate T cells after they leave the thymus.

When positively and negatively selected T cells leave the thymus, they migrate to the secondary lymphoid organs (lymph nodes, spleen, and mucosa-associated lymphoid tissue; ☞ Section 24.1). These antigen-reactive T cells have not yet encountered specific antigen; they are naive or uncommitted T cells. Uncommitted T cells must be activated by an APC to become competent effector cells.

The first step in activation of uncommitted T cells is binding of the MHC–foreign peptide complex on the APC by the TCR (Figure 26.13). This first signal is absolutely required for activation. Without TCR interacting with MHC–peptide, a Tc cell cannot be activated. The next step requires the interaction of two more proteins, one found on the APC, called B7, and one found only on T cells, called CD28. The binding of B7 to CD28, a second signal, activates the Tc cell, making it an effector cell. In the absence of a B7–CD28 interaction, the T cell is not activated (Figure 26.13). A Tc cell that is activated will kill any target cell that displays the MHC–foreign peptide complex, even those cells that do not display B7. After a T cell is activated, only the first signal (TCR binding to MHC–peptide) is necessary to induce killer activity. An analogous situation occurs with Th cells.

T Cell Anergy

The requirement for a second activation signal has major implications for establishing and maintaining clonal anergy. Self antigens that are not found in the thymus are present on many other cells in the body. An uncommitted Tc cell that interacts with a self antigen found on a cell that is not an APC will receive only an MHC–peptide signal because non-APCs do not display the B7 protein necessary to complete the second signal. In the absence of the B7–CD28 interaction, a Tc cell that engages MHC–peptide is permanently anergized and can never be activated (Figure 26.13); the B7–CD28 second signal is absolutely required for activation. Uncommitted Th lymphocytes are activated in the same way, also using the B7–CD28 coreceptor second signal.

B Cell Activation

The B cell also has independent signals other than antigen interaction for activation and antibody production. However, different signals activate B cells than those that activate T cells. As we have seen, B cells are responsible for antigen uptake, processing,

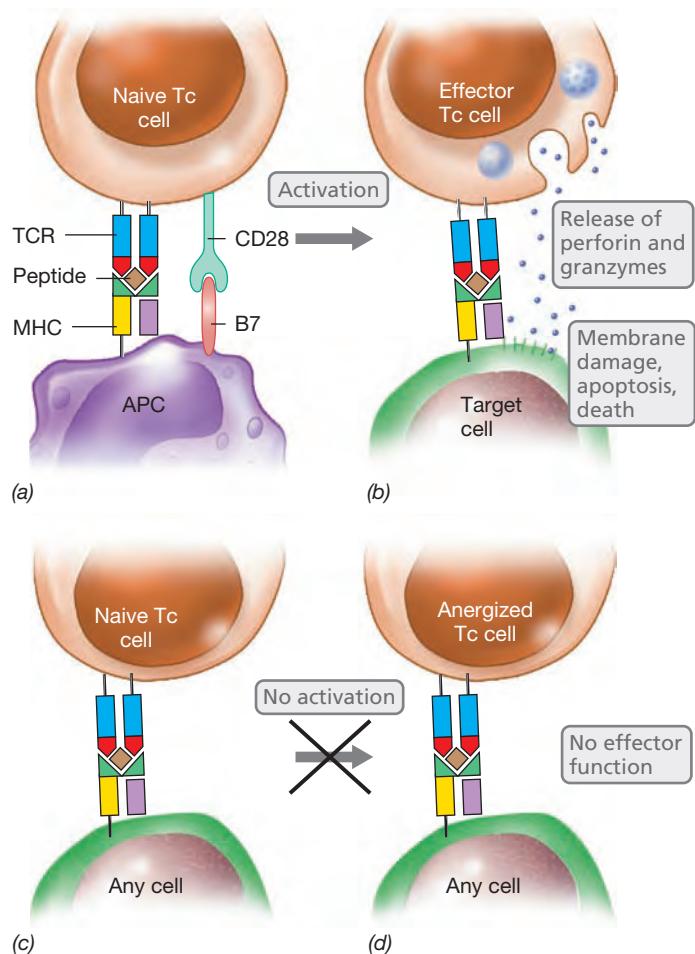

Figure 26.13 T cell activation. (a) A naive Tc cell interacts via TCR with the MHC-peptide complex on an APC, the first required activation signal. CD28 on the Tc cell interacts with B7 on the APC, the second required interaction necessary to activate the naive T cell. (b) The activated Tc cell can kill any target cell with the same MHC-peptide. (c) A naive Tc cell interacts via the TCR with the MHC-peptide complex on any cell. and presentation as well as the production of specific antibodies (Figure 26.14 and [Section 25.8](#)). The first signal for the B cell is antigen binding and cross-linking of surface immunoglobulin.

The second signal for B cell activation involves several molecules. The antigen–Ig interaction first signal generates a transmembrane signal that stimulates the B cell to express CD40 on its surface. Meanwhile, the B cell ingests the antigen bound on the Igs, processes the ingested antigen to peptides, and presents peptide antigen embedded in MHC II to neighboring Th cells (both Th1 and Th2 cells can be involved in this process). Interaction via the TCR:MHC II–peptide complex stimulates expression of CD40L (CD40 ligand) by the Th cells, which in turn binds to the B cell CD40. The CD40L–CD40 interaction initiates signal transduction in the Th cell, leading to transcription of a number of T cell proteins, including IL-4 and other soluble cytokines. The cytokines, secreted by the T cell, interact with cytokine receptors

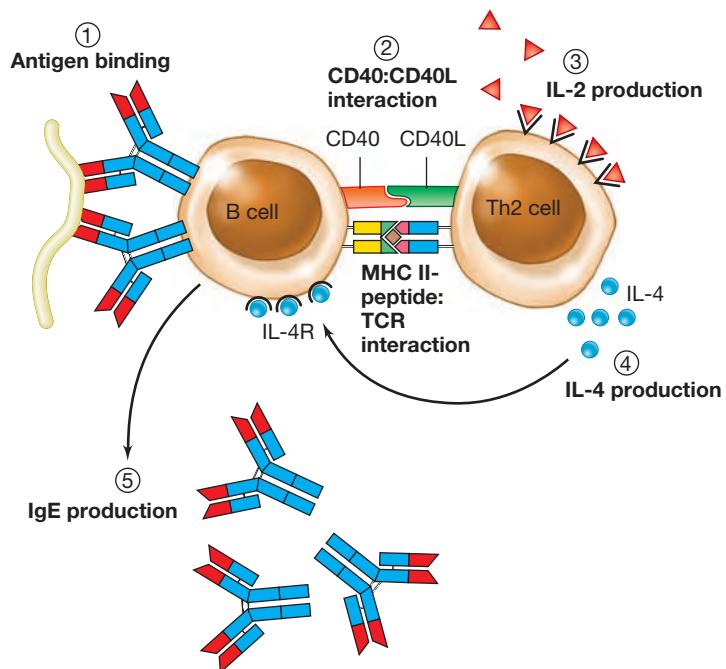

Figure 26.14 B cell activation. ① Antigen binds and cross-links the Ig receptors on a naive B cell, stimulating the B cell to produce CD40 and express it on the cell surface. The B cell processes the antigen and presents it to a Th2 cell via MHC II. ② The Th2 cell TCR interacts with the MHC II–peptide. The Th2 CD40L then interacts with the B cell CD40. ③ These interactions stimulate the Th2 cell to produce IL-2, which stimulates the same Th2 cell (autocrine function). ④ The stimulated Th2 cell can make several cytokines, one of which is IL-4. IL-4 is a final activation signal for this B cell. ⑤ The IL-4-stimulated B cell then produces IgE. Th2 cytokines stimulate both T and B lymphocytes.

on the B cell, completing the second signal for the B cells and stimulating antibody production. Thus, the complete second signal for B cell activation requires two distinct interactions: (1) the interaction of CD40 on the B cell with CD40L on the Th cell; and (2) the interaction of a cytokine produced by the Th cell with the cytokine receptor on the B cell.

After a B cell is activated, it no longer needs T cell interactions or cytokines to make antibody; antigen interaction alone can then stimulate antibody production. Some activated B cells will be transformed into plasma cells that will secrete large amounts of antibody in the primary immune response. Others remain as *memory B cells* and play a major role in the secondary immune response during subsequent exposure to an antigen ([Section 25.8](#)).

26.10 Cytokines and Chemokines

Intercellular communication in the immune system is accomplished in many cases through a heterogeneous family of *cytokines*, soluble proteins produced by leukocytes and other cells.

Cytokines regulate cellular functions in immune cells and activate various cell types. The cytokines produced by lymphocytes are often called *lymphokines* or *interleukins* (ILs).

Cytokines bind specific receptors. Some cytokines bind to receptors on the cell that produced them. Thus, these cytokines have autocrine (self-stimulatory) abilities. Other cytokines bind to receptors on other cells. Cytokine–receptor binding generally activates a signal transduction pathway that controls transcription and protein synthesis. These signals ultimately result in cell differentiation and clonal proliferation.

Chemokines are a group of small proteins produced by macrophages, lymphocytes, and other cells in response to bacterial products, viruses, and other cell-damaging agents. Chemokines attract phagocytes and T cells to the site of injury, stimulating an inflammatory response and recruiting the cells necessary to initiate a specific immune response.

Table 26.3 lists some important immune cytokines and chemokines, the cells that produce them, their most common target cells, and their most important biological effects. Over 50 cytokines are known, most of which are produced by either T cells or monocytes and macrophages. About 40 chemokines are known. We first examine the activity of cytokines required for the induction of an antigen-specific, antibody-mediated immune response. We then look at cytokines produced by Th1 cells that activate macrophages to produce the cytokines and chemokines that trigger macrophage-mediated inflammation.

Cytokines and Antibody Production

B cells are responsible for antigen uptake, processing, and presentation as well as the production of specific antibodies. As we discussed in the previous section, B cells require two independent signals for activation and antibody production. B cells are activated by antigen binding to surface immunoglobulin (signal 1) followed by interaction between the B cell CD40 and CD40L on the T cell (Figure 26.14). The activated Th cell responds by

producing IL-2, which is secreted and bound by the IL-2R on the surface of the Th cells. Thus, IL-2 can activate the same cell that secreted it. Under the influence of IL-2, the cell divides, making clonal copies. In the process, the Th cell also makes other cytokines such as IL-4 and IL-5.

IL-4 then binds to the IL-4R on the original antigen-presenting B cell. The IL-4:IL-4R interaction stimulates the B cell to differentiate into a plasma cell, which ultimately produces antibodies (► Section 25.8). The IL-4 generated by the responding T cell is the second signal (signal 2) necessary for initiation of antibody production. In addition, the IL-4 interaction signals an immunoglobulin class switch. For example, IL-4:IL-4R interaction can switch antibody production from IgM to IgE or IgG1.

Alternatively, IL-5 produced by Th cells can bind an IL-5R on the antigen-presenting B cell. Parallel to the situation with IL-4:IL-4R interaction, the IL-5:IL-5R also stimulates the B cell to differentiate into a plasma cell, which ultimately produces antibodies, and induces a class switch, but this time to IgA.

As these two examples show, IL-2, IL-4, and IL-5 cytokines are soluble mediators and activators for both T and B lymphocytes. They interact to induce the antibody-mediated immune response; Th cells in different locations produce different B cell–activating cytokines to focus the antibody response to that environment. For example, Th cells near the skin produce more IL-4, inducing production of IgE, while Th cells in the gut produce IL-5, inducing production of secretory IgA. Thus, IL-4 and IL-5 not only control activation of the B cell, but also control the quality of the antibody response, directing the class switch from IgM to IgE or IgA, respectively, thereby focusing the antibody production for a particular environment.

Th1 Activation of Macrophages

Table 26.3 shows the activity of several cytokines produced by some Th1 cells. These cytokines are important in the activation of macrophages. The cytokines IFN- γ (gamma interferon), GM-CSF

Table 26.3 Major immune cytokines and chemokines

Cytokine (chemokine)	Major producer cells	Major target cells	Major effect
IL-4 ^a	Th2	B cells	Activation, proliferation, differentiation, IgG1 and IgE synthesis

(granulocyte–monocyte colony-stimulating factor), and TNF- α (tumor necrosis factor alpha) are produced by antigen-activated Th1 cells. These cytokines stimulate macrophage differentiation and activation.

Stimulated macrophages produce a number of cytokines and chemokines, many of which play a role in initiating inflammation. Some of the most important macrophage-produced *proinflammatory* cytokines are IL-1 β , TNF- α , IL-6, and IL-12. IL-1 β and TNF- α induce activation of vascular endothelium. IL-6 activates lymphocytes, and all except IL-12 induce fever at the systemic level. IL-12 acts to stimulate natural killer (NK) cells and to induce naive T cells to differentiate to Th1 cells (Table 26.3).

Chemokines produced by activated macrophages include CXCL8 and CCL2, also called MCP-1. CXCL8, also called IL-8, is produced by monocytes, macrophages, and other cells. CXCL8 is secreted by the activated cells and binds to receptors on T cells and neutrophils, where it acts as a chemoattractant. This results

in a neutrophil-mediated inflammatory response followed by a specific immune response by the attracted T cells. As is the case for the cytokine receptors, engaged chemokine receptors on the target cells act through signal transduction pathways to induce activation of effector cells such as neutrophils or T cells.

CCL2 is produced by macrophages and other cells. CCL2 attracts basophils, eosinophils, monocytes, dendritic cells, natural killer cells, and T cells, stimulating production of more inflammatory mediators and potentially organizing an antigen-specific immune response.

- Identify the major cytokines and chemokines produced by Th1 cells, Th2 cells, and macrophages.
- Identify the proinflammatory cytokines, the cells that produce them, and their effects on other cells.

BIG IDEAS

26.1 • PRRs interact with PAMPs shared by various pathogens, activating complement and phagocytes to target and destroy pathogens. PRR–PAMP interactions initiate signal transduction cascades that activate effector cells.

26.2 • The Ig gene superfamily encodes proteins that are evolutionarily, structurally, and functionally related to immunoglobulins. The antigen-binding Iggs, TCRs, and MHC proteins are members of this family. Antigen binding to Ig or TCR facilitates signal transduction through adaptor molecules containing ITAMs.

26.3 • Class I MHC proteins are expressed on all nucleated cells and function to present endogenous antigenic peptides to TCRs on Tc cells. Class II MHC proteins are expressed only on APCs. They function to present exogenously derived peptide antigens to TCRs on Th cells.

26.4 • MHC genes encode proteins used to present peptide antigens to T cells. Class I and class II MHC genes are highly polymorphic. MHC class I and class II alleles encode proteins that bind and present peptides with conserved structural motifs.

26.5 • The antigen-binding site of Ig is composed of the V (variable) domains of one heavy chain and one light chain. Each V region contains three complementarity-determining regions, or CDRs, that are folded together to form the antigen-binding site.

26.6 • Immunoglobulin diversity is generated by several mechanisms. Somatic recombination of gene segments allows shuffling of the various Ig gene segments. Random reassortment of the heavy- and light-chain genes, imprecise joining of VDJ and VJ gene segments, and hypermutation mechanisms contribute to nearly unlimited immunoglobulin diversity.

26.7 • T cell receptors bind to peptide antigens presented by MHC proteins. The CDR3 regions of both the α chain and the β chain bind to the antigen epitope; the CDR1 and CDR2 regions bind to the MHC protein. The β -chain V domain is encoded by VDJ gene segments. The α -chain V domain is encoded by VJ gene segments. TCR diversity, generated by a variety of mechanisms, is nearly unlimited.

26.8 • The thymus is a primary lymphoid organ that provides an environment for the maturation of antigen-reactive T cells. Immature T cells that do not interact with MHC–peptide (positive selection) or that react strongly with self antigens (negative selection) are eliminated by clonal deletion in the thymus. T cells that survive positive and negative selection leave the thymus and can participate in the immune response. B cell reactivity to self antigens is controlled through clonal deletion and anergy.

26.9 • Uncommitted T cells are activated in the secondary lymphoid organs by first binding MHC–peptide with their TCRs (signal 1), followed by binding of the B7 APC protein to the CD28 T cell protein (signal 2). B cell activation is initiated by antigen interaction with surface immunoglobulin (signal 1), followed by interaction between the B cell CD40 protein and CD40L on the T cell to generate cytokine production (signal 2).

26.10 • Cytokines produced by leukocytes and other cells are soluble mediators that regulate interactions between cells. Several cytokines, such as IL-2 and IL-4, affect lymphocytes and are critical components in the generation of specific immune responses. Other cytokines, such as IFN- γ and TNF- α , affect a wide variety of cell types. Chemokines produced by various cells are released in response to injury and are strong attractants for nonspecific inflammatory cells and T cells.

Clonal anergy the inability to produce an immune response to specific antigens due to the neutralization of effector cells
Clonal deletion for T cell selection in the thymus, the killing of useless or self-reactive clones

Clonal selection the production by a B or T cell of copies of itself after antigen interaction
Complementarity-determining region (CDR) a varying amino acid sequence within the variable domains of immunoglobulins or T cell receptors where contacts with antigen are made

Human leukocyte antigen (HLA) an antigen-presenting protein encoded by a major histocompatibility complex gene in humans
Immunoglobulin gene superfamily a family of genes that are evolutionarily, structurally, and functionally related to immunoglobulins

Motif in antigen presentation, a conserved amino acid sequence found in all peptides that bind to a given MHC protein

Negative selection in T cell selection, the deletion of T cells that interact with self antigens in the thymus (*see also* clonal deletion)

Polygeny the occurrence of multiple copies of evolutionarily, genetically, structurally, and functionally related genes

Polymorphism in a population, the occurrence of multiple alleles for a gene locus at a higher frequency than can be explained by recent random mutations

Positive selection in T cell selection, the growth and development of T cells that interact with self MHC-peptide in the thymus

Somatic hypermutation the mutation of immunoglobulin genes at rates higher than those observed in other genes

REVIEW QUESTIONS

- Identify at least one soluble pattern recognition receptor (PRR), its interacting pathogen-associated molecular pattern (PAMP), and the resulting host response. (Section 26.1)
- Define the criteria used to assign a gene and its encoded protein to the Ig gene superfamily. (Section 26.2)
- Identify the major structural features of class I and class II MHC proteins. (Section 26.3)
- Polymorphism implies that each different MHC protein binds a different peptide motif. For the MHC class I polymorphisms, how many different MHC proteins are expressed in an individual? By the entire human population? (Section 26.4)
- Which Ig chains are used to construct a complete antigen-binding site? Which domains? Which CDRs? (Section 26.5)
- Calculate the total number of germ-line-encoded V_H and V_L domains that can be constructed from the available Ig genes.

Compare this to the numbers of germ-line-encoded V_B and V_α domains of the TCR. How is diversity expanded in each pair of antigen-receptor proteins? (Section 26.6)

- In TCRs, diversity can be generated by recombination and reassortment events as in IgGs. As is the case in IgGs, additional diversity is generated with somatic events such as N nucleotide additions and reading of the D segment in all three reading frames. Explain these diversity-generating mechanisms. (Section 26.7)
- Explain positive and negative selection of T cells. (Section 26.8)
- What molecular interactions are necessary for activation of uncommitted T cells? For activation of uncommitted B cells? (Section 26.9)
- What are the major cytokines and their effects in an antibody-mediated response? In a Th1-mediated response? (Section 26.10)

APPLICATION QUESTIONS

- Identify the consequences of a genetic mutation that eliminates a PRR by predicting the outcome for the host. Do this for at least one soluble PRR and one membrane-bound PRR.
- Polymorphism implies that each different MHC protein binds a different peptide motif. However, for the MHC class I proteins, only 6 peptide motifs can be recognized in an individual, whereas over 6000 motifs can be recognized by the entire human population. What advantage does recognition of multiple motifs have for the individual? What potential advantage does recognition of the extremely large number of motifs have for the population? Can everyone process and present the same antigens?

- Although genetic recombination events are important for generating significant diversity in the antigen-binding site of IgGs, post-recombination somatic events may be even more important in achieving overall Ig diversity. Do you agree or disagree with this statement? Explain.
- What would be the result of activation of all T cells that contact antigen? How does the multiple signal mechanism prevent this from happening?

Antibiotics and Honeybees

Honeybees (*Apis mellifera*, photo) produce honey and are key agricultural pollinators. In the 1950s, the broad-spectrum antibiotic oxytetracycline was introduced into honeybee hives in the United States to prevent bee diseases caused by bacterial pathogens. After over 50 years of routine antibiotic use, a study now shows that the gut microflora of most honeybees in the United States contain a set of eight tetracycline resistance genes in high copy number.¹

The composition of the honeybee gut bacterial community is surprisingly conserved and is dominated by eight species that contribute to defense against parasitic infections and aid in nutrition. The resistance genes are carried between and among these species on plasmids and other mobile genetic elements. Comparisons of American honeybees with those from Europe and New Zealand, where antibiotic use in honeybees is not allowed, show that the bacterial community from bees in untreated hives has not acquired resistance genes. This is also true of honeybees in the United States that have not been exposed to antibiotics for over 25 years and for bumblebees, which share a similar gut microflora with honeybees but are not domesticated and therefore not exposed to oxytetracycline.

Do we really need to treat honeybees with antibiotics, and can we accurately foresee the consequences of long-term antibiotic use? There is no evidence that tetracycline-resistant honeybee bacteria have been transferred to or caused disease in humans, but these antibiotic-resistant bacteria comprise a reservoir of resistance genes that can be transferred to honeybee pathogens and other bacteria. More important, prolonged exposure to a single antibiotic may alter the honeybee microflora in unknown ways that could affect the insects' long-term health and disease resistance.

Clinical microbiology laboratories must identify pathogens safely, rapidly, and efficiently. The clinical microbiologist examines patient samples using direct observation, culture, immunological

assays, and molecular tools to identify pathogens. Identification of pathogens guides infection control by targeting antimicrobial drugs to specific pathogens.

I • The Clinical Environment

27.1 Safety in the Microbiology Laboratory

Safety in the clinical laboratory prevents the spread of infections to laboratory workers. Standard laboratory practices for handling clinical samples have been established to prevent accidental laboratory infections.

Laboratory Safety

The clinical laboratory has potential biohazards for all personnel and is especially dangerous for untrained personnel or those who do not employ the necessary precautions. All laboratories that handle human or primate tissue must have an occupational exposure control plan for handling bloodborne pathogens, designed specifically to protect workers from infection by hepatitis B virus (HBV, the cause of infectious hepatitis, [Section 29.11](#)) and human immunodeficiency virus (HIV, the cause of acquired immunodeficiency syndrome [AIDS], [Section 29.14](#)). The occupational exposure plan limits infection by all pathogens.

The two most common causes of laboratory infections are ignorance and carelessness. Training and enforcement of established safety procedures, however, can prevent most accidental infections. Most laboratory-acquired infections do not result from identifiable exposures like culture spills but from routine handling of patient specimens. Infectious aerosols generated during microbiological procedures are the most common causes of laboratory infections. Clinical laboratories follow the general safety rules outlined in [Table 27.1](#) to minimize laboratory infections. Adherence to safety rules ensures a safe laboratory environment that is in compliance with governmental regulations.

These are general standards in all laboratories that handle potential infectious agents and are the basis for all aspects of healthcare infection control. Laboratories that handle particularly dangerous or transmissible agents may have additional rules and procedures in addition to these to ensure a safe work environment, as discussed below. In the final analysis, safety in the workplace is the responsibility of laboratory personnel.

Biological Containment and Biosafety Levels

The level of containment used to prevent accidental infections or accidental environmental contamination (escape) in clinical, research, and teaching laboratories must be adjusted to counter the biohazard potential of the organisms handled in the laboratory. Laboratories are classified according to their containment capabilities from least to greatest by their *biosafety level (BSL)*, designated as *BSL-1*, *BSL-2*, *BSL-3*, and *BSL-4* ([Figure 27.1](#)). Personnel in laboratories working at all biosafety levels must follow good laboratory practices that ensure basic cleanliness and limit contamination, as we outlined in [Table 27.1](#). [Table 27.2](#) shows requirements for each biosafety level. At each level, the precautions, equipment, and costs increase.

Most universities have BSL-1 and BSL-2 facilities for teaching and research. Standard clinical laboratories operate at BSL-2. The

Rule	Implementation
Restrict access	Only laboratory workers and trained support personnel have access.
Practice good personal hygiene	Eating, drinking, and application of cosmetics are forbidden in the lab. Handwashing prevents spread of pathogens.
Use personal protection equipment	Lab coats, gloves, eye protection, and respirators are recommended or required depending on the pathogens being handled.
Vaccinate	Personnel must be vaccinated for agents they may contact.
Handle specimens safely	Consider clinical specimens to be infectious and handle appropriately.
Decontaminate	After use or exposure, decontaminate specimens, surfaces, and materials by disinfecting, autoclaving, or incinerating.

specialized physical requirements for BSL-3 facilities limit them to major clinical centers and research settings. Because BSL-4 facilities must ensure total isolation and physical containment of pathogens, fewer than fifty BSL-4 laboratories are operational worldwide. Most BSL-4 laboratories are associated with government facilities such as the Centers for Disease Control and Prevention (Atlanta, Georgia, USA) and the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID; Fort Detrick, Maryland, USA).

27.2 Healthcare-Associated Infections

A **healthcare-associated infection (HAI)** is a local or systemic infection acquired by a patient in a healthcare facility, particularly during a stay in the facility. HAIs cause significant morbidity and mortality. About 1 in 20 patients admitted to healthcare facilities acquire HAIs, also called *nosocomial infections* (*nosocomium* is the Latin word for “hospital”). Nearly 1.7 million HAIs occur annually in the United States, leading directly or indirectly to almost 100,000 deaths.

Mechanisms of Transfer of Healthcare-Associated Infections

Some HAIs are acquired from patients with communicable diseases, but others are caused by pathogens that are selected and maintained within the hospital environment, spread by cross-infection from patient to patient or from healthcare personnel. Healthcare-associated pathogens are often present as normal flora in either patients or healthcare staff.

Healthcare facilities are high-risk environments for the spread of infectious disease because these facilities concentrate

individuals who have infectious disease or are at risk for acquiring infectious disease because of their underlying health conditions. Some of the common risk factors for acquiring infectious diseases in healthcare settings are summarized in **Table 27.3**.

The most common sites of HAIs are shown in **Figure 27.2**. Of the nearly 100,000 estimated annual deaths caused by HAIs in the United States, about 36,000 are from pneumonia, 31,000 from bloodstream infections, 13,000 from urinary tract infections, 8,000 from surgical site infections, and 11,000 from other sites. A relatively small number of pathogens cause most HAIs (**Table 27.4**), but a number of other infectious agents can also cause HAIs.

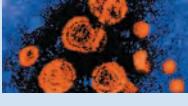

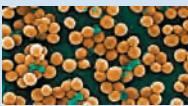

Common Pathogens in Healthcare-Associated Infections

Staphylococcus aureus is one of the most important and widespread HAI pathogens (☞ Section 29.9). It is the most common cause of pneumonia, the third most common cause of blood

Risk factor	Rationale
Patients	Patients are already ill or compromised
Newborn infants and the elderly	Not fully immune competent
Infectious disease patients	Pathogen reservoirs
Patient proximity	Increases cross-infection
Healthcare personnel	Can transfer pathogens between and among patients
Medical procedures (blood draws, etc.)	Breaching the skin barrier can introduce pathogens
Surgery	Exposes internal organs, may introduce pathogens, and stress lowers resistance to infection
Anti-inflammatory drugs	Lower resistance to infection
Antibiotic treatment	May select for resistant and opportunistic pathogens

infections, and is particularly problematic in nurseries. Many hospital strains of *S. aureus* are unusually virulent and are resistant to common antibiotics, making treatment very difficult. The staphylococci are the most common cause of bloodborne HAIs and are also very prevalent in wound infections.

Staphylococcus and *Enterococcus*, and *Escherichia coli*, *Klebsiella pneumoniae*, and other *Enterobacteriaceae* all have the potential for causing HAIs, but they may also be members of the normal

flora in some individuals, making it difficult to eliminate them in healthcare settings. In addition, these organisms can acquire drug resistance. Pathogens that are not part of the normal flora such as *Acinetobacter* and *Mycobacterium* spp. can be eliminated from the healthcare environment. These pathogens are carried into the healthcare environment by infected individuals or, in the case of some mycobacteria, as environmental contaminants that enter in dust and air.

Prevention of HAIs involves cooperation between the healthcare facility infection-control team and the facility staff, including direct healthcare workers and supporting staff such as housekeeping. Infection control starts with management of incoming patients at the point of entry to the healthcare facility; incoming patients should be assessed for possible infections and isolated as necessary to prevent spread of infections to other staff and patients. From this point, the healthcare facility staff employs standard procedures that limit infection, applying the same general precautions outlined for laboratory workers in Table 27.1.

II • Microbiological Identification of Pathogens

The observation and growth of pathogens from patient specimens are important strategies for identification of the causative agent of an infectious disease. Identification leads to antimicrobial drug susceptibility testing and development of a specific treatment plan. We begin by looking at methods for observing, growing, and isolating pathogens, followed by methods for identification and drug susceptibility testing.

27.3 Direct Detection of Pathogens

If clinically relevant organisms are to be isolated and identified, the specimen must be obtained and handled properly to ensure that the pathogen survives. First, the specimen must be obtained from the actual site of the infection; the sample must be taken aseptically to avoid contamination with irrelevant microorganisms. Next, the sample size must be large enough to ensure an inoculum sufficient for growth. Third, the metabolic requirements for organism survival must be maintained during sampling, storage, and transport. Finally, the sample must be processed as quickly as possible to avoid degradation. For example, samples obtained from anoxic sites must be obtained, stored, and transported under anoxic conditions to ensure the survival of potential anaerobic pathogens.

Samples of tissues or fluids are collected for microbiological, immunological, and molecular biological analyses if a healthcare provider suspects a disease is caused by an infectious agent (Figure 27.3). Typical samples include blood, urine, feces, sputum, cerebrospinal

fluid, or pus from a wound. Sterile swabs are often used to obtain samples from suspected infected areas such as wounds, skin, nares, or throat (Figure 27.4). The swab is then used to inoculate the surface of an agar plate or a tube of liquid culture medium. In some cases, a small piece of tissue (biopsy) may be obtained for culture or microscopic examination. Blood and other fluids are initially analyzed using automated microbiology methods.

Most pathogens are detected by direct means using one or more of several diagnostic tests. The reliability of any diagnostic test depends on both the *specificity* and the *sensitivity* of the test. **Specificity** is the ability of the test to recognize a single pathogen. Optimal specificity implies that the test is specific for a single pathogen, and will not identify any other pathogen. High specificity reduces false-positive results. For example, for the detection of *Neisseria gonorrhoeae*, the organism that causes gonorrhea, the specificity of Gram-stained smears of urethral exudates from men is about 99% and about 95% for endocervical exudates from women; false-positive tests for gonorrhea are therefore rare.

Sensitivity defines the lowest numbers of a pathogen or the lowest amount of a pathogen product that can be detected. The highest level of sensitivity requires that the test be capable of identifying a single organism or molecule. High sensitivity prevents false-negative reactions. For example, for the detection of *N. gonorrhoeae*, the sensitivity of Gram-stained smears of urethral exudates from men is about 90%, and about 50% for endocervical exudates from women. Thus, the test is a sensitive indicator for gonorrhea in men, but is much less sensitive for women.

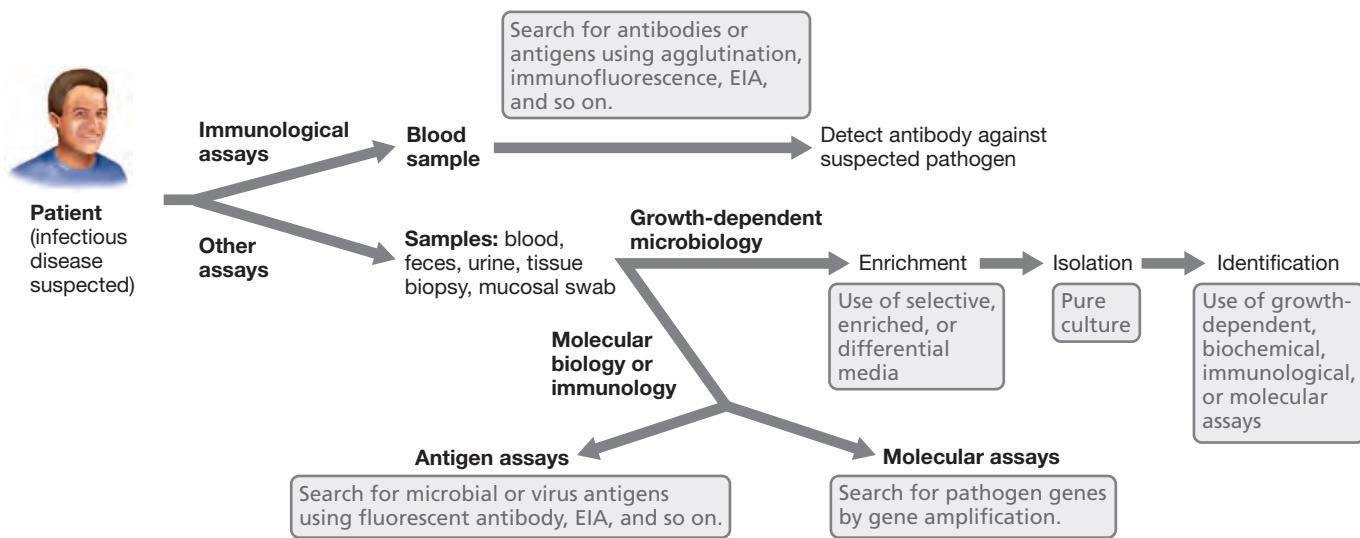

Figure 27.3 Laboratory identification of microbial pathogens. The flowchart shows alternative paths for identifying pathogens or pathogen exposure in the clinical laboratory.

In suspected cases of gonorrhea in females, false-negative Gram stains are relatively common, and thus females must be examined by more sensitive methods, including culture techniques.

Direct Observation and Culture

Direct observation of pathogens in clinical specimens is an important tool for diagnosis of many infectious diseases. Examples include the observation of acid-fast stained *Mycobacterium tuberculosis* in sputum from patients, proving infection with *M. tuberculosis* (Section 29.4 and Figure 29.16a). Likewise, infection with *N. gonorrhoeae* can be diagnosed by direct observation of Gram-stained smears of a patient sample such as urethral exudates from men. The presence of gram-negative diplococci in clumps and in inclusions in neutrophils is diagnostic for the disease (Figure 27.5a). In women, however, cervical smears often do not reveal the presence of the infecting organism; cultures or molecular techniques are used to establish or confirm a diagnosis of gonorrhea (Section 29.12 and Figure 27.5b).

Most pathogens can be readily grown in laboratory cultures. **Enrichment culture**, the use of selected culture media and incubation conditions to isolate microorganisms from samples (Section 18.1), is thus an important tool in the clinical laboratory.

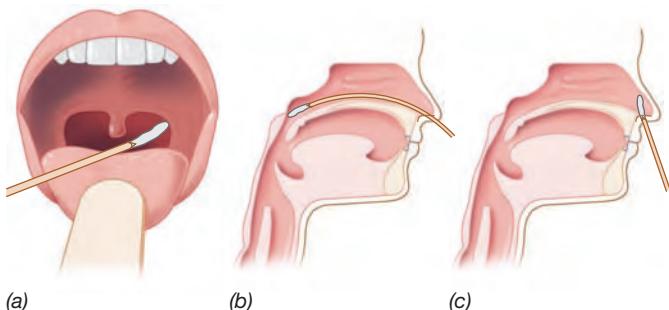

Figure 27.4 Specimens from the upper respiratory tract. (a) Throat swab. (b) Nasopharyngeal swab passed through the nose. (c) Swabbing the inside of the nose.

Most microorganisms of clinical importance can be grown, isolated, and identified using specialized growth media. Clinical samples are inoculated on **general-purpose media** such as *blood agar* (Figure 27.6a) and *chocolate agar* (Figure 27.6b) that support the growth of many aerobic and facultatively aerobic pathogens. Chocolate agar, named because of its deep brown appearance, contains heat-lysed blood. The heated blood interacts with the other media components, absorbing compounds that are toxic for fastidious microorganisms such as *N. gonorrhoeae*. More specialized media may also be used.

(b) *N. gonorrhoeae* growing on Thayer–Martin agar. The plate has been stained in the middle with a reagent that turns colonies blue if cells contain cytochrome c (the oxidase test). *N. gonorrhoeae* colonies in contact with the reagent are blue, indicating that they are oxidase-positive.

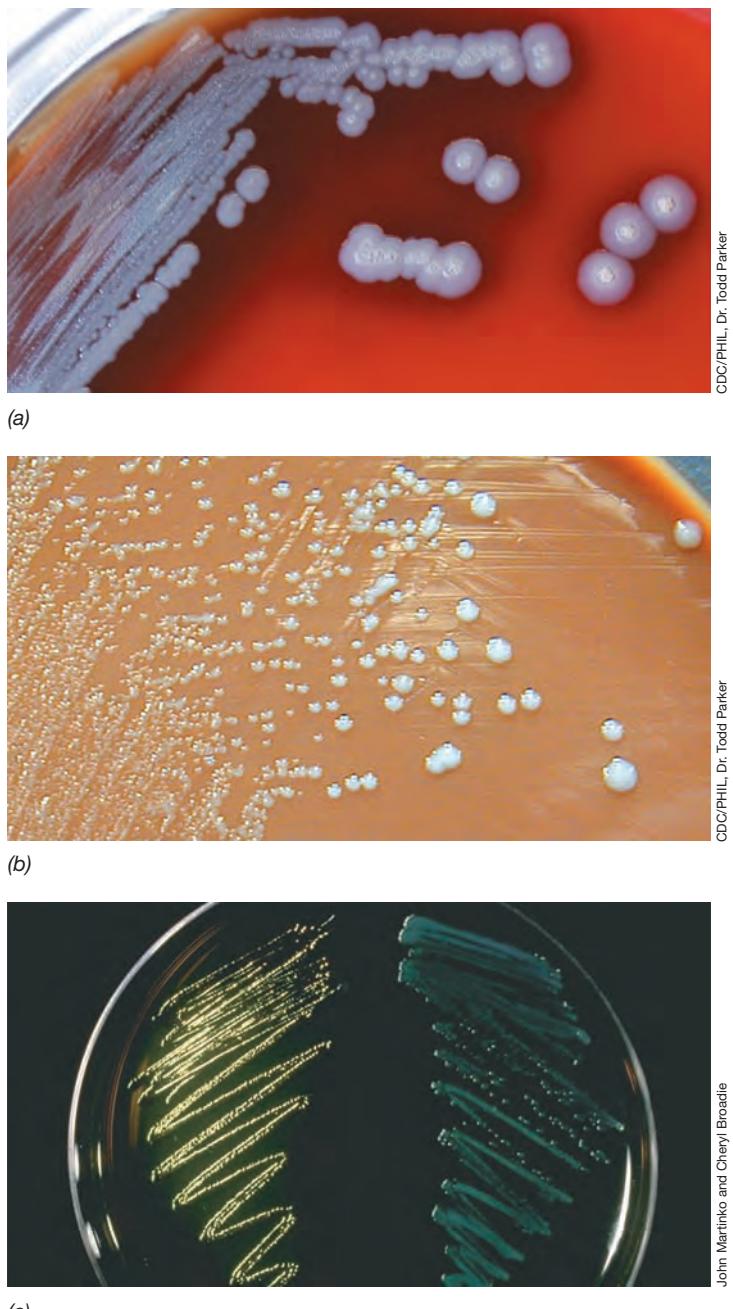

Figure 27.6 Enriched media. (a) *Burkholderia* growing on sheep blood agar (SBA); the red color is from blood suspended in a rich medium such as trypticase soy agar. (b) *Francisella tularensis* growing on chocolate agar; the brown color is due to heat-lysed blood in a rich medium such as trypticase soy agar. (c) *Escherichia coli*, a lactose fermenter (left), and *Pseudomonas aeruginosa*, a non-lactose fermenter (right) growing on an eosin–methylene blue (EMB) agar. The green metallic sheen of the colonies identifies *E. coli* as a lactose fermenter.

The next step in identification makes use of *enriched media* to culture selected pathogens. **Enriched media** contain specific growth factors that enhance the growth of selected pathogens. For example, the Thayer–Martin medium enhances the growth of bacteria such as *N. gonorrhoeae* (Figure 27.5b). **Selective media** allow for some organisms to grow while inhibiting the growth of others due to the presence of inhibitory agents. Finally,

differential media are specialized media that allow identification of organisms based on their growth, color, and appearance on the medium. Eosin–methylene blue (EMB) agar is a selective medium that inhibits growth of Gram-positive organisms while supporting growth of Gram-negative organisms. In addition, EMB agar is a differential medium because it distinguishes lactose fermenters such as *Escherichia coli* from non-lactose-fermenting Gram-negative organisms such as *Pseudomonas aeruginosa* (Figure 27.6c). **Table 27.5** indicates the specimens usually inoculated onto each of the most commonly used general-purpose and enriched culture media.

Blood and Liquid Specimens

Pathogens in large-volume liquid samples like blood and cerebrospinal fluid are routinely detected using automated culture systems, followed by microscopic examination and subculture.

The standard blood culture procedure is to draw 10 to 20 ml of blood aseptically from a vein and inject it into two culture bottles containing both an anticoagulant and a general-purpose culture medium. One bottle is incubated aerobically and one is incubated under anoxic conditions, and both are kept at 35°C for up to 5 days. Automated culture systems detect growth by monitoring gas consumption (in oxic conditions) or production (carbon dioxide in anoxic conditions) as often as every 10 minutes. Some systems also measure turbidity. Most clinically significant bacteria are recovered within 2 days, but growth of organisms such as mycobacteria or fungi may take 3 to 5 days or longer. Bottles that contain growth are examined first by Gram stain (see Section 2.2) and then inoculated onto enrichment and differential media for further isolation and identification.

Bacteremia is the presence of bacteria in the blood. Bacteremia is extremely uncommon in healthy individuals, normally occurring only transiently due to tooth brushing, dental surgery, or trauma. The prolonged presence of bacteria in the blood is generally

indicative of systemic infection. **Septicemia**, or **sepsis**, is a blood infection by a virulent organism that enters the blood from a focus of infection, multiplies, and travels to various body tissues to initiate new infections. Sepsis is extremely serious and can be fatal.

The most common pathogens found in blood include gram-positive *Staphylococcus* spp. and *Enterococcus* spp., but about 2–3% of blood cultures are contaminated by microorganisms such as *Staphylococcus epidermidis*, coryneform bacteria, or propionibacteria introduced from the skin during blood sampling. However, these organisms can also infect the heart (subacute bacterial endocarditis) or colonize artificial heart valves. Thus, the results of a positive blood culture must be reconciled with clinical observations for an accurate diagnosis.

Urinary Tract and Fecal Cultures

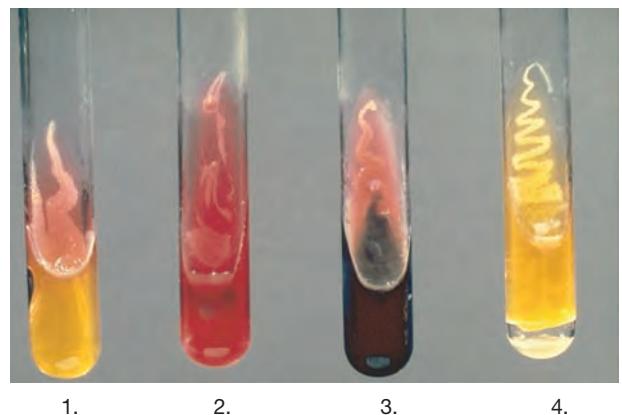

Urinary tract infections are common, especially in women. Interpretation of microbiological findings from urine cultures can be confusing because the disease-causing agents are often members of the normal flora (for example, *E. coli*). In most cases, the urinary tract becomes infected by organisms that ascend into the bladder from the urethra. Urinary tract infections are, however, the most common healthcare-associated infections, often introduced through catheters.

Direct microscopic examination of urine may indicate *bacteriuria*, the presence of abnormal numbers of bacteria in the urine, but nearly all urine contains some bacterial growth. A Gram stain may be done directly on urine samples to identify the morphology of potential urinary tract pathogens. This method can be used to putatively identify gram-negative rods including the enteric bacteria, gram-negative cocci such as *Neisseria*, and gram-positive cocci such as *Enterococcus*. The Gram stain and other direct staining methods are also useful for direct detection of bacteria in other body fluids such as sputum and wound exudates.

A significant urinary tract infection typically results in bacterial counts of 10^5 or more organisms per milliliter of urine. The most common urinary tract pathogens are enteric bacteria, with *E. coli* accounting for about 90% of the cases. Two media types are normally used to culture urinary tract pathogens. Blood agar can be used for initial isolation. Selective and differential enteric media such as eosin–methylene blue (EMB) agar permit the initial differentiation of lactose fermenters from non-lactose fermenters and inhibit the growth of possible contaminants such as gram-positive *Staphylococcus* species (Figure 27.6c). Additional differential and selective media may be used to differentiate between and among potential gram-negative pathogens (Figure 27.7).

Urine cultures can be done quantitatively by counting colonies on blood agar or a selective agar medium. A calibrated loop is used to deliver a specified amount of urine, usually 1 μl , as the inoculum for a plate. If no bacterial growth is obtained despite persistent urinary tract infection symptoms, a clinician may request additional cultures for more nutritionally demanding organisms such as *N. gonorrhoeae* and *Chlamydia trachomatis*.

Proper collection and preservation of feces is important for the isolation of intestinal pathogens. During storage, feces become more acidic, so delay between sampling and processing must be minimized. This is especially critical for the isolation of acid-sensitive pathogens such as *Shigella* and *Salmonella*.

Leon J. LeBeau

Figure 27.7 A growth-dependent diagnostic test for gram-negative pathogens. Four different enteric bacteria are shown growing on triple-sugar iron (TSI) agar. The medium contains glucose, lactose, and sucrose. Organisms able to ferment only glucose cause acid formation only in the butt, whereas lactose- or sucrose-fermenting organisms cause acid formation throughout the slant. Gas formation is indicated by the breaking up of the agar in the butt. Hydrogen sulfide formation (either from protein degradation or from reduction of thiosulfate in the medium) is indicated by blackening due to reaction with ferrous iron in the medium. The medium is inoculated both on the surface of the slant and by stabbing into the solid agar butt. From left to right: 1. Fermentation of glucose only, typical of *Shigella*. 2. Growth but no fermentation, typical of *Pseudomonas*, a nonfermenting obligate aerobe. 3. Hydrogen sulfide formation, typical of *Salmonella*. 4. Fermentation of sugars and hydrogen gas production, typical of *Escherichia coli*.

Freshly collected fecal samples are placed in a sterile sealed container for transport to the laboratory. Bloody or pus-containing stools as well as stools from patients with suspected foodborne or waterborne infections are inoculated into selective media for isolation of individual bacteria. Intestinal eukaryotic pathogens are identified by direct microscopic observation of cysts in the stool sample or through antigen-detection assays rather than by culture methods. Many laboratories also use selective and differential media to identify *E. coli* O157:H7 and *Campylobacter*, two important intestinal pathogens typically acquired from contaminated food or water (Sections 31.11 and 31.12).

Wounds and Abscesses

Infections associated with traumatic injuries such as animal bites, burns, or cuts are sampled to recover the relevant pathogen. The results must be interpreted carefully to differentiate between infection and contamination. Wound infections and abscesses are frequently contaminated with normal flora, and swab samples from such lesions are frequently misleading. For abscesses and other purulent lesions, pus is aspirated with a sterile syringe and needle following disinfection of the skin surface. Internal purulent lesions are sampled by biopsy or from tissues removed in surgery.

Pathogens commonly associated with wound infections are *Staphylococcus aureus*, enteric bacteria, *Pseudomonas aeruginosa*, and anaerobes such as *Bacteroides* and *Clostridium*. Because of the varied oxygen requirements of these bacteria, samples must be obtained, transported, and cultured under anoxic as well as oxic conditions. The major isolation media are blood agar, selective media for enteric bacteria, and enrichment media containing additional supplements and reducing agents for

obligate anaerobes. Gram stains from such specimens are examined directly by microscopy.

Genital Specimens and Culture for Gonorrhea

In males, a purulent urethral discharge indicates a sexually transmitted infection (STI). These STIs are classified as nongonococcal or gonococcal urethritis. Nongonococcal urethritis is usually caused by *Chlamydia trachomatis*, *Ureaplasma urealyticum*, or *Trichomonas vaginalis* (☞ Section 29.13). Gonococcal urethritis is caused by *Neisseria gonorrhoeae* (☞ Section 29.12).

N. gonorrhoeae is usually found as gram-negative diplococci. No similar microorganisms are normally found in the urogenital tract and so a Gram stain of a urethral, vaginal, or cervical smear showing gram-negative diplococci is diagnostic for gonorrhea. Microscopic examination of purulent discharges usually reveals gram-negative diplococci in neutrophils (Figure 27.5a). Chocolate agar, a nonselective enriched medium, is often used for specimens suspected to contain *N. gonorrhoeae*. A selective medium used for primary isolation is modified Thayer–Martin (MTM) agar (Figure 27.5b). This medium incorporates the antibiotics vancomycin, nystatin, trimethoprim, and colistin to suppress the growth of normal flora. These antibiotics have no effect on *N. gonorrhoeae* or *Neisseria meningitidis*, a cause of bacterial meningitis (☞ Section 29.5).

Inoculated plates are incubated in a humid environment in an atmosphere containing 3–7% CO₂ for 24 and 48 hours and tested for their oxidase reaction because *Neisseria* are oxidase-positive (Figure 27.5b). Oxidase-positive, gram-negative diplococci growing on chocolate agar or selective media are presumed to be gonococci if the inoculum was derived from genitourinary sources. Definitive identification of *N. gonorrhoeae* requires determination of carbohydrate utilization patterns and immunological or nucleic acid probe tests. Laboratory testing of urogenital samples for *N. gonorrhoeae* (and the often-associated *C. trachomatis*) is often done using DNA amplification via polymerase chain reaction (PCR) or other molecular methods.

Culture of Anaerobic Microorganisms

Obligately anaerobic bacteria are common causes of infection, and their identification requires special isolation and culture methods. In general, media for anaerobes do not differ greatly from those used for aerobes, except that they are (1) usually richer in organic constituents, (2) contain reducing agents (usually cysteine or thioglycolate) to remove oxygen, and (3) contain a redox indicator to indicate that conditions are anoxic. Collection, handling, and processing of specimens must exclude oxygen contamination because oxygen is toxic to obligately anaerobic organisms.

Several habitats in the body, such as portions of the oral cavity and the lower intestinal tract, are anoxic and support the growth of anaerobic normal flora. Other parts of the body, however, can also become anoxic as a result of tissue injury or trauma that reduces blood supply and oxygen perfusion to the injured site. These anoxic sites can then be colonized by obligate anaerobes. In general, potentially pathogenic anaerobic bacteria are part of the normal flora but are kept in check by competition from other members of the normal flora. Under certain conditions, however, these normally benign bacteria may become opportunistic

pathogens. For example, *Clostridium difficile* is usually a harmless member of the normal flora in the lower intestinal tract, but commonly emerges as a healthcare-associated pathogen after intensive antibiotic therapy destroys the competing normal microbial flora (Table 27.4).

Isolation, growth, and identification of anaerobic pathogens are complicated by specimen contamination as well as the constant challenge of maintaining an anoxic environment during collection, transport, and culture. Samples collected by syringe aspiration or biopsy must be immediately placed in a tube containing oxygen-free gas, usually with a dilute salt solution containing a reducing agent such as thioglycolate and a redox indicator such as resazurin (☞ Figure 5.27) to monitor oxygen contamination.

For anoxic incubation, specimens are inoculated into anaerobic culture bottles in an automated culture system or incubated under anoxic conditions after inoculation of culture media containing reducing agents, usually in an anoxic “glove box” filled with an oxygen-free gas such as nitrogen or hydrogen (☞ Figure 5.28b).

27.4 Growth-Dependent Identification Methods

If growth is detected after inoculation of a specimen on a general-purpose medium, the clinical microbiologist must identify the organism or organisms present. Many microorganisms recovered from clinical samples can be identified using growth-dependent assays.

Based on its growth characteristics on the enriched media used for primary isolation, a presumptive pathogen is subcultured onto specialized media designed to measure one of many different biochemical reactions. Here we give examples of a few standard laboratory biochemical tests. Each test is designed to differentiate bacterial growth and metabolism patterns, with the goal of identifying an individual pathogen based on its unique pattern of growth on the selected media.

The media employed are selective, differential, or both. Eosin–methylene blue (EMB) agar, for example, is a widely used selective and differential medium for the isolation and differentiation of enteric bacteria. Methylene blue is selective because it inhibits the growth of gram-positive bacteria, and thus only gram-negative organisms can grow. EMB agar has an initial pH of 7.2 and contains lactose and sucrose, but not glucose, as energy sources. Acidification changes eosin, the differential media component, from colorless to red or black. Strong lactose-fermenting bacteria such as *Escherichia coli* acidify the medium and the colonies appear black with a greenish sheen. Enteric bacteria such as *Klebsiella* or *Enterobacter* produce less acid, and colonies on EMB are pink to red. Colonies of non-lactose fermenters,

such as *Salmonella*, *Shigella*, and *Pseudomonas*, are translucent or pink (Figure 27.6c). Thus, EMB is selective for the growth of gram-negative bacteria and also differentiates among common enteric bacteria.

Many differential media incorporate biochemical tests to measure the presence or absence of enzymes involved in catabolism of a specific substrate or substrates. Hundreds of differential biochemical tests are known, but only about 20 are used routinely. One example is the differential triple-sugar iron (TSI) agar test used to differentiate enteric pathogens. The fermentation and gas production patterns differentiate these bacteria at the genus and sometimes species levels (Figure 27.7). Another testing method uses chromogenic substrates that alter the color of colonies of targeted organisms. For instance, CHROMagar, a proprietary selective and differential media, inhibits the growth of most microorganisms. Methicillin-resistant *Staphylococcus aureus* (MRSA), however, produces distinctive pink colonies; the fluorogenic medium contains compounds that fluoresce when metabolized by MRSA.

The biochemical reaction patterns for pathogens are stored in a databank. Using the results of differential tests on an unknown pathogen, the computer matches the characteristics of the unknown organism to metabolic patterns of known pathogens, allowing identification. As few as three or four key tests are sufficient to make an unambiguous identification of many pathogens. However, in some cases more sophisticated identification procedures are required. The clinical microbiologist decides which diagnostic tests to use based on the origin of the clinical specimen, the characteristics of a pure culture of the specimen grown on general-purpose media (for example, morphology and Gram stain), and previous experience with similar cases.

MINIQUIZ

27.5 Antimicrobial Drug Susceptibility Testing

Pathogens isolated from clinical specimens are identified to confirm medical diagnoses and to guide antimicrobial therapy. For many pathogens, appropriate and effective antimicrobial treatment is based on current experience and practices. For a select group of pathogens, however, decisions about appropriate antimicrobial therapy must be made on a case-by-case basis. Such pathogens include those for which antimicrobial drug resistance is common (for example, gram-negative enteric bacteria), those that cause life-threatening disease (for example, meningitis caused by *Neisseria meningitidis*), and those that require bacteriocidal rather than bacteriostatic drugs (Section 5.19) to prevent disease progression and tissue damage. Bacteriocidal agents are indicated, for example, for organisms that cause bacterial endocarditis, where total and rapid killing of the pathogen is critical for patient survival.

Minimum Inhibitory Concentration

Antimicrobial susceptibility is measured by determining the smallest amount of agent needed to completely inhibit the growth of the tested organism *in vitro*, a value called the **minimum inhibitory concentration (MIC)**. To determine the MIC for a given agent against a given organism, a series of culture tubes is prepared and inoculated with the same number of microorganisms. Each tube contains medium with an increasing concentration of the antimicrobial agent. After incubation, the tubes are checked for visible growth (turbidity). In practice, this is done in an automated format using microliter amounts of media and reagents. The MIC is the lowest concentration of an agent that completely inhibits the growth of the test organism (Figure 5.40). A miniaturized version of this test shows a standard microtiter method for determining MIC using twofold dilutions of several antibiotics in medium inoculated with a standard amount of the test bacteria (Figure 27.8a). In a clinical microbiology laboratory, the tests for routine MIC determinations are automated.

Measuring Antimicrobial Susceptibility

The standard assay for antimicrobial activity is the *disc diffusion test* (Figure 27.8b–f). A Petri plate containing an agar medium is inoculated by evenly spreading a suspension of a pure culture of the suspected pathogen on the agar surface. Known amounts of an antimicrobial agent on filter-paper discs are then placed on the surface of the agar. During incubation, the agent diffuses from the disc into the agar during a specified period of incubation, establishing a gradient; the farther the chemical diffuses away from the filter paper, the lower is the concentration of the agent. At some distance from the disc, the effective MIC is reached. Beyond this point the microorganism grows, but closer to the disc, growth is absent. A *zone of inhibition* forms with a diameter proportional to the amount of antimicrobial agent added to the disc, the solubility of the agent, the diffusion coefficient, and the overall effectiveness of the agent.

Figure 27.8g demonstrates antibiotic susceptibility using a preformed and predefined gradient of an antimicrobial agent immobilized on a plastic strip. The concentration gradient covers an MIC range across 15 twofold dilutions. When applied to the surface of an inoculated agar plate, the gradient transfers from the strip to the agar and remains stable for a period that covers the wide range of critical times associated with the growth characteristics of different pathogenic bacteria. After a suitable incubation period, an elliptical zone of inhibition centered along the axis of the strip develops. The MIC value (in micrograms per milliliter) can be read at the point where the ellipse edge intersects the precalibrated test strip, providing a precise MIC.

The MIC is not a constant for a given agent; it varies with the test organism, the inoculum size, the composition of the culture medium, the incubation time, and the conditions of incubation, such as temperature, pH, and aeration. When culture conditions are standardized, however, different antimicrobial agents can be compared to determine which is most effective against the isolated pathogen. Standards for antimicrobial agents are constantly updated by the Clinical and Laboratory Standards Institute, an organization that develops and establishes voluntary consensus standards for antimicrobial testing (<http://www.clsi.org>). The United States Food and Drug Administration sets standards for automated instruments used for susceptibility testing in the United States.

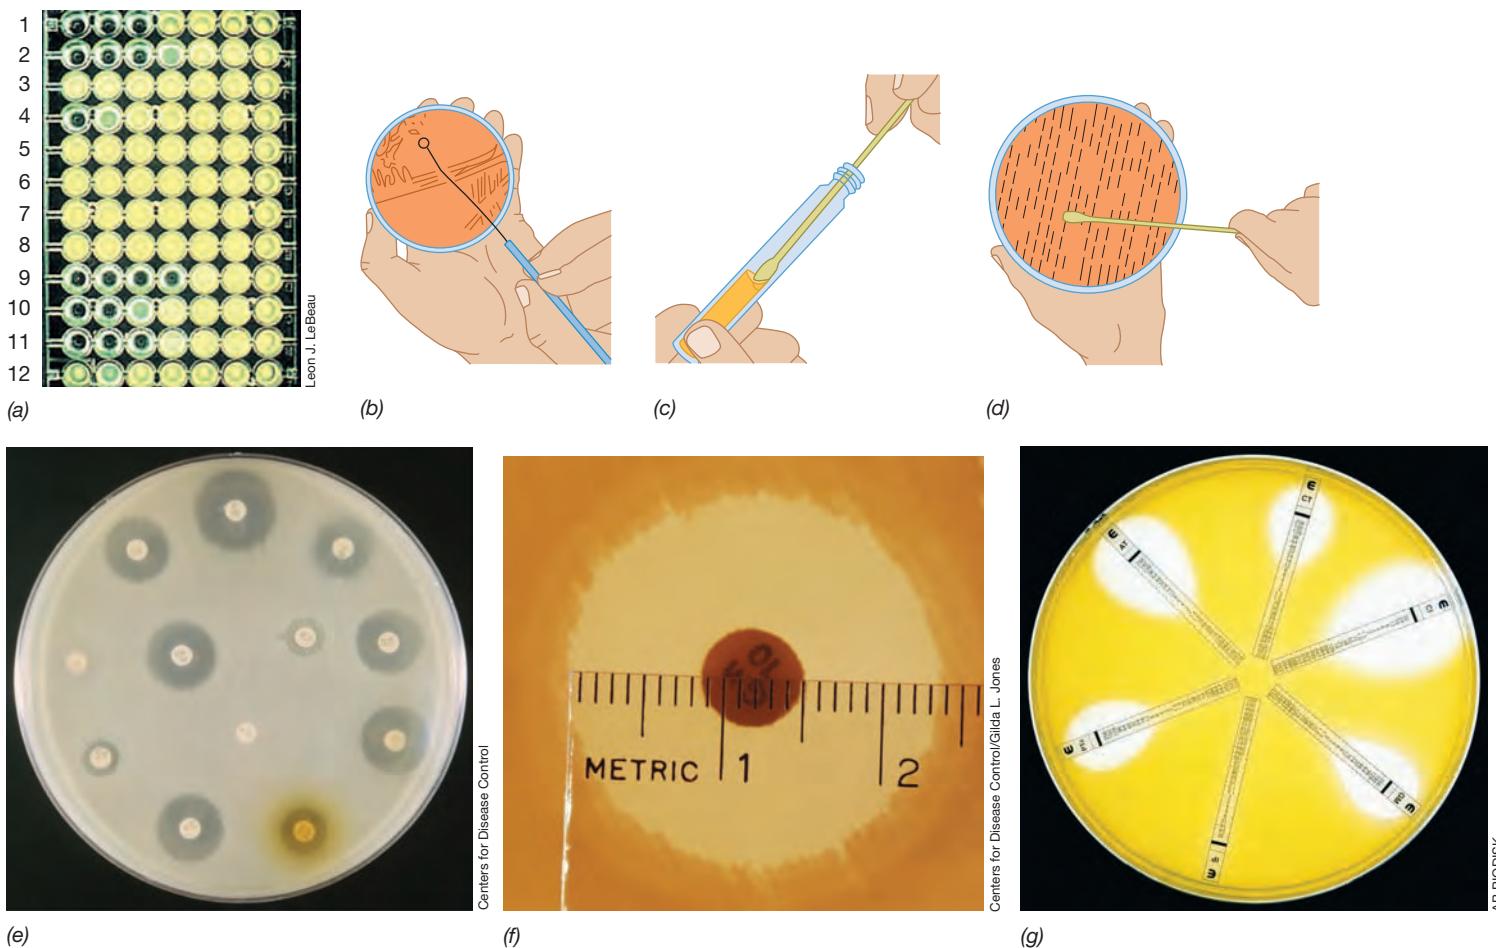

Figure 27.8 Antibiotic susceptibility testing.

Methods for determining the susceptibility of an organism to antibiotics. (a) Antibiotic susceptibility as determined by the broth dilution method in a microtiter plate. The organism is *Pseudomonas aeruginosa*. Each row has a different antibiotic. The end point is the well with the lowest concentration of antibiotic that shows no visible bacterial growth. The highest concentration of antibiotic is in the well at the left; serial twofold dilutions are made in the wells to the right. In rows 1 and 2, the end point is the third well.

In row 3, the antibiotic is ineffective at the concentrations tested, since there is bacterial growth in all the wells. In row 4, the end point is in the first well. (b) For the disc diffusion test, isolated pure colonies are homogenized in liquid medium to standard turbidity. (c, d) A sterile cotton swab is dipped into the bacterial suspension and streaked evenly over the surface of an appropriate agar medium. (e) Discs containing known amounts of different antibiotics are placed on the inoculated agar surface. (f) After incubation, inhibition zones are observed and measured; the

susceptibility of the organism is determined by reference to an interpretive chart of zone sizes. (g) Antibiotic susceptibility determined by the Etest (AB BIODISK, Solna, Sweden) for different antibiotics. Each strip, laid on an inoculated plate before incubation, is calibrated in $\mu\text{g}/\text{ml}$ starting with the lowest concentration from the center of the plate. The lowest concentration of antibiotic that inhibits bacterial growth is the MIC value. For example, the MIC for cefotaxime (CT) is 16 $\mu\text{g}/\text{ml}$. This organism is resistant to imipenem (IP); $\text{MIC} > 27 \mu\text{g}/\text{ml}$.

Hospital infection-control microbiologists generate and examine susceptibility data to generate periodic reports called **antibiograms**. These reports define the susceptibility of clinically isolated organisms to the antibiotics in current use. Antibiograms are used to monitor control of known pathogens, to track the emergence of new pathogens, and to identify the emergence of antibiotic resistance at the local level.

III • Growth-Independent Diagnostic Methods

Immunological assays are used in clinical, reference, and research laboratories to detect specific pathogens or pathogen products. When culture methods for pathogens are not routinely available or are prohibitively difficult to perform, as is the case with many

viral infections or some bacterial pathogens, immunoassays or pathogen-specific nucleic acid amplification assays using the polymerase chain reaction (PCR) provide means to identify individual pathogens or host exposure to pathogens.

27.6 Immunoassays for Infectious Diseases

The immune response was discussed in Chapters 24–26. Many immunoassays utilize antibodies specific for pathogens or their products for in vitro tests designed to detect individual infectious agents. Patient immune responses can also be monitored to obtain evidence of pathogen exposure and infection.

Serology, Specificity, and Sensitivity

The study of antigen–antibody reactions in vitro is called **serology**. When extended to diagnostic microbiology, serology means detection of pathogen-induced antibodies. Serological tests assay patient serum for antibody content and are the basis for a number of diagnostic tests. Antigen–antibody reactions rely on the specific interaction of antigen with an antibody molecule (➡ Section 25.7).

For serological tests, *specificity* means that the antibody–antigen reaction that is observed identifies exposure to a single pathogen. Thus, the antigen used to detect antibodies in patient serum must be unique to the pathogen in question, avoiding false-positive reactions. The *sensitivity* of some common serological tests in terms of the amount of antibody necessary to detect antigen varies considerably. Passive *agglutination* reactions, which are fast and easy to perform, require antibody concentrations of up to 6 nanograms (ng, 10^{-9} g) per ml, while the very sensitive but more technically demanding *enzyme immunoassay* (EIA) tests require as little as 0.1 ng of antibody per ml and can detect as little as 0.1 ng of antigen (Section 27.9). Agglutination assays and EIAs are used to detect either antigens or antibodies in patient sera.

Antibody Titers

An alternative approach to isolation and culture of a pathogen that provides strong indirect evidence for infection is to measure antibody *titer* (quantity) directed to antigens produced by the suspected pathogen. If an individual is infected with a suspected pathogen, the immune response—in this case, the antibody titer—to that pathogen should become elevated. Serial dilutions of patient serum are assayed by methods we will discuss in Sections 27.7–27.9. The *titer* is defined as the highest dilution (lowest concentration) of serum at which an antigen–antibody reaction is observed (Figure 27.9).

A positive antibody titer indicates previous infection or exposure to a pathogen. For pathogens rarely found in a population, a single positive test for a pathogen-specific antibody without a follow-up test may indicate ongoing, active infection. For example, this is the case for hantavirus diseases (➡ Section 30.2). In most cases, however, the mere presence of antibody does not indicate active infection. Antibody titers typically remain detectable for long periods after a previous infection has been resolved. To link an acute illness to a particular pathogen, it is essential to show a *rise* in antibody titer in serum samples taken from a patient during the acute disease and later during the convalescent phase of the disease. Frequently, the antibody titer is low during the acute stage of the infection and rises during convalescence (Figure 27.9). A rise in antibody titer is strong circumstantial evidence that the illness is due to the suspected pathogen.

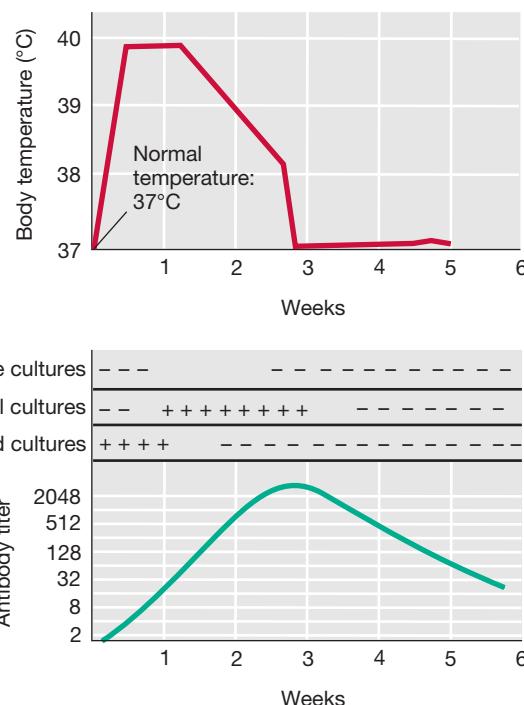

Figure 27.9 Infection and immunity in typhoid fever. The data are a composite pattern seen in untreated patients. Body temperature indicates acute disease progression over time. Antibody titer was measured by determining the highest twofold serum dilution causing agglutination of *Salmonella enterica* serovar Typhi (➡ Section 31.5). Titer is shown as the reciprocal of the highest dilution showing an agglutination reaction. Presence of viable bacteria in blood, feces, and urine was determined from cultures. The pathogen clears from the blood as the antibody titer rises, while clearance from feces and urine requires more time. Body temperature gradually drops to normal as the antibody titer rises. Typhoid used to be a major public health threat in the United States before drinking water was routinely filtered and chlorinated (➡ Section 28.5).

Skin Tests

A number of pathogens induce a delayed-type hypersensitivity (DTH) response mediated by Th1 cells (➡ Sections 24.3 and 24.8). For these pathogens, skin testing may be useful for determining exposure. As an example, a commonly used skin test is the *tuberculin test*, which consists of an intradermal injection of a soluble extract from cells of *Mycobacterium tuberculosis*. A positive inflammatory reaction at the site of injection within 48 hours indicates current infection or previous exposure to *M. tuberculosis*. This test identifies responses caused by pathogen-specific inflammatory Th1 cells (➡ Figure 24.6). Skin tests are routinely used for aiding in diagnosis of tuberculosis, Hansen's disease (leprosy), and some fungal diseases because the antibody responses for intracellular and fungal infections are often undetectable or are very weak.

If a pathogen is extremely localized, there may be little induction of a systemic immune response and no rise in antibody titer or skin test reactivity, even if the pathogen is proliferating profusely at the site of infection. A good example is gonorrhea, caused by infection of mucosal surfaces with *Neisseria gonorrhoeae*. Gonorrhea does not elicit a systemic or protective immune response, there is no serum antibody titer or skin test reactivity, and reinfection of individuals is common (➡ Section 29.12).

27.7 Agglutination

Agglutination is a reaction between antibody and particle-bound antigen resulting in visible clumping of the particles. Agglutination tests can be done in test tubes or in small-volume microtiter plates, or can be done by mixing reagents on glass slides. Agglutination tests are widely used in clinical and diagnostic laboratories; they are simple to perform, highly specific, inexpensive, rapid, and reasonably sensitive. Standardized agglutination tests are used for the identification of blood group (red blood cell) antigens (Figure 27.10a) as well as pathogens and pathogen products. To determine blood groups, blood samples are mixed with either anti-A antisera or anti-B antisera and the agglutination of red blood cells is assessed (Figure 27.10).

Direct agglutination results when soluble antibody causes clumping due to interaction with an antigen that is an integral part of the surface of a cell or other insoluble particle such as a red blood cell (erythrocyte). Agglutination of red blood cells is called *hemagglutination* and is the basis for human blood typing (Figure 27.10). *Passive agglutination* is the agglutination of soluble antigens or antibodies that have been adsorbed or chemically coupled to insoluble particles such as latex beads or charcoal particles.

Figure 27.11 Latex bead agglutination test for *Staphylococcus aureus*

aureus. Panel 1 shows a negative control. Note the uniform pink color of the suspended latex beads coated with antibodies to protein A and clumping factor, two antigens found exclusively on the surface of *S. aureus* cells. Panel 2 shows the same suspension after a loopful of material from a bacterial colony was mixed into the suspension. The bright red clumps indicate a positive agglutination, identifying the colony as *S. aureus*.

The insoluble antigen or antibody can then be detected by agglutination reactions. The cell or particle serves as an inert carrier. Passive agglutination is up to five times more sensitive than direct agglutination.

The agglutination of antigen-coated or antibody-coated latex beads by complementary antibody or antigen from a patient is a typical rapid assay. Small (0.8-μm diameter) latex beads coated with a specific antigen are mixed with patient serum on a microscope slide and incubated for a short period. If patient antibody binds the antigen on the bead surface, the milky white latex suspension will become visibly clumped, indicating a positive agglutination reaction and exposure to the pathogen.

Latex agglutination is also used to detect bacterial surface antigens by mixing a small amount of a bacterial colony with antibody-coated latex beads. For example, a commercially available suspension of latex beads coated with antibodies to protein A and clumping factor, two proteins found exclusively on the surface of *Staphylococcus aureus* cells, is specific for identification of clinical isolates of *S. aureus*. Unlike traditional growth-dependent tests for *S. aureus*, the latex bead assay takes less than a minute and can be used directly on a clinical sample, such as the material from a purulent infection possibly caused by *S. aureus* (Figure 27.11). Latex bead agglutination assays have also been developed to identify other common pathogens such as *Streptococcus pyogenes*, *Neisseria gonorrhoeae*, *Escherichia coli* O157:H7, the fungus *Candida albicans*, and many others.

Passive agglutination assays require no expensive equipment or particular expertise, and can be highly specific and reasonably sensitive. The cost-effective nature of the assays makes them suitable for large-scale screening programs. These tests are therefore widely used in clinical applications.

27.8 Immunofluorescence

Antibodies containing conjugated fluorescent dyes can be used to detect antigens on intact cells. Such **fluorescent antibodies** are widely used for diagnostic and research applications.

Fluorescent Methods

Fluorescent antibody-staining methods can be either direct or indirect (Figure 27.12). In the *direct method*, the antibody that interacts with the surface antigen is itself covalently linked to the fluorescent dye. In the *indirect method*, the presence of a non-fluorescent antibody on the surface of a cell is detected by the use of a fluorescent antibody directed against the nonfluorescent antibody.

Antibodies can be covalently modified by fluorescent dyes such as rhodamine B, which fluoresces red, or fluorescein isothiocyanate, which fluoresces yellow-green. The attached dyes do not alter the specificity of the antibody but make it possible to detect the complex by use of a fluorescence microscope once it has bound to cell or tissue surface antigens. The cell-bound fluorescent antibodies emit their characteristic fluorescent color when excited with light of particular wavelengths. Fluorescent antibodies can be used to identify a microorganism directly in a patient specimen (*in situ*), bypassing the need for the isolation and culture of the organism.

Applications

In a typical test using fluorescent antibodies, a specimen containing a suspected pathogen is mixed with a specific fluorescent antibody and observed with a fluorescence microscope. If the pathogen contains surface antigens reactive with the antibody, the pathogen cells fluoresce (Figure 27.13). Fluorescent antibodies can be applied directly to infected host tissues, permitting diagnosis long before primary isolation techniques yield a suspected pathogen. For example, for diagnosing legionellosis (or Legionnaires' disease), a form of infectious pneumonia (see Section 31.4), a positive identification can be made by staining biopsied lung tissue directly with fluorescent antibodies specific for cell wall antigens

of *Legionella pneumophila* (Figure 27.13b), the causative agent of the disease. Likewise, a direct fluorescent antibody test detecting the capsule of *Bacillus anthracis* can be used to confirm a diagnosis for anthrax (see Figure 23.11a).

Direct or indirect fluorescent antibody tests are also used to help diagnose viral infections with pathogens such as human B lymphotropic virus (HBLV), respiratory syncytial virus (RSV), and Epstein-Barr virus (EBV) (Figure 27.14). The common respiratory pathogens influenza A and B, parainfluenza, and adenovirus can also be identified using immunofluorescence of tissue-culture cells infected with virus from respiratory tract specimens.

27.9 Enzyme Immunoassays, Rapid Tests, and Immunoblots

Enzyme immunoassays (EIAs), or *enzyme-linked immunosorbent assays (ELISAs)*, are very sensitive immunological assays widely used in clinical and research applications. An EIA can detect as little as 0.01 nanograms of antigen or antibody. The speed (the assay typically can be done in several hours), low cost, lack of hazardous waste, long shelf life, high specificity, and high sensitivity of EIA tests make them particularly useful immunodiagnostic tools. **Rapid tests** are similar to EIAs except that results can often be reported within minutes. Many rapid tests are designed to be given as point-of-care tests but are generally not as specific or sensitive as EIAs. The comparatively complex and time-consuming **immunoblot (Western blot)** uses immobilized pathogen proteins to bind antibodies from patient specimens such as serum, providing highly specific evidence for pathogen exposure. The immunoblot is often used to confirm results obtained from other serological tests such as rapid tests or EIAs.

EIA

In EIA tests, an enzyme is covalently attached to an antigen or antibody molecule, creating an immunological tool with high specificity and high sensitivity. The enzyme's catalytic properties and the specific binding properties of the labeled antigen or antibody are unaltered. Enzymes typically bound to antigen or antibody include peroxidase, alkaline phosphatase, and β -galactosidase, all of which interact with enzyme-specific substrates to form colored reaction products that can be detected in very low amounts.

Four EIA formats are commonly used for evaluation of specimens for infectious disease, one for detecting antigen (*direct EIA*), another for detecting antibodies (*indirect EIA*), one that detects antibody using a sandwich technique (*antigen sandwich EIA*), and one that detects both antigen and antibody (*combination EIA*). The principal features of each platform are illustrated in **Figure 27.15**.

Direct EIAs are designed to detect antigens such as virus particles in a blood or fecal sample (Figure 27.15a). Antibodies directed to a pathogen antigen are coated onto a matrix such as

a plastic microtiter plate. The patient sample such as serum is then added. After antigen in the sample binds to the antibody, a second antibody is added. This antibody is also specific for the antigen, and coupled to an enzyme. Finally, enzyme substrate is added and the enzyme converts the substrate to its colored product in proportion to the amount of patient antigen bound by the enzyme–antibody complex. Direct EIAs are useful for detecting antigens including cholera toxin, enteropathogenic *Escherichia coli* toxin, and *Staphylococcus aureus* enterotoxin. Viruses currently detected using direct EIA techniques include influenza, rotavirus, hepatitis viruses, rubella virus, bunyavirus, measles virus, mumps virus, and parainfluenza virus.

Indirect EIAs are used to detect antibodies to pathogens in body fluids (Figure 27.15b). The indirect test starts with pathogen antigen immobilized on the matrix. Patient serum is added and, if antibodies are present, they bind to the antigen. Next, an antibody–enzyme complex specific for the patient antibodies is added. Finally, the addition of the enzyme substrate results in the development of a colored product that is proportional to the concentration of patient antibody on the sample.

Indirect EIAs have been developed for detecting serum antibodies to *Salmonella* (gastrointestinal diseases), *Yersinia* (plague), rickettsias (Rocky Mountain spotted fever, typhus, Q fever), *Vibrio cholerae* (cholera), *Mycobacterium tuberculosis* (tuberculosis), *Legionella pneumophila* (legionellosis), *Borrelia burgdorferi* (Lyme disease), and *Treponema pallidum* (syphilis), among others (Chapters 29, 30, and 31). EIAs have also been developed for detecting antibodies to *Candida* (yeast) and other eukaryotic pathogens, including those causing amebiasis, Chagas' disease, schistosomiasis, and malaria (Chapter 32).

The antigen sandwich EIA also detects antibodies to pathogens in body fluids (Figure 27.15c). The sandwich test starts with pathogen antigen immobilized on the matrix. Patient serum is added and, if antibodies are present, they bind to the antigen. Next, the same antigen coupled to enzyme is added. Finally, the addition of the enzyme substrate results in the development of colored product that is proportional to the concentration of patient antibody on the sample.

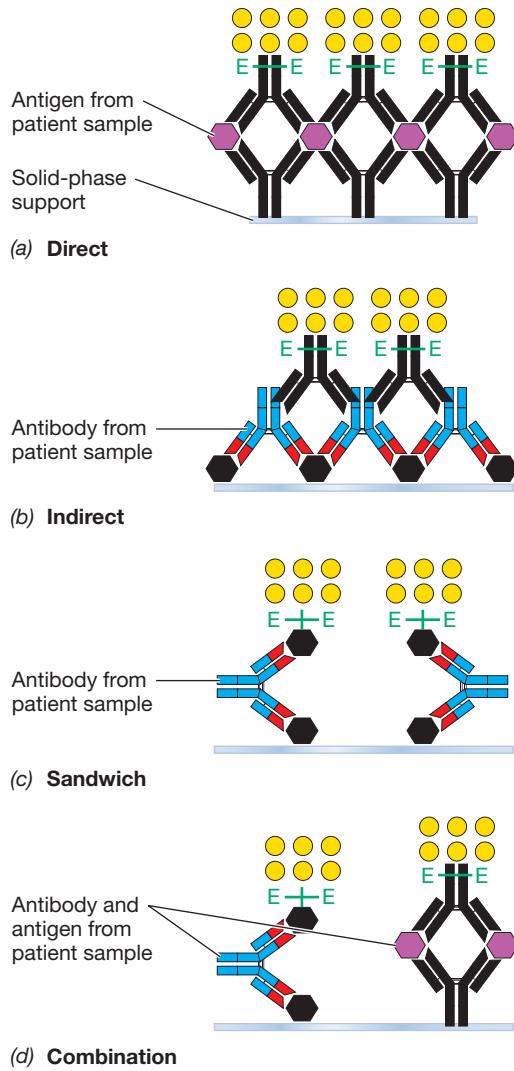

Figure 27.15 Enzyme immunoassays (EIAs). Patient samples are in color. Assay reagents are shown in black. All assays are fixed to a solid-phase support (light blue). Enzymes bound to antigen or antibody convert substrate to a colored product, shown in yellow. In each assay, the amount of colored product produced is proportional to the amount of pathogen-specific antibody or antigen derived from a patient sample. (a) The *direct EIA* uses immobilized pathogen-specific antibody and enzyme-labeled pathogen-specific antibody to detect pathogen antigen in patient samples such as blood. (b) The *indirect EIA* uses immobilized pathogen antigen and enzyme-labeled antibody directed to immunoglobulin to detect pathogen-specific antibodies in patient samples such as blood. (c) The *sandwich EIA* uses immobilized pathogen antigen and enzyme-labeled pathogen antigen to detect pathogen-specific antibodies in patient samples such as blood. The sandwich EIA is more sensitive than the direct or indirect EIA methods. (d) The *combination EIA* uses both the sandwich and direct assays in one platform to identify antibody and antigen in patient samples, maximizing sensitivity. Although a less sensitive assay, the immunoblot (see Figure 27.17) has greater specificity than EIAs.

The antigen sandwich method is considered the most sensitive antibody screening method because it detects pathogen-specific antibody irrespective of antibody isotype. This method is used for HIV screening (third-generation HIV test) and is preferable to indirect EIA tests because the sandwich test can detect the IgM isotype, produced in the primary immune response to HIV, about four weeks after infection. Most indirect tests use anti-IgG as the enzyme-conjugated antibody, delaying observation of antibodies to HIV to the onset of a secondary antibody response, about five weeks after infection (Figure 25.21).

The combination EIA, shown in Figure 27.15d, makes use of a direct EIA to detect pathogen antigen and the sandwich method to detect pathogen-specific antibodies, both on a single matrix. This method is used for a fourth-generation HIV test. This fourth-generation test is more sensitive than the third-generation sandwich test; antigen can be detected as little as 2.5 weeks after HIV infection, reducing the time to treatment.

Rapid Tests

Rapid immunoassay procedures use reagents adsorbed to a fixed support material such as paper strips, nitrocellulose, or plastic membranes. These tests cause a color change on the strip in a very short time. These “point-of-care” tests are rapid diagnostic aids for infectious diseases such as HIV/AIDS (Section 29.14), “strep throat” (pharyngeal infection with *Streptococcus pyogenes*, Section 29.2), influenza (Section 29.8), and gonorrhea (Section 29.12). Results can often be reported in minutes; however, the sensitivity and specificity of rapid tests are usually not as good as EIA tests for the same pathogens.

In most of these tests, a body fluid, generally urine, blood, saliva, or sputum, is applied to the reagent–support matrix (Figure 27.16). To detect patient antibody positive for a given antigen, as in rapid HIV tests, the matrix contains soluble antigen conjugated to a colored molecule called a *chromophore*. As the liquid sample diffuses through the matrix, antibodies bind the labeled antigen. Incorporated into the matrix is a single line of antigen fixed to the matrix. The labeled antigen–antibody complex migrates through the matrix, where it contacts and binds the fixed antigen, immobilizing the labeled antigen–antibody complex. As the concentration of labeled complex builds up, the chromophore becomes visible as a colored line on the line of fixed antigen, indicating a positive test for the antibody.

Similarly, to detect antigen in patient samples, for example for identification of infection by *S. pyogenes* (strep throat), the same system is used, but the chromophore is now bonded to antibody, and the putative antigen sample is applied to the matrix where it binds the soluble antibody–chromophore complex. As the liquid sample diffuses through the matrix, the patient antigen binds the labeled antibody. Fixed to the matrix is a single line of antibody. The now-labeled antigen–antibody complex migrates through the matrix, where it contacts the fixed antibody. The labeled antibody–antigen complex binds the fixed antibody, immobilizing the entire complex. As the concentration of labeled complex builds up, the chromophore becomes visible on the line of fixed antibody, indicating a positive test for the antigen.

These tests are valuable for point-of-care analysis at the site where the sample is collected (for instance, away from a clinical

laboratory) and for rapid tests in the laboratory. Results can be reported almost immediately, avoiding the need for delays in patient care or for follow-up visits to obtain test results. The drawback to these tests, however, is that they are often less specific or less sensitive than more elaborate tests. As a result, rapid tests are often confirmed by EIA or other tests.

Immunoblots

Immunoblot method employs three techniques: (1) the *separation* of proteins on polyacrylamide gels, (2) the *transfer* (blotting)

of proteins from gels to a nitrocellulose or nylon membrane, and (3) the *identification* of the proteins by specific antibodies. The HIV immunoblot (**Figure 27.17**) is widely used for confirmation of HIV infection. HIV immunoblots are generally less sensitive, more laborious, more time consuming, and more costly than the HIV EIA, so they are not used as HIV exposure screening tools. Immunoblots are used for confirmation of HIV infection, however, because the HIV EIA, while very sensitive, occasionally yields false-positive results. The more specific immunoblot is used to confirm positive EIA results. The HIV immunoblot procedures are similar to those used for immunoblots to diagnose infection by other pathogens. In general, immunoblot procedures are used to detect pathogen-specific antibody in patient samples.

To perform the HIV immunoblot, membrane strips with fixed HIV proteins are incubated with the patient serum sample. If the sample is HIV-positive, patient antibodies will bind to the HIV proteins on the membrane. To detect whether antibodies from the serum sample have bound to HIV antigens, a detecting antibody, anti-human IgG conjugated to an enzyme, is added to the strips. If the detecting antibody binds, the activity of the conjugated enzyme, after addition of substrate, will form a colored band on the strip at the site of antibody binding. The patient is HIV-positive if the position of the bands resolved by exposure to the patient serum and a positive control serum are identical; a control negative serum is also analyzed in parallel and must show no bands (Figure 27.17). Although the intensity of the bands obtained in the HIV immunoblot varies somewhat from sample to sample, the interpretation of an immunoblot is generally unequivocal; the test is most commonly used to confirm positive EIA results for HIV and eliminate false positives.

27.10 Nucleic Acid Amplification

We discussed in Section 11.3 how the polymerase chain reaction (PCR) amplifies nucleic acids, forming multiple copies of target sequences. PCR techniques use primers for a pathogen-specific gene to examine DNA derived from suspected infected tissue, even in the absence of an observable, culturable pathogen. As a result, PCR-based tests are widely used for identification of a number of individual pathogens and are particularly useful for identifying viral and intracellular infections, where culturing the responsible agents may be very difficult or even impossible. Extremely sensitive methods based on nucleic acid analyses are widely used in clinical microbiology to detect pathogens.

These methods do not depend on pathogen isolation or growth, or on the detection of an immune response to the pathogen. Instead, it is species-specific nucleic acid sequences that are detected in the assays.

PCR Testing and Analysis

PCR-based tests include three basic components. First, DNA or RNA must be extracted from the sample to be tested. Second, the nucleic acid must be amplified using appropriate gene-specific nucleic acid primers. Short oligonucleotides (typically 15–27 nucleotides in length) are used as primers for PCR amplification of a specific gene or genes characteristic for a specific pathogen. This requires knowledge of the sequence of the pathogen target genes. Third, the amplified nucleic acid product (the *amplicon*) must be visualized, a procedure that can involve gel electrophoresis or other methods. The presence of the appropriate amplified gene segment confirms the presence of the pathogen. PCR diagnostic methods are used for identification of nearly all pathogens.

Quantitative PCR

Many PCR tests employ *quantitative real-time PCR* (*qPCR*). The qPCR test uses fluorescently labeled PCR amplicons that yield an almost immediate result, avoiding the need for postamplification nucleic acid purification and visualization. The accumulation of target DNA is monitored during the qPCR process. This is achieved by adding fluorescent probes to the PCR reaction mixture. Probe fluorescence increases upon binding to DNA. As the target DNA is amplified, the level of fluorescence increases proportionally. The fluorescent probes may be nonspecific or may be specific for the target DNA. For example, the dye SYBR Green binds *nonspecifically* to double-stranded DNA, but does not bind to single-stranded DNA or RNA; SYBR Green added to the PCR mixture becomes fluorescent only when bound, indicating that double-stranded DNA is present, in this case due to the amplification process (Figure 27.18). *Gene-specific* fluorescent probes are made by attaching a fluorescent dye to a short DNA probe that matches the target sequence being amplified: The dye fluoresces only when double-stranded DNA of the correct sequence accumulates.

Because qPCR amplification can be monitored continuously, visualization by gel electrophoresis or other detection methods is not necessary to confirm amplification; detection of a gene diagnostic for a particular pathogen in a clinical sample may be performed in several hours instead of the usual overnight processing

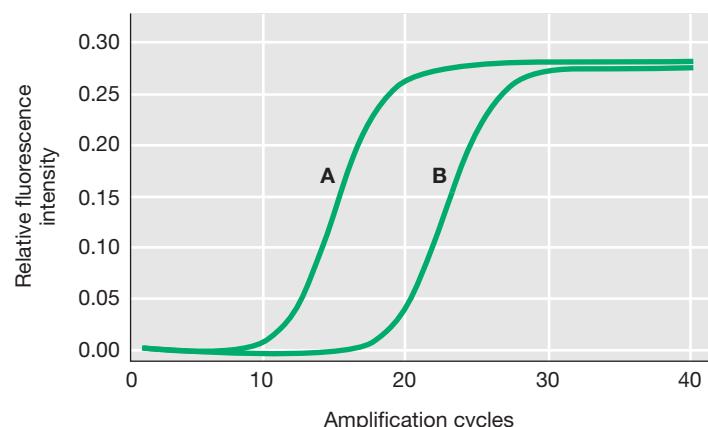

Figure 27.18 Quantitative real-time polymerase chain reaction (qPCR) of 16S RNA genes from a gram-negative bacterium. DNA extracted from a laboratory culture was monitored for expression of 16S RNA (curve A) and *npt* (curve B), a kanamycin resistance marker, using gene-specific primers. SYBR Green, a fluorescent dye that fluoresces only when bound by double-stranded DNA, was mixed with the PCR mixture and used to visualize amplified DNA as it formed. The curve on the left (A) had 0.15 fluorescence units after 15 cycles, while the curve on the right (B) had 0.15 fluorescence units after 22 cycles, indicating that the 16S RNA had a higher template abundance in this strain as compared to the abundance of the template for *npt*.

required by standard PCR. Moreover, by monitoring the *rate* of fluorescence increase in the PCR reaction, it is possible to accurately determine the *amount* of target DNA present in the original sample; qPCR can be used to assess the abundance of a pathogen in a sample by quantifying a gene characteristic for that particular organism.

Reverse Transcription PCR

PCR has been extended by the development of *reverse transcription PCR* (*RT-PCR*). This technique is applied to the analysis of environmental samples in addition to clinical samples for identification of pathogens.

RT-PCR uses pathogen-specific RNA to produce complementary DNA (cDNA) directly from patient samples, and can be used for detection of RNA retroviruses such as HIV and other RNA viruses (Figure 11.6). The first step in RT-PCR is to use the enzyme reverse transcriptase (Section 9.11) to make a cDNA copy of an RNA sample. Next, PCR is used to amplify the cDNA. Expression of a particular gene from a pathogen may be monitored by isolating RNA and employing qPCR to make DNA copies of the corresponding gene(s). The amplified DNA can then be sequenced or probed for identification.

Qualitative PCR

Some diagnostic tests based on the qPCR format use a slightly different amplification protocol and an additional step to identify pathogen-associated genes. This method, called *qualitative PCR*, uses labeled hybridization primers that incorporate into an amplicon product of a qPCR reaction (Figure 27.19). In the example shown, the hybridization probes hybridize to the DNA *pol* gene of both herpes simplex 1 and 2 viruses (HSV-1 and HSV-2).

The amplicon is detected by fluorescence using a pair of specific hybridization probes. The probes are two different

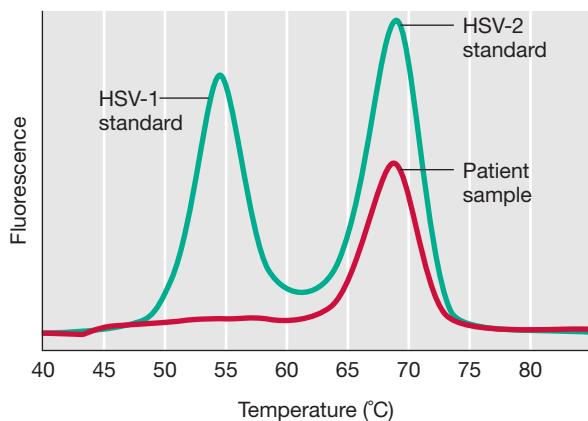

Figure 27.19 Qualitative real-time polymerase chain reaction for the *pol* gene of HSV-1 (herpes simplex 1 virus) and HSV-2. DNA from a patient sample was assayed for the *pol* gene of both HSV-1 and HSV-2 following quantitative PCR (qPCR). The assay uses two hybridization probes that incorporate into the qPCR amplicon product. The probes are labeled with fluorescent dyes that hybridize with an internal sequence of the amplified fragment of each viral genome during the PCR cycle. After hybridization to the template DNA, the probes are excited by a light source and their fluorescence is measured. After the PCR cycle, the DNAs are melted and each virus shows a distinct melting curve. The melting point in the patient sample (red) corresponds to the HSV-2 standard (green), indicating that the patient is infected with HSV-2.

oligonucleotides, labeled with fluorescent dyes. The probes hybridize to an internal sequence of the amplified fragment during the annealing phase of the PCR cycle. After hybridization to the template DNA, the probes are excited by a light source in the PCR instrument. The emitted fluorescence is then measured and, after the PCR cycle, a melting curve analysis is performed to differentiate between samples positive for HSV-1 and HSV-2. The melting curve will show a type-specific melting behavior due to nucleotide polymorphisms in the targeted hybridization sequences of HSV-1 and HSV-2. Because of these polymorphisms, the melting points for HSV-1 and HSV-2 are significantly different and allow clear determination of the HSV subtype.

This method provides results within hours. Results are compared to internal assay control reactions, avoiding the need for postamplification nucleic acid purification and visualization.

IV • Antimicrobial Drugs

Antimicrobial drugs are compounds that kill or control the growth of microorganisms in the host (in vivo). Effective antimicrobial drugs exhibit **selective toxicity**; they inhibit or kill pathogens without adversely affecting the host. Antimicrobial drugs are classified based on their molecular structure, mechanism of action (Figure 27.20), and spectrum of antimicrobial activity (Figure 27.21). Worldwide, 10,000 metric tons or more of various antimicrobial drugs are manufactured and used annually (Figure 27.22). Antimicrobial agents fall into two broad categories, *synthetic antimicrobial drugs* and *antibiotics*.

27.11 Synthetic Antimicrobial Drugs

Synthetic antimicrobial drugs include *growth factor analogs* that interfere with microbial metabolism and *quinolones* that interfere with DNA packaging in bacteria.

Growth Factor Analogs

Growth factors are specific chemical substances required by an organism that is unable to synthesize them. As a result, an outside source is essential for survival (► Section 3.1). A **growth factor analog** is a synthetic compound that is structurally similar to a growth factor, but subtle structural differences between the analog and the growth factor prevent the analog from functioning in the cell, thereby disrupting cell metabolism. Analogs are known for many important biomolecules such as certain vitamins, amino acids, and nucleosides. Some growth factor analogs are antibacterial. Those effective for the treatment of viral and fungal infections will be discussed in Sections 27.15 and 27.16.

Sulfa drugs were the first widely used growth factor analogs that specifically inhibited the growth of bacteria. The discovery of the first sulfa drug resulted from the large-scale screening of chemicals for activity against streptococcal infections in experimental animals. Sulfanilamide, the simplest sulfa drug, is an analog of *p*-aminobenzoic acid, which is a part of the vitamin folic acid, a nucleic acid precursor (Figure 27.23).

Sulfanilamide blocks the synthesis of folic acid, thereby inhibiting nucleic acid synthesis. Sulfanilamide is selectively toxic in bacteria because bacteria synthesize their own folic acid, whereas humans and most animals obtain folic acid from their diet. Initially, sulfa drugs were widely used for treatment of streptococcal infections. However, resistance to sulfonamides increased because many formerly susceptible pathogens developed an ability to take up folic acid from their environment. Antimicrobial therapy with sulfamethoxazole (a sulfa drug) plus trimethoprim, a related folic acid synthesis competitor, is still effective in many instances because the drug combination blocks two sequential steps in the folic acid synthesis pathway; resistance to this drug combination requires two mutations in genes of the same pathway, a relatively rare event.

Isoniazid (► Figure 29.17) is an important growth factor analog with a very narrow spectrum of activity (Figure 27.21). Effective only against *Mycobacterium*, isoniazid interferes with the synthesis of mycolic acid, a mycobacterial cell wall component. A nicotinamide (vitamin) analog, isoniazid is the most effective single drug used for control and treatment of tuberculosis (► Section 29.4).

Quinolones

The **quinolones** are synthetic antibacterial compounds that disrupt bacterial metabolism by interfering with bacterial DNA

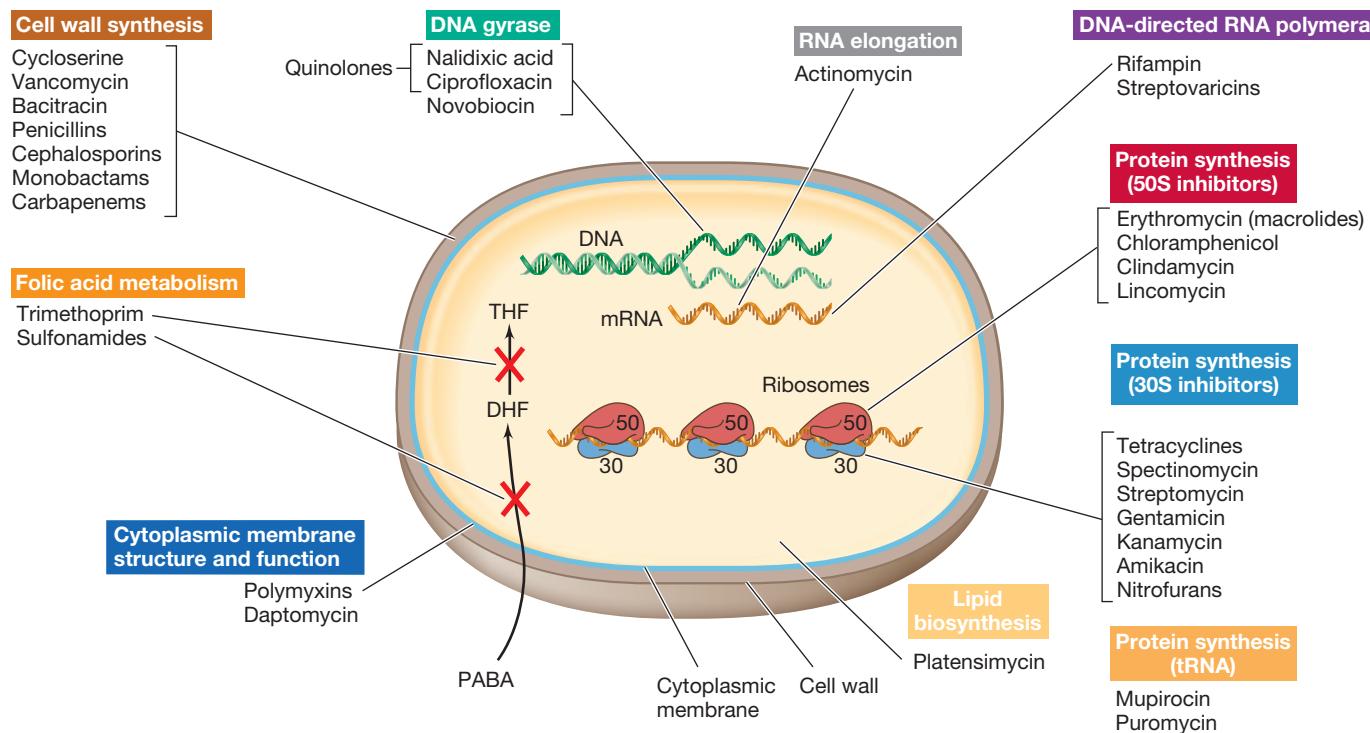

Figure 27.20 Targets of major antibacterial agents. Agents are classified according to their target structures in the bacterial cell. THF, tetrahydrofolate; DHF, dihydrofolate; mRNA, messenger RNA.

gyrase, preventing the supercoiling of DNA, a required step for packaging DNA in the bacterial cell (► Section 4.3). Because DNA gyrase is found in all *Bacteria*, the fluoroquinolones are effective for treating both gram-positive and gram-negative bacterial infections (Figure 27.21). Fluoroquinolones such as ciprofloxacin (Figure 27.24a) are routinely used to treat urinary tract infections in humans and have been widely used in the beef and poultry industries for prevention and treatment of respiratory

diseases in animals. Ciprofloxacin is also the drug of choice for treating anthrax because some strains of *Bacillus anthracis*, the causative agent of anthrax (► Section 30.8), are resistant to penicillin. Moxifloxacin (Figure 27.24b) is one of only a few drugs proven effective for treatment of tuberculosis. In combination with other anti-tuberculosis drugs (► Section 29.4), moxifloxacin may significantly reduce treatment time, a major problem with isoniazid-based treatments.

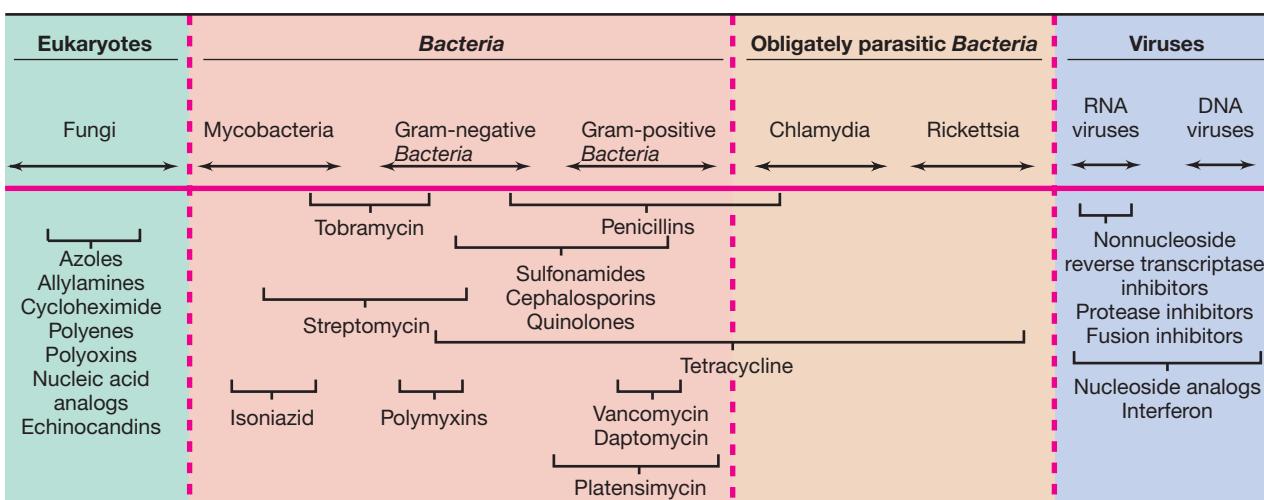

Figure 27.21 Antimicrobial spectrum of activity. Each antimicrobial agent affects a limited and well-defined group of microorganisms. A few agents are very specific and affect the growth of only a single genus. For example, isoniazid affects only organisms in the genus *Mycobacterium*.

The β-lactam antibiotics include cephalosporins (30%), penicillins (7%), and other β-lactams (15%). “Other” includes tetracyclines, aminoglycosides, and all other antimicrobial drugs.

27.12 Natural Antimicrobial Drugs: Antibiotics

Antibiotics are antimicrobial agents produced by microorganisms. Antibiotics are produced by a variety of *Bacteria* and fungi (*Eukarya*) and apparently function in nature as they do clinically:

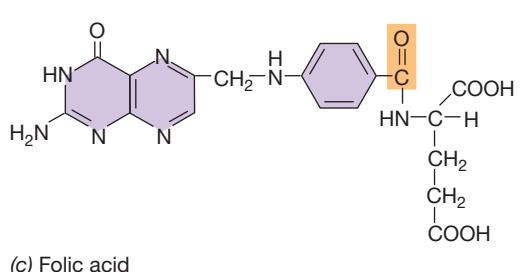

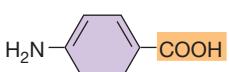

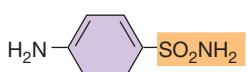

Figure 27.23 Sulfa drugs. (a) The simplest sulfa drug, sulfanilamide. (b) Sulfanilamide is an analog of *p*-aminobenzoic acid, a precursor of (c) folic acid, a growth factor.

(a) Ciprofloxacin, a fluorinated derivative of nalidixic acid with broad-spectrum activity, is more soluble than the parent compound, allowing it to reach therapeutic levels in blood and tissues. to inhibit or kill other microorganisms. Although thousands of antibiotics are known, less than 1% are clinically useful, often because of problems with host toxicity or lack of uptake by host cells. However, the clinically useful antibiotics have had a dramatic impact on the treatment of infectious diseases. Natural antibiotics can often be artificially modified to enhance their efficacy. These are said to be *semisynthetic* antibiotics.

Antibiotics and Selective Antimicrobial Toxicity

The susceptibility of individual microorganisms to individual antimicrobial agents varies significantly (Figure 27.21). For example, gram-positive *Bacteria* and gram-negative *Bacteria* differ in their susceptibility to an individual antibiotic such as penicillin; gram-positive *Bacteria* are generally affected, whereas most gram-negative *Bacteria* are naturally resistant. Certain **broad-spectrum antibiotics** such as tetracycline, however, are effective against both groups. As a result, a broad-spectrum antibiotic finds wider medical use than a narrow-spectrum antibiotic. An antibiotic with a limited spectrum of activity may, however, be quite valuable for the control of pathogens that fail to respond to other antibiotics. A good example is vancomycin, a narrow-spectrum antibiotic that is an effective bacteriocidal agent for gram-positive, penicillin-resistant enterococci as well as *Staphylococcus*, *Bacillus*, and *Clostridium* (Figure 27.21). Ribosomes, the cell wall, the cytoplasmic membrane, lipid biosynthesis enzymes, and DNA replication and transcription elements are important targets of antibiotics in *Bacteria* (Figure 27.20).

Antibiotics Affecting Translation

Some antibiotics inhibit protein synthesis by disrupting translation through interactions with the ribosome, often involving binding to ribosomal RNA (rRNA) (Figure 27.20). Many, such as chloramphenicol, streptomycin, and the tetracyclines, target ribosomes from only one phylogenetic domain, *Bacteria*, but have no effect on the cytoplasmic ribosomes of *Eukarya*. However, since mitochondria and chloroplast ribosomes in *Eukarya* have their evolutionary origins from bacterial ribosomes (that is, they are 70S ribosomes), antibiotics that inhibit protein synthesis in *Bacteria* also inhibit protein synthesis in these organelles (➡ Section 17.1). For example, tetracycline antibiotics inhibit 70S ribosomes, but are still medically useful because the eukaryotic 70S mitochondrial ribosomes are affected only at higher concentrations than are used for antimicrobial therapy.

Antibiotics Affecting Bacterial Transcription

A number of antibiotics specifically inhibit transcription by inhibiting RNA synthesis (Figure 27.20). For example, rifampin and the streptovaricins inhibit RNA synthesis by binding to the β -subunit of RNA polymerase in *Bacteria*, chloroplasts, and mitochondria. Actinomycin inhibits RNA synthesis by combining with DNA and blocking RNA elongation. This agent binds most strongly to DNA at guanine–cytosine base pairs, fitting into the major groove in the double strand where RNA is synthesized.

- What is a broad-spectrum antibiotic?

27.13 β -Lactam Antibiotics: Penicillins and Cephalosporins

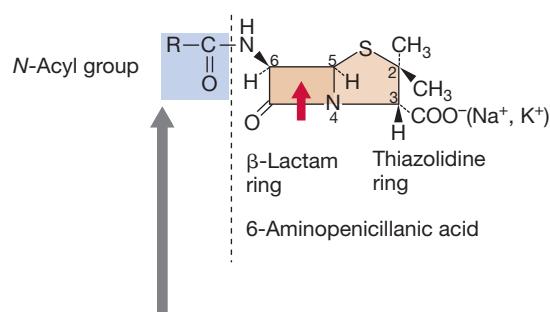

β -lactam antibiotics are cell-wall synthesis inhibitors that include the medically important penicillins and cephalosporins. These antibiotics share a characteristic structural component, the β -lactam ring (Figure 27.25). Together, the β -lactam antibiotics account for over one-half of all antibiotics produced and used worldwide (Figure 27.22).

Penicillins

In 1929 Alexander Fleming characterized the first antibiotic, an antibacterial compound called **penicillin** (Figure 27.25) isolated from the fungus *Penicillium chrysogenum*. This new β -lactam antibiotic was dramatically effective for controlling staphylococcal and pneumococcal infections and was more effective for treating streptococcal infections than sulfa drugs. Penicillin revolutionized the treatment of infectious diseases when it came into general use after World War II.

The β -lactam antibiotics are inhibitors of bacterial cell wall synthesis. An important feature of bacterial cell wall synthesis is *transpeptidation*, the reaction that results in the cross-linking of two glycan-linked peptide chains (Section 5.4). Because the cell wall and its synthesis mechanisms are unique to *Bacteria*, the β -lactam antibiotics are highly selective and nontoxic to host cells.

Penicillin G (Figure 27.25) is active primarily against gram-positive *Bacteria* because gram-negative *Bacteria* are impermeable to the antibiotic, but chemical modification of the penicillin G structure significantly changes the resulting antibiotic; many chemically modified semisynthetic penicillins are effective against gram-negative *Bacteria*. For example, ampicillin and carbenicillin are semisynthetic penicillins effective against some gram-negative *Bacteria*. The structural differences in these semisynthetic penicillins allow them to be transported inside the gram-negative outer membrane (Section 2.11), where they inhibit cell wall synthesis. Penicillin G is also sensitive to β -lactamase, an enzyme produced by a number of penicillin-resistant *Bacteria* (see Section 27.17). Oxacillin and methicillin are widely used β -lactamase-resistant semisynthetic penicillins.

<i>N</i> -Acyl group	Designation

	SEMSYNTETIC PENICILLINS Methicillin acid-stable, β -lactamase-resistant
	Oxacillin acid-stable, β -lactamase-resistant
	Ampicillin broadened spectrum of activity (especially against gram-negative <i>Bacteria</i>), acid-stable, β -lactamase-sensitive
	Carbenicillin broadened spectrum of activity (especially against <i>Pseudomonas</i> <i>aeruginosa</i>), acid-stable but ineffective orally, β -lactamase-sensitive

Figure 27.25 Penicillins. The red arrow (top panel) is the site of activity of most β -lactamases, enzymes that destroy penicillin and other β -lactam antibiotics. Most acid-stable penicillins can be administered orally.

Cephalosporins

Cephalosporins, produced by the fungus *Cephalosporium* sp., differ structurally from the penicillins. They retain the β -lactam ring but have a six-member dihydrothiazine ring instead of the five-member thiazolidine ring (Figure 27.26). The cephalosporins have the same mode of action as the penicillins; they bind irreversibly to PBPs and prevent the cross-linking of peptidoglycan. Clinically important cephalosporins are semisynthetic antibiotics with a broader spectrum of antibiotic activity than the penicillins. In addition, cephalosporins are typically more resistant to the enzymes that destroy β -lactam rings, the β -lactamases. For example, ceftriaxone (Figure 27.26) is highly resistant to β -lactamases and has replaced penicillin for treatment of *Neisseria gonorrhoeae* (gonorrhea) infections because many *N. gonorrhoeae* strains are now resistant to penicillin (Section 29.12).

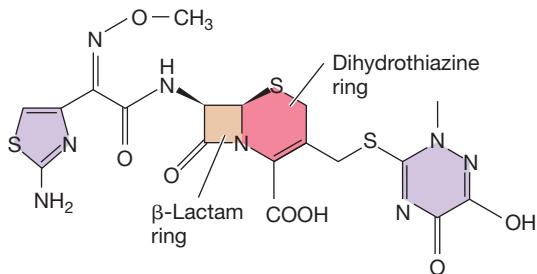

Figure 27.26 Ceftriaxone. Ceftriaxone is a β -lactam antibiotic that is resistant to most β -lactamases due to the adjacent six-member dihydrothiazine ring. Compare this structure to the five-member thiazolidine ring of the β -lactamase-sensitive penicillins (Figure 27.25).

- Of what clinical value are semisynthetic penicillins over natural penicillin?

27.14 Antibiotics from Bacteria

Many antibiotics active against *Bacteria* are also produced by *Bacteria*. These include many antibiotics that have major clinical applications.

Aminoglycosides

Antibiotics that contain amino sugars bonded by glycosidic linkage are called **aminoglycosides**. Clinically useful aminoglycosides include streptomycin (produced by *Streptomyces griseus*) and its relatives, kanamycin (Figure 27.27), neomycin, and gentamicin. The aminoglycosides target the 30S subunit of the ribosome,

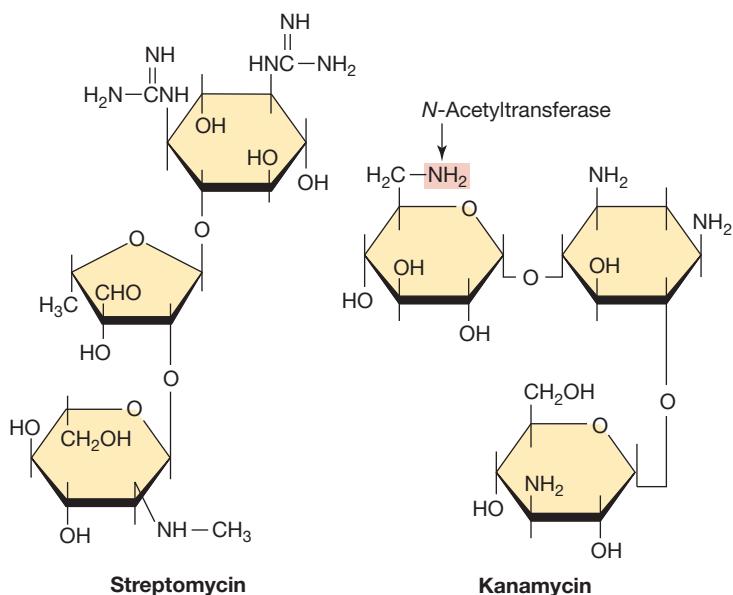

Figure 27.27 Aminoglycoside antibiotics: streptomycin and kanamycin. The amino sugars are in yellow. At the position indicated, kanamycin can be modified by a resistance plasmid that encodes *N*-acetyltransferase. Following acetylation, the antibiotic is inactive. Both kanamycin and streptomycin are synthesized by *Streptomyces* species.

inhibiting protein synthesis (Figure 27.20), and are useful for treatment of infections by gram-negative *Bacteria* (Figure 27.21).

The use of aminoglycosides for treatment of gram-negative infections has decreased since the development of the semisynthetic penicillins (Section 27.13) and tetracyclines (discussed later in this section). Aminoglycoside antibiotics are now used primarily when other antibiotics fail.

Macrolides

Macrolide antibiotics contain lactone rings bonded to sugars (Figure 27.28). Variations in both the lactone ring and the sugars result in a large number of macrolide antibiotics. Common macrolides are erythromycin (produced by *Streptomyces erythreus*), clarithromycin, azithromycin, and telithromycin. The macrolides account for about 20% of the total world production and use of antibiotics (Figure 27.22). Erythromycin is a broad-spectrum antibiotic that targets the 50S subunit of the bacterial ribosome, partially inhibiting protein synthesis (Figure 27.20). The partial inhibition of protein synthesis leads to preferential translation of some proteins and restricts translation of others, resulting in an imbalance in the proteome, which may disrupt metabolic functions at all levels. Often used clinically in patients allergic to penicillin or other β -lactam antibiotics, erythromycin is particularly useful for treating legionellosis (Section 31.4).

Tetracyclines

The **tetracyclines**, produced by several species of *Streptomyces*, are broad-spectrum antibiotics that inhibit almost all gram-positive and gram-negative *Bacteria* (Figure 27.21). The basic structure of the tetracyclines consists of a naphthacene ring system (Figure 27.29). Substitutions to the basic naphthacene ring occur naturally and form new tetracycline analogs. Semisynthetic tetracyclines having substitutions in the naphthacene ring system have also been developed. Like erythromycin and the aminoglycoside antibiotics, tetracycline is a protein synthesis inhibitor, interfering with bacterial 30S ribosome subunit function (Figure 27.20).

The tetracyclines and the β -lactam antibiotics comprise the two most important groups of antibiotics in the medical field. The tetracyclines are also widely used in veterinary medicine and in some countries are used as nutritional supplements for poultry and swine. Because extensive nonmedical uses of medically important antibiotics can contribute to antibiotic resistance among pathogens, this use is now discouraged.

Novel Antibiotics: Daptomycin and Platensimycin

Some antibiotics have novel structures or targets. For example, the antibiotic daptomycin is produced by a species of *Streptomyces* and is a cyclic lipopeptide (Figure 27.30) with a unique mode of action. Used mainly to treat infections by gram-positive *Bacteria*

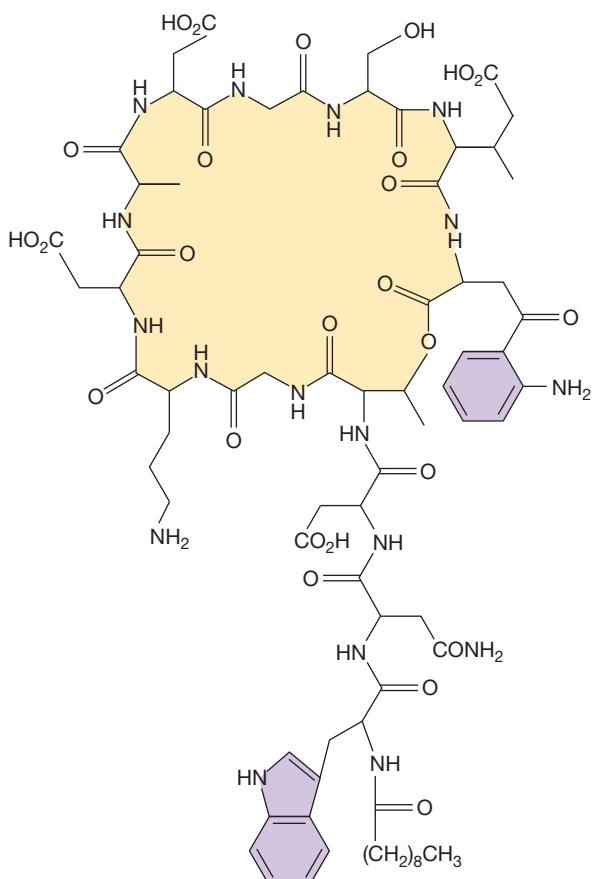

Figure 27.30 Daptomycin. Daptomycin is a cyclic lipopeptide that depolarizes cytoplasmic membranes in gram-positive *Bacteria*.

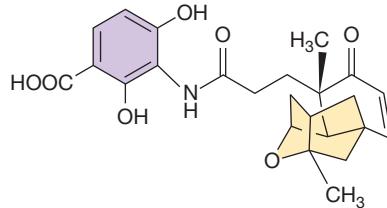

Figure 27.31 Platensimycin. Platensimycin selectively inhibits lipid biosynthesis in *Bacteria*.

such as the pathogenic streptococci and staphylococci (► Sections 29.2 and 29.9), daptomycin binds specifically to bacterial cytoplasmic membranes, forms a pore, and induces rapid depolarization of the membrane. The depolarized cell quickly loses its ability to synthesize macromolecules such as nucleic acids and proteins, resulting in cell death. Alterations in cytoplasmic membrane structure, however, may lead to resistance.

Platensimycin (Figure 27.31), produced by *Streptomyces platen-sis*, is the first member of a new class of antibiotics that inhibits fatty acid biosynthesis, thus disrupting lipid biosynthesis. Platensimycin is effective against a broad range of gram-positive *Bacteria*, including nearly untreatable infections caused by methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci. Platensimycin has a unique mode of action, shows no host toxicity, and there is no known potential for development of resistance by pathogens. We discuss the discovery of platensimycin in Section 27.18.

- How does the activity of each antibiotic class lead to control of affected pathogens?

27.15 Antiviral Drugs

Drugs that control viruses of eukaryotes often affect their host cells as well because the viruses depend on the host cell biosynthetic machinery for their replication. As a result, selective toxicity for viruses is very difficult to attain; only agents that preferentially affect unique viral pathways involved in replication or viral assembly of structural components are useful. In spite of these limitations, a number of drugs are more toxic for viruses than for the host, and a few agents specifically target individual viruses. The development and use of antiviral agents has been successful largely because of efforts to control infections with the human immunodeficiency virus (HIV) (► Section 29.14).

HIV Antiviral Agents

The most successful and commonly used agents for antiviral chemotherapy are the nucleoside analogs (Table 27.6). The first compound to be widely used in this category was zidovudine, also called azidothymidine (AZT) (► Figure 29.48a). AZT inhibits multiplication of HIV and other retroviruses by blocking reverse transcription and production of the virally encoded DNA

intermediate (Section 29.14); it is chemically related to thymidine but is a dideoxy derivative, lacking the 3'-hydroxyl group. A number of other nucleoside analogs such as acyclovir (Table 27.6 and Figure 29.42) have analogous mechanisms and were developed for the treatment of HIV and other viruses.

Nearly all nucleoside analogs are **nucleoside reverse transcriptase inhibitors (NRTIs)** and work by inhibiting elongation of the viral nucleic acid chain by a nucleic acid polymerase. Because the normal cell function of nucleic acid replication is targeted, these drugs usually induce some host toxicity. Many NRTIs also lose their antiviral potency due to the emergence of drug-resistant viruses over time (Section 29.14).

Several antiviral agents target the key enzyme of retroviruses, reverse transcriptase. Nevirapine, a **nonnucleoside reverse transcriptase inhibitor (NNRTI)**, binds directly to reverse transcriptase and inhibits reverse transcription. Phosphonoformic acid, an analog of inorganic pyrophosphate, inhibits normal internucleotide linkages, preventing synthesis of viral nucleic acids. As with the NRTIs, the NNRTIs generally induce some level of host toxicity because their action also affects normal host cell nucleic acid synthesis.

Protease inhibitors are another class of antiviral drugs that are effective for treatment of HIV (Table 27.6 and see Figure 27.37). These drugs prevent viral replication by binding the active site of HIV protease, inhibiting this enzyme from processing large viral proteins into individual viral components, thus preventing virus maturation (Section 9.11).

Another category of anti-HIV drugs is represented by a single drug, enfuvirtide, a **fusion inhibitor** composed of a 36-amino acid synthetic peptide that binds to the gp41 membrane protein of HIV (Table 27.6 and Section 29.14). Binding of the gp41 protein by enfuvirtide stops the conformational changes necessary for the fusion of HIV and T lymphocyte membranes, thus preventing infection of cells by HIV.

Other Antiviral Agents

A single category of drugs effectively limits influenza infection. The neuraminidase inhibitors oseltamivir (brand name Tamiflu) and zanamivir (Relenza) block the active site of neuraminidase in influenza A and B viruses, inhibiting virus release from infected cells. Zanamivir is used only for treatment of influenza, whereas oseltamivir is used for both treatment and prophylaxis (Table 27.6).

Virus interference is a phenomenon in which infection with one virus interferes with subsequent infection by another virus. Several small proteins called interferons are the cause of interference. **Interferons** are small proteins in the cytokine family (Section 26.10) that prevent viral replication by stimulating the production of antiviral proteins in uninfected cells. Interferons are formed in response to live virus, inactivated virus, and viral nucleic acids. Interferon is produced in large amounts by cells infected with viruses of low virulence, but highly virulent viruses inhibit host protein synthesis before interferon can be produced, significantly reducing interferon production. Interferons are also induced by double-stranded RNA (dsRNA). In nature, dsRNA exists only in virus-infected cells as the replicative form of RNA viruses such as rhinoviruses (cold viruses) (Section 29.7); the viral dsRNA signals the animal cell to produce interferon.

Interferon activity is *host*-specific rather than *virus*-specific. That is, interferon produced by one species activates receptors only on cells from the same species. As a result, interferon produced by cells of an animal in response to, for example, a rhinovirus, could also inhibit multiplication of, for example, influenza viruses in cells within the same species, but has no effect on the multiplication of any virus, including rhinovirus, in other species.

Clinical utility of interferon depends on our ability to deliver it to local areas in the host through injections or aerosols to stimulate the production of antiviral proteins in uninfected host cells. Alternatively, appropriate interferon stimulators such as viral nucleotides, nonvirulent viruses, or even synthetic nucleotides, if given to host cells prior to infection, may stimulate natural production of interferon.

MINIQUIZ

- Why are there relatively few effective antiviral agents? Such agents are not used to treat common viral illnesses such as colds; why not?
- What steps in the viral maturation process are inhibited by nucleoside analogs? By protease inhibitors? By interferons?

27.16 Antifungal Drugs

Like viruses, fungi pose special problems for the development of effective drugs. Because fungi are *Eukarya*, antifungal agents that act on metabolic pathways in fungi often affect corresponding pathways in host cells, making the drugs toxic. As a result, many antifungal drugs can be used only for topical (surface) applications. However, a few drugs are selectively toxic for fungi because they target unique fungal structures or metabolic processes. Fungus-specific drugs are becoming increasingly important as fungus infections in immunocompromised individuals become more prevalent (🔗 Sections 32.1 and 32.2).

Ergosterol inhibitors encompass two types of antifungal compounds that work by interacting with ergosterol or inhibiting its synthesis (Table 27.7). Ergosterol is present in fungal cytoplasmic membranes in place of the cholesterol found in animal cell cytoplasmic membranes. Ergosterol inhibitors include the *polyene* antibiotics, a group of antifungal drugs produced by species of *Streptomyces*. Polyenes bind specifically to ergosterol, causing membrane permeability and eventually cell death (Figure 27.32).

Azoles and *allylamines* constitute a second functional group of drugs that affect ergosterol. They work by selectively inhibiting ergosterol biosynthesis and therefore have broad antifungal activity. Treatment with azoles results in abnormal fungus cytoplasmic membranes, leading to membrane damage and alteration of critical membrane transport activities. Allylamines also inhibit ergosterol biosynthesis, but are restricted to topical use because they are not readily taken up by animal tissues.

Echinocandins are cell wall inhibitors that block the activity of 1,3- β -D-glucan synthase, the enzyme that forms β -glucan polymers in the fungal cell wall (Figure 27.32 and Table 27.7). Because mammalian cells do not have 1,3- β -D-glucan synthase (or cell walls), the action of these agents is specific, resulting in selective fungal cell death. Echinocandins are used to treat infections with fungi such as *Candida* and some fungi that are resistant to other agents (🔗 Section 32.1).

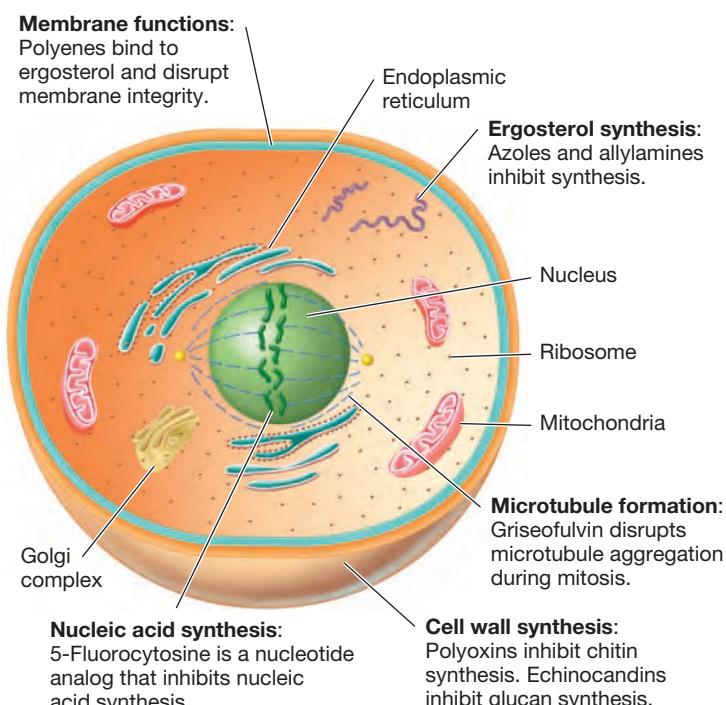

Figure 27.32 Targets of some antifungal agents. Traditional antibacterial agents are generally ineffective because fungi are eukaryotic cells. The cytoplasmic membrane and cell wall targets shown here are unique structures not present in vertebrate host cells.

Fungal cell walls also contain chitin, a polymer of *N*-acetylglucosamine found only in fungi and insects. Several polyoxins inhibit cell wall synthesis by interfering with chitin biosynthesis. Polyoxins are not used clinically, but are widely used as agricultural fungicides.

Other antifungal drugs inhibit folate biosynthesis, interfere with DNA topology during replication, or, in the case of drugs such as griseofulvin, disrupt microtubule aggregation during

mitosis. Moreover, the nucleic acid analog 5-fluorocytosine (flucytosine) is an effective nucleic acid synthesis inhibitor in fungi. Some very effective antifungal drugs also have other applications. For example, vincristine and vinblastine are effective antifungal agents and also have anticancer properties.

Predictably, the use of antifungal drugs has resulted in the emergence of populations of resistant fungi and the emergence of opportunistic fungal pathogens. For example, *Candida* species, which are normally not pathogenic, now produce disease in immunocompromised individuals. Drug-resistant *Candida*

infections now occur in individuals who have been treated with antifungal drugs, and some *Candida* are resistant to multiple antifungal agents (see Figure 27.35).

MINIQUIZ

- Why are there very few clinically effective antifungal agents?
- What factors contribute to an increased incidence of fungal infections?

V • Antimicrobial Drug Resistance

Antimicrobial drug resistance is the acquired ability of a microorganism to resist the effects of an antimicrobial agent to which it is normally susceptible. No single antimicrobial agent inhibits all microorganisms, and some form of antimicrobial drug resistance is an inherent property of virtually all microorganisms.

27.17 Resistance Mechanisms and Spread

As we have discussed, antibiotic producers are microorganisms and we know that genes encoding antibiotic resistance are present in virtually every organism that makes an antibiotic. Widespread antimicrobial drug resistance is routinely passed by horizontal gene transfer between and among microorganisms. Thus, for any of several different reasons, some microorganisms are resistant to certain antibiotics.

Resistance Mechanisms

Some specific examples of bacterial resistance to antibiotics are shown in Table 27.8. Sites of enzymatic modification of selected antibiotics are shown in Figure 27.33. Antibiotic resistance can be genetically encoded by the microorganism on either the bacterial chromosome or on a plasmid called an *R* (for *resistance*) plasmid (Section 4.3) (Table 27.8). Because of widespread existing antibiotic resistance and continual emergence of new resistance, pathogens isolated from clinical specimens must be tested for antibiotic susceptibility to ensure appropriate treatment of an infection (Section 27.5).

Most drug-resistant bacteria isolated from patients contain drug-resistance genes located on horizontally transmitted *R* plasmids rather than on the chromosome. The *R* plasmid genes encode enzymes that modify and inactivate the drug (Figure 27.33) or genes that encode enzymes that prevent uptake of the drug or actively pump it out. For example, *Bacteria* carrying *R* plasmids that encode resistance for the aminoglycoside streptomycin may make enzymes that phosphorylate, acetylate, or adenylate the drug. The modified drug then lacks antibiotic activity.

For the penicillins, *R* plasmids encode β -lactamase, an enzyme that splits the β -lactam ring, inactivating the antibiotic (Figure 27.33). Chloramphenicol resistance is due to an *R* plasmid-encoded enzyme that acetylates the antibiotic. *R* plasmids may contain multiple resistance genes and confer antibiotic resistance on a cell previously sensitive to each antibiotic.

R plasmids and resistance genes predate the widespread use of antibiotics. A strain of *Escherichia coli* that was freeze-dried in 1946 contained a plasmid with genes conferring resistance to both tetracycline and streptomycin, even though neither of these antibiotics was used clinically until several years later. Similarly, *R* plasmid genes for resistance to semisynthetic penicillins existed before the semisynthetic penicillins had been synthesized. Another study examined 30,000-year-old permafrost and found bacterial genes for β -lactamases as well as tetracycline and vancomycin resistance genes. The inevitable conclusion is that human and veterinary antibiotic use does not produce resistance but rather selects for microorganisms with preexisting resistance mechanisms.

Of perhaps even more ecological significance, *R* plasmids with antibiotic resistance genes are found in many nonpathogenic gram-negative soil bacteria. While the ecological role of antibiotics and *R* plasmids in nature is open to speculation—concentrations of

antibiotics in natural environments are so low that they pose no threat to neighboring bacteria—some suggest that antibiotics function as signaling molecules between neighboring cells. Regardless of their true function, it is clear that antibiotic resistance genes arose in bacteria long before antibiotics were ever used in clinical medicine. These naturally occurring genes have been strongly selected for in the past 80 years or so by the common use of antibiotics in human and veterinary medicine and in certain agricultural applications.

Spread of Antimicrobial Drug Resistance

The widespread use of antibiotics in medicine, veterinary medicine, and agriculture provides favorable conditions for the spread of R plasmids with resistance genes that confer an immediate selective advantage. The R plasmid and other sources of resistance genes put significant limits on the long-term use of any single antibiotic as an effective antimicrobial agent.

Inappropriate use of antimicrobial drugs is the leading cause of rapid development of drug-specific resistance in disease-causing microorganisms. The discovery and clinical use of the many known antibiotics is paralleled by the emergence of bacteria that resist them. **Figure 27.34** shows examples of correlations between the amounts and types of antibiotics used and the appearance and numbers of bacteria resistant to each antibiotic.

Overuse of antibiotics accelerates resistance. Antibiotic use in agriculture correlates with the appearance of antibiotic-resistant infections in humans (Figure 27.34a). Indiscriminant, nonmedical use of antibiotics contributes to the emergence of resistant strains. In addition to their traditional use as a treatment for infections, antibiotics are used in agriculture as supplements to animal feeds both as growth-promoting substances and as prophylactic additives to prevent the occurrence of disease. Worldwide, about 50% of all antibiotics produced are used in farm animal applications.

In one study in China, manure from swine farms that used antibiotics was tested for resistance genes using PCR arrays; the tests detected 149 unique resistance genes. The most prevalent genes were enriched as much as 28,000-fold as compared to antibiotic-free farms or soil. In addition, the manure itself still contained residual antibiotics, further enhancing potential selection for the resistance genes outside the host animal.

The broad-spectrum fluoroquinolones such as ciprofloxacin have been used extensively for over 20 years as growth-promoting and prophylactic agents in agriculture. Correlating with this use, fluoroquinolone-resistant *Campylobacter jejuni* emerged as a foodborne pathogen in poultry (☞ Section 31.12), presumably because of the routine treatment of poultry flocks with fluoroquinolones to prevent respiratory diseases. Voluntary guidelines used by both poultry and drug producers are in place to monitor and reduce the use of fluoroquinolones with the goal of preventing resistance to new fluoroquinolone antibiotics.

Increasingly, the antimicrobial agent prescribed for treatment of a particular infection must be changed because of increased resistance of the microorganism causing the disease. A classic example is the development of resistance to penicillin and other antimicrobial drugs in *Neisseria gonorrhoeae*, the bacterium that causes the sexually transmitted disease gonorrhea (Figure 27.34b). Penicillin, widely used until after 1980, was replaced by ciprofloxacin, but its effective use to treat gonorrhea in selected populations lasted only about ten years, prompting a change in treatment recommendations to ceftriaxone, a penicillinase-resistant β -lactam antibiotic (Figure 27.34c). Treatment guidelines are updated nearly every year to cope with continually emerging drug resistance in *N. gonorrhoeae* (☞ Section 29.12).

Antibiotics are used in clinical practice far more often than necessary. Antibiotic treatment is warranted in about 20% of

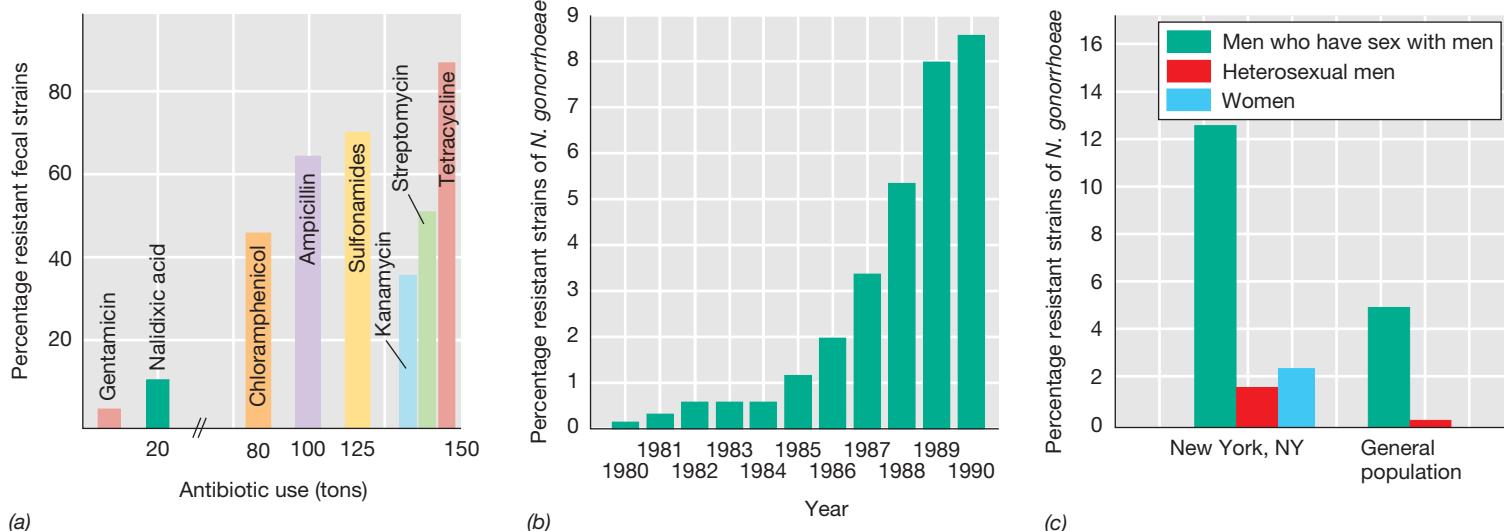

Figure 27.34 Patterns of drug resistance in pathogens. (a) The relationship between antibiotic use and the percentage of antibiotic-resistant bacteria isolated from diarrheal patients. Those agents that have been used in the largest amounts, as indicated by the amount produced commercially, are those for which drug-resistant

strains are most frequent. (b) Percentage of reported cases of gonorrhea caused by drug-resistant strains. The actual number of reported drug-resistant cases in 1985 was 9,000. This number rose to 59,000 by 1990. Greater than 95% of reported drug-resistant cases were due to penicillinase-producing strains of *Neisseria gonorrhoeae*. Since 1990,

penicillin has not been recommended for treatment of gonorrhea because of the emerging drug resistance. (c) The prevalence of fluoroquinolone-resistant *N. gonorrhoeae* in certain populations in the United States in 2003. individuals who seek treatment, but antibiotics are prescribed up to 80% of the time. Furthermore, in up to 50% of cases, prescribed doses or duration of treatments are not correct. This is compounded by patient noncompliance: Many patients stop taking medications, particularly antibiotics, as soon as they feel better. For example, the emergence of isoniazid-resistant tuberculosis correlates with a patient's failure to take the oral medication daily for the full course of 6–9 months (Section 29.4). Exposure of virulent pathogens to sublethal doses of antibiotics for inadequate periods of time selects for drug-resistant strains. Other recent studies, however, indicate that this trend is changing in the United States. Physicians prescribe about one-third fewer antibiotics for treatment of childhood infections than they did in the year 2000. This reduction is largely due to better education of physicians, healthcare providers, and patients concerning the proper role of antibiotic therapy.

Antibiotic-Resistant Pathogens

Largely as a result of failures to properly use antibiotics and monitor resistance, many pathogens have developed resistance to some antimicrobial agents since widespread use of antimicrobial drugs began in the 1950s (Figure 27.35). Penicillin and sulfa drugs, the first widely used antimicrobial agents, are not used as extensively today because so many pathogens have acquired resistance. Even the organisms that are still uniformly sensitive to penicillin, such as *Streptococcus pyogenes* (the cause of strep throat, scarlet fever, and rheumatic fever; Section 29.2), now require larger doses of penicillin for successful treatment.

A few pathogens have developed resistance to all known antimicrobial agents (Figure 27.35). Among these are several isolates of methicillin-resistant *Staphylococcus aureus* (MRSA; methicillin is a semisynthetic penicillin) (Section 29.9). Although MRSA infections most often occur in healthcare settings, MRSA also causes a

significant number of community-associated infections. An increasing number of independently derived MRSA strains have developed reduced susceptibility to even vancomycin and are termed “vancomycin intermediate *Staphylococcus aureus*” (VISA) strains.

Vancomycin-resistant *Enterococcus faecium* (VRE) and some isolates of *Mycobacterium tuberculosis* and *Candida albicans* have

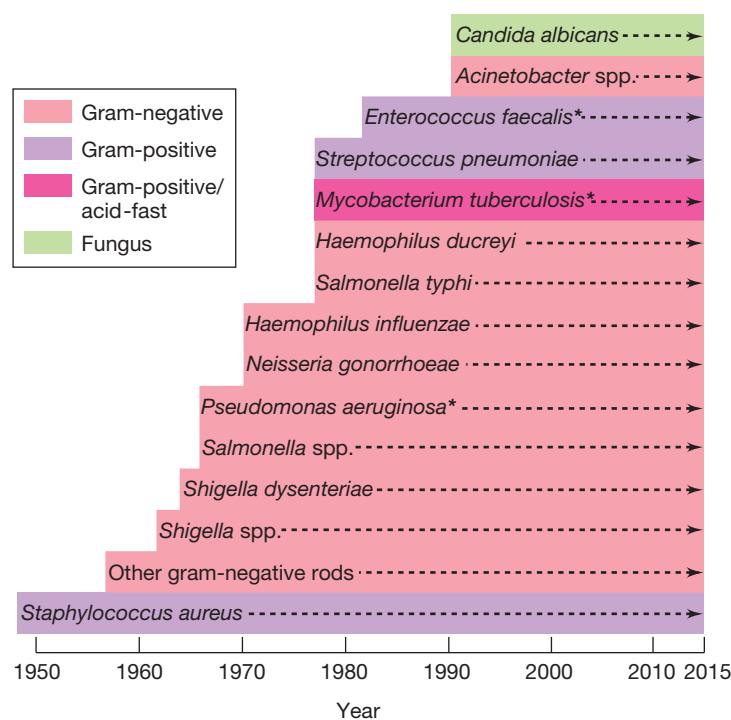

Figure 27.35 The appearance of antimicrobial drug resistance in some human pathogens. The asterisks indicate that some strains of these pathogens are now untreatable with known antimicrobial drugs.

Table 27.9 Guidelines for prevention of antimicrobial drug resistance

Directive	Action/examples	Rationale
Vaccinate to prevent common diseases	Immunize with DPT and other required and recommended vaccines.	Immunization prevents diseases that may require antimicrobial drug treatment.
Avoid unnecessary invasive procedures	Avoid catheters, biopsies, and so on unless absolutely necessary.	Parenteral procedures increase the risk of pathogen exposure.
Identify and target the pathogen	Use the antibiotic that selectively targets the pathogen of concern. For example, treat streptococcal sore throat with penicillin instead of erythromycin.	Exposure to broader-spectrum antibiotics is unnecessary and may damage local microflora, leading to infection by opportunistic pathogens.
Treat with the oldest effective antimicrobial drug	For example, treat streptococcal sore throat with penicillin instead of vancomycin.	Treatment with the latest antimicrobials enhances potential for resistance selection.
Monitor antimicrobial use	Discontinue treatment after the prescribed course.	Unnecessary treatment enhances potential for antibiotic resistance selection.
Break the chain of contagion	Isolate patients when practical and practice good housekeeping and personal hygiene.	Reducing contact and practicing good hygiene limits potential for cross-contamination of healthcare providers and clients.
Access experts	Consult with healthcare infection-control teams.	Local information can best inform selection of antibiotic therapy.

also developed resistance to all known antimicrobial drugs. Antibiotic resistance can be minimized if drugs are used only for treatment of susceptible diseases and are given in sufficiently high doses and for sufficient lengths of time to eradicate the microbial population in the host before resistant mutants can propagate. Combining two unrelated antimicrobial agents may also reduce resistance; it is less likely that a mutant strain resistant to one antibiotic will also be resistant to the second antibiotic. However, certain common R plasmids confer multiple drug resistance and make multiple antibiotic therapy less useful as a clinical treatment strategy.

Preventing Antimicrobial Drug Resistance

To prevent the further emergence of multi-drug-resistant (MDR) *Mycobacterium tuberculosis* and drug-resistant strains of *Staphylococcus aureus*, *Enterococcus faecium*, and *Candida albicans*, the U.S. Centers for Disease Control and Prevention promotes guidelines stressing the importance of preventing infection, rapidly and conclusively diagnosing and treating infections, using antimicrobial agents prudently, and preventing pathogen transmission, summarized in **Table 27.9**.

If the use of a particular antibiotic is stopped, the resistance to that antibiotic can be reversed, at least temporarily, over the course of several years. On the other hand, antibiotic-resistant organisms may persist, for example in the gut, for some time. This implies that the efficacy of some antibiotics may be reestablished by withdrawing the antibiotic from use, but only by following a carefully monitored plan of prudent reintroduction and future use to prevent recurrence of resistance. Finally, as we discuss below, new antimicrobial agents are being developed.

MINIQUIZ

- Identify the six basic mechanisms of antibiotic resistance among bacteria.
- What practices encourage the development of antibiotic-resistant pathogens?

27.18 New Antimicrobial Drugs

Resistance will eventually develop to any antimicrobial drug. Conservative, appropriate use of antibiotics can prolong or even resurrect the effective clinical use of available drugs, but the long-term solution to antimicrobial drug resistance requires continuous development of new antimicrobial drugs through design or discovery.

Candidate antimicrobial drugs must then be tested for efficacy and toxicity in animals and finally in clinical trials in humans. This entire process from discovery through laboratory and clinical trials typically takes 10–25 years before a drug is approved for clinical use. Each year, the pharmaceutical industry spends up to \$4 billion on new antimicrobial drug development and each new drug approved for human use costs the industry over \$500 million in initial investment.

Antimicrobial Drug Design

New analogs of existing antimicrobial compounds are often effective because the new compounds have the same proven mechanism of action. The analog may actually be more effective than the parent compound and, because resistance is based on structural recognition, analogs may not be recognized by resistance factors. For example, Figure 27.29 shows the structure of tetracycline. Using natural tetracycline as the lead compound, systematic chemical substitutions at the four R group sites can generate an almost endless series of tetracycline analogs. Using this basic strategy, semisynthetic analogs of tetracycline, β -lactam antibiotics (Section 27.13), and vancomycin (**Figure 27.36**) have been synthesized.

Novel antimicrobial compounds are much more difficult to identify than analogs of existing drugs because new antimicrobial compounds must work at unique sites in metabolism or be structurally dissimilar to existing compounds to avoid known resistance mechanisms. Computer technology and structural biology methods make it possible to model and design novel compounds, maximizing binding and efficacy in the computer environment, all at relatively low cost.

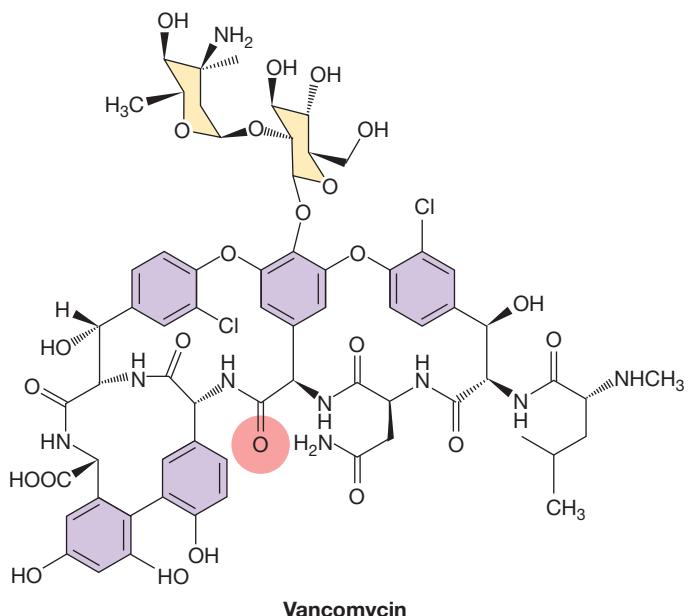

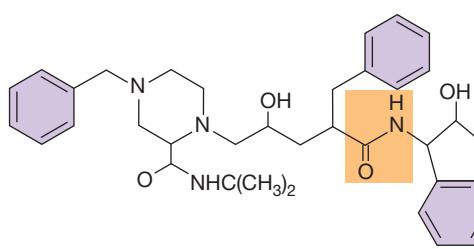

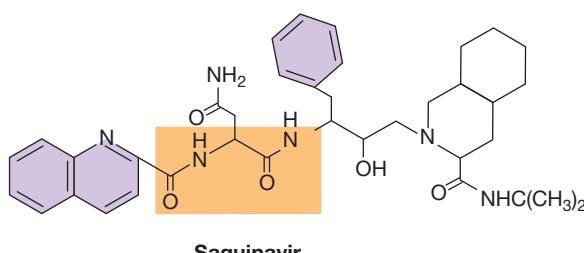

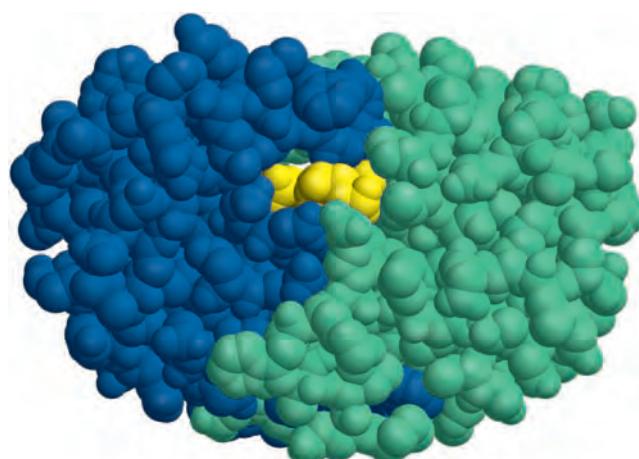

Figure 27.36 Vancomycin. Intermediate drug resistance to the parent structure of vancomycin has developed in recent years. However, modification at the position shown in red by substitution of a methylene ($=\text{CH}_2$) group for the carbonyl oxygen restores much of the lost activity. Like penicillin, vancomycin functions by preventing cross-linking of peptidoglycan and is most effective against gram-positive pathogens.

One of the most dramatic successes in computer-directed drug design is the development of *saquinavir*, a protease inhibitor that is used to slow the growth of the human immunodeficiency virus (HIV) in infected individuals (Figure 27.37). Saquinavir binds the active site of the HIV protease enzyme. The structure of saquinavir was modeled on the known three-dimensional structure of the protease–substrate complex. The HIV protease normally cleaves a virus-encoded precursor protein to produce the mature viral core and activate the reverse transcriptase enzyme necessary for replication (Sections 8.10 and 9.11). Saquinavir is a high-affinity peptide analog of the HIV precursor protein that displaces the authentic protein substrate, inhibiting virus maturation. A number of other computer-designed protease inhibitors are in use as antiviral drugs for the treatment of HIV/AIDS.

Novel Targets for Antibiotics

Traditional candidate antimicrobial drugs were biomolecules isolated from natural sources such as *Streptomyces* or *Penicillium* and systematically screened for antimicrobial activity. These sources and their semisynthetic derivatives isolated through the combinatorial chemistry and computer design methods discussed above have been largely exhausted.

One key to overcoming this problem is to select for antibiotics that interact with targets that are relatively unexploited. A second key is to increase assay sensitivity to select antibiotics that are produced in smaller amounts than those recognized by traditional antibiotic susceptibility methods. Platensimycin (Figure 27.31) was discovered using these principles. First, platensimycin is the first antimicrobial drug targeted to disrupt bacterial lipid biosynthesis. It is especially active against gram-positive pathogens, including drug-resistant staphylococci and enterococci. To select

(b)

HIV protease cleaves an HIV precursor protein, a necessary step in virus maturation. Blocking of the protease site by the bound peptide inhibits precursor processing and HIV maturation. This structure is derived from information in the Protein Data Bank. an agent for a defined target, in this case an enzyme in the lipid synthesis pathway of gram-positive bacteria, scientists reduced the amount of the target lipid molecule by introducing a defect in the lipid synthase gene *FabF* in *Staphylococcus aureus*. They achieved this by using a strain expressing antisense *FabF* RNA (Section 7.14). The gene-specific antisense RNA decreased expression of *FabF*, reducing fatty acid synthesis and increasing the sensitivity of the crippled *S. aureus* strain to antibiotics that inhibit fatty acid synthesis. After screening natural products from 83,000 strains of potential antibiotic producers, the scientists identified and isolated platensimycin from a soil microorganism,

Streptomyces platensis. The method identifies target-specific antibiotics present in low concentrations. This strategy is applicable to virtually any target for which the gene sequence (and, hence, the corresponding antisense RNA sequence) is known.

Drug Combinations

The efficacy of some antibiotics can be retained if they are given with compounds that inhibit antibiotic resistance. Several β -lactam antibiotics can be combined with β -lactamase inhibitors to preserve antibiotic activity in β -lactamase-resistant microorganisms. For example, the broad-spectrum β -lactam antibiotic ampicillin (Figure 27.25) can be mixed with sulbactam (Unasyn), or clavulanic acid (Augmentin), both β -lactamase inhibitors. The inhibitors bind β -lactamase irreversibly, preventing degradation of the ampicillin. This combination preserves the effectiveness of the β -lactamase-sensitive ampicillin for treatment of β -lactamase producers such as staphylococci. Likewise, we have already mentioned the use of sulfamethoxazole-trimethoprim (Bactrin), a mixture of two folic acid synthesis

inhibitors, to prevent the loss of efficacy through mutation and selection for resistance (Section 27.11).

Drug combination therapy approaches have revolutionized treatment of HIV infections. Currently, a combination therapy consisting of nucleoside analogs and a protease inhibitor is recommended. This drug treatment protocol is termed HAART, for highly active anti-retroviral therapy. As with antimicrobial combination regimens, HAART is designed to target two independent viral functions; nucleoside analogs target virus replication and the protease inhibitors target virus maturation. Because the probability of a single virus developing resistance to multiple drugs is less than the probability of developing resistance to a single drug, HAART-resistant strains are relatively uncommon (➡ Section 29.14).

BIG IDEAS

27.1 • Clinical laboratory safety requires training and planning to prevent contamination and possible infection of laboratory workers. Specific precautions and procedures proportional to the risk of infection by a given agent, designated by biosafety levels (BSL), must be in place to handle contaminated materials and patient specimens.

27.2 • Patients in healthcare facilities are unusually susceptible to infectious disease because of their compromised health and potential exposure to various pathogens in the facilities. Many healthcare-associated infections are drug resistant.

27.3 • Appropriate sampling, observation, and culture techniques are necessary to isolate and identify potential pathogens. The selection of techniques requires knowledge of the ecology, physiology, and metabolism of suspected pathogens.

27.4 • Most pathogens exhibit unique metabolic patterns when grown on specialized selective and differential media. Growth-dependent patterns provide information necessary for accurate pathogen identification.

27.5 • Pathogens isolated from clinical samples are often tested for antibiotic susceptibility to ensure appropriate antibiotic therapy. Testing is based on the minimum inhibitory concentration of an agent necessary to completely inhibit growth of a pathogen.

27.6 • An immune response is often a natural outcome of infection. Specific immune responses involving a rise in antibody titers and positive T cell-mediated skin tests can be used to provide evidence for infections and to monitor convalescence.

27.7 • Direct agglutination tests are used for determination of blood types. Passive agglutination tests are available for identification of a variety of pathogens and pathogen-related products. Agglutination tests are rapid, relatively sensitive, highly specific, simple to perform, and inexpensive.

27.8 • Fluorescent antibodies are used for quick, accurate identification of pathogens and other antigenic substances in tissue samples, blood, and other complex mixtures. Fluorescent antibody-based methods can be used for identification of a variety of prokaryotic and eukaryotic cell types.

27.9 • Enzyme immunoassays, rapid tests, and immunoblots are sensitive and specific immunological assays. These tests can be engineered to detect either antibody or antigen for diagnosis of infections by a large number of pathogens.

27.10 • Nucleic acid amplification (PCR) methods are applied as extremely specific diagnostic tools used for a large number of pathogens. qPCR and qualitative PCR techniques provide quantification and identification of pathogens.

27.11 • Synthetic antimicrobial agents are selectively toxic for bacteria, viruses, and fungi. Synthetic growth factor analogs are metabolic inhibitors. Quinolones inhibit the action of DNA gyrase in *Bacteria*.

27.12 • Antibiotics are chemically diverse antimicrobial compounds produced by microorganisms. Although many antibiotics are known, only a few are clinically effective. Each antibiotic works by inhibiting a specific cellular process in the target microorganisms.

27.13 • The β -lactam antibiotics including penicillins and cephalosporins are the most important class of clinical antibiotics. These antibiotics and their semisynthetic derivatives target cell wall synthesis in *Bacteria*. They have low host toxicity and collectively have a broad spectrum of activity.

27.14 • The aminoglycosides, macrolides, and tetracycline antibiotics selectively interfere with protein synthesis in *Bacteria*. Daptomycin and platensimycin are structurally novel antibiotics that target cytoplasmic membrane functions and lipid biosynthesis, respectively. These antibiotics are structurally complex molecules produced by *Bacteria* and are active against other *Bacteria*.

27.15 • Antiviral agents selectively target virus-specific enzymes and processes. Useful agents include analogs and compounds that inhibit nucleic acid polymerases and viral genome replication. Protease inhibitors interfere with viral maturation steps. Host cells also produce antiviral interferon proteins that stop viral replication.

27.16 • Antifungal agents exhibiting selective toxicity are hard to find because fungi are *Eukarya*, but some effective antifungal agents are available. Treatment of fungal infections is an emerging human health issue.

27.17 • The use of antimicrobial drugs inevitably leads to resistance in the targeted microorganisms. The development of resistance can be accelerated by the indiscriminate use of the drugs. Many pathogens have developed resistance to common antimicrobial drugs.

27.18 • New antimicrobial compounds are constantly being discovered and developed to deal with drug-resistant pathogens and to enhance our ability to treat infectious diseases.

REVIEW OF KEY TERMS

Agglutination a reaction between antibody and particle-bound antigen resulting in visible clumping of the particles

Aminoglycoside an antibiotic such as streptomycin, containing amino sugars linked by glycosidic bonds

Antibiogram a report indicating the susceptibility of clinically isolated microorganisms to the antibiotics in current use

Antibiotic a chemical substance produced by a microorganism that kills or inhibits the growth of another microorganism

Antimicrobial drug resistance the acquired ability of a microorganism to resist the effects of an antimicrobial agent to which it is normally susceptible

Bacteremia the presence of bacteria in the blood

β -lactam antibiotic penicillin or a related antibiotic that contains the four-membered heterocyclic β -lactam ring

Broad-spectrum antibiotic an antibiotic that acts on both gram-positive and gram-negative *Bacteria*

Differential media growth media that allow identification of microorganisms based on phenotypic properties

Enriched media media that allow metabolically fastidious microorganisms to grow because of the addition of specific growth factors

Enrichment culture the use of selective culture media and incubation conditions to isolate specific microorganisms from natural samples

Enzyme immunoassay (EIA) a test that uses antibodies linked to enzymes to detect antigens or antibodies in body fluids

Fluorescent antibody an antibody molecule covalently modified with a fluorescent dye that makes the antibody visible under fluorescent light

Fusion inhibitor a peptide that blocks the fusion of viral and target cytoplasmic membranes

General-purpose media growth media that support the growth of most aerobic and facultatively aerobic organisms

Growth factor analog a chemical agent that is related to and blocks the uptake or utilization of a growth factor

Healthcare-associated infection (HAI) a local or systemic infection acquired by a patient in a healthcare facility, particularly during a stay in the facility. Also called *nosocomial infection*.

Immunoblot (Western blot) the use of labeled antibodies to detect specific proteins after separation by electrophoresis and transfer to a membrane

Interferon a cytokine protein produced by virus-infected cells that induces signal transduction in nearby cells, resulting in transcription of antiviral genes and expression of antiviral proteins

Minimum inhibitory concentration (MIC) the smallest amount of an agent needed to completely inhibit the growth of an organism in vitro

Nonnucleoside reverse transcriptase inhibitor (NNRTI) a nonnucleoside analog used to inhibit viral reverse transcriptase

Nucleoside reverse transcriptase inhibitor (NRTI) a nucleoside analog used to inhibit viral reverse transcriptase

Penicillin a class of antibiotics that inhibit bacterial cell wall synthesis, characterized by a β -lactam ring

Protease inhibitor an inhibitor of a viral protease

Quinolone a synthetic antibacterial compound that interacts with DNA gyrase and prevents supercoiling of bacterial DNA

Selective media media that enhance the growth of certain organisms while retarding the growth of others due to an added media component

Selective toxicity the ability of a compound to inhibit or kill pathogenic microorganisms without adversely affecting the host

Sensitivity the lowest amount of antigen that can be detected by a diagnostic test

Septicemia (sepsis) a blood infection

Serology the study of antigen–antibody reactions in vitro

Specificity the ability of an antibody or a lymphocyte to recognize a single antigen, or of a diagnostic test to identify a specific pathogen

Tetracycline an antibiotic characterized by the four-ring naphthacene structure

Titer the quantity of antibody present in a solution

MERS-CoV: An Emerging Disease

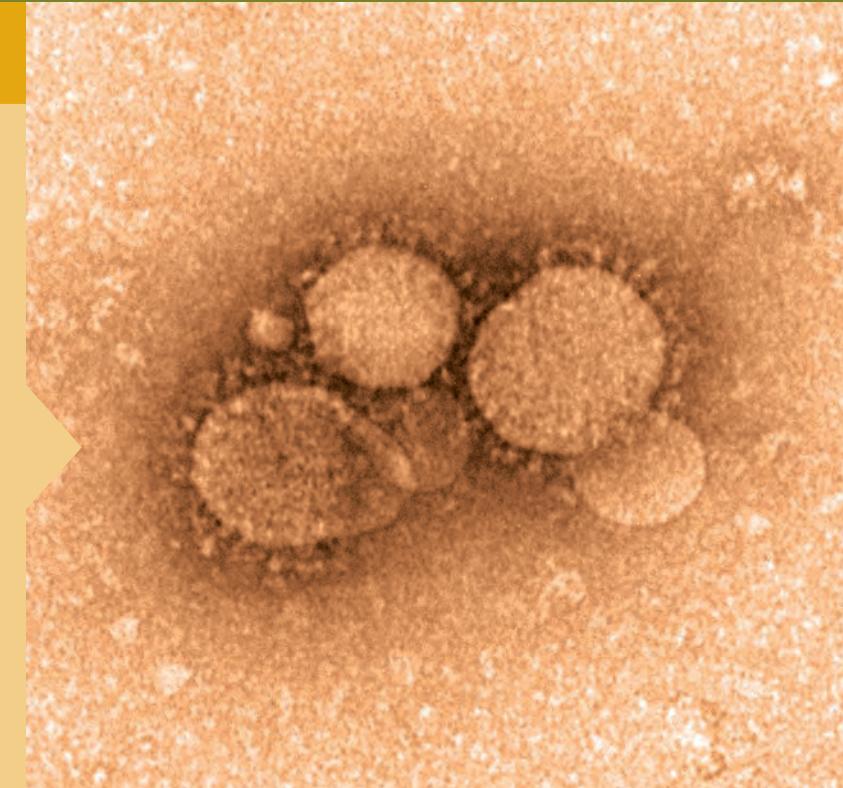

New emerging diseases often appear suddenly. For example, Middle East respiratory syndrome coronavirus (MERS-CoV) was first identified as the cause of serious cases of pneumonia in 2012. The first outbreak occurred in Saudi Arabia and then spread by way of travelers to other Arabic countries and Europe. From September 2012 through June 2013, 58 cases were confirmed, with 33 deaths.¹

An investigative team traveled to Saudi Arabia to observe an ongoing healthcare-associated outbreak of MERS-CoV and reported that the virus spread easily from patient to patient in three different healthcare facilities. Two healthcare workers were also infected, with 15 fatalities in 23 cases. The incubation time for infection is about 5 days, with rapid spread to the next host. Genomic sequencing data confirmed that a single group of closely related viruses (photo) was responsible for the outbreak.

The confirmed cases and two possible cases were linked to contact with infected individuals in the healthcare facilities. MERS-CoV is highly virulent and spreads easily in healthcare settings, probably by way of airborne droplets or indirect contacts. Thus healthcare facilities that care for MERS-CoV patients are on high alert to protect both workers and patients from further spread of this disease.

Another coronavirus, SARS-CoV, discussed later in this chapter, causes a similar illness to MERS-CoV with correspondingly high mortality rates. Like SARS-CoV, MERS-CoV probably originated in bats. All of its reservoirs are unknown but include camels. Is it spread from bats and camels via respiratory droplets and close contact? Because MERS-CoV spreads so easily from person to person and has such high mortality, epidemiologists need to answer these questions if they are to break the chain of infection and prevent a possible MERS-CoV pandemic.

Epidemiology is the study of the occurrence, distribution, and determinants of health and disease in a population; it deals with **public health**, the health of the population as a whole. Here we consider the epidemiology of infectious diseases and the public health methods used to control them.

In Chapter 1 we compared the current common causes of death in the United States with those at the beginning of the twentieth century (☞ Figure 1.8). In the United States and other

developed countries, infectious diseases no longer kill as they once did, but globally they still account for almost one-quarter of annual deaths. Even developed countries are affected by the antibiotic-resistant pathogens and pandemic influenzas that cause new illnesses and new infectious diseases to continue to emerge throughout the world (Figure 28.1). Identifying and solving problems associated with infectious disease is the goal of the epidemiologist.

I • Principles of Epidemiology

Here we consider the principles of epidemiology of infectious diseases and define key terms in the language of the epidemiologist.

28.1 Epidemiology Basics

The epidemiologist traces the spread of a disease to identify its origin and mode of transmission. Epidemiological data are obtained by collecting disease information in a *population*. Data are gathered from disease-reporting surveillance networks, clinical records, and patient interviews with the goal of defining common factors for an illness. This is in contrast to individual patient treatment and diagnosis in the clinic or laboratory. The epidemiologist couples host–pathogen population dynamics to clinical problems to formulate effective public health measures for disease control.

Epidemiology Vocabulary

A well-adapted pathogen lives in balance with its host, taking what it needs for existence and causing only a minimum of harm. Such

pathogens may cause **chronic infections** (long-term infections) in the host. When there is a balance between host and pathogen, both host and pathogen survive. On the other hand, a host whose resistance is compromised because of factors such as poor diet, age, and other stressors can be harmed (☞ Section 23.12). In addition, new pathogens occasionally emerge to which the individual host, specific populations, or even an entire species has not developed resistance. Such emerging pathogens often cause **acute infections**, characterized by rapid and dramatic disease onset.

Certain terms have specialized meanings in epidemiology. A disease is an **epidemic** when it simultaneously infects an unusually high number of individuals in a population; a **pandemic** is a widespread, usually worldwide, epidemic. By contrast, an **endemic disease** is one that is constantly present, usually in low numbers, in a population (Figure 28.2). An endemic disease implies that the pathogen may not be highly virulent or that the majority of individuals in the population may be immune, resulting in low but persistent numbers of cases. Individuals infected with an

(b) Epidemic diseases show high incidence in a wider area, usually developing from an endemic focus. (c) Pandemic diseases are distributed worldwide.

organism that causes an endemic disease are **reservoirs** of infection, a source of infectious agents from which susceptible individuals may be infected.

The **incidence** of a particular disease is the *number of new cases* in a population in a given time period. For example, in 2010 there were 47,500 new cases of HIV infection in the United States, for an incidence of 15.5 new cases per 100,000 people per year. The **prevalence** of a given disease is the *total number of new and existing disease cases* in a population in a given time period. For example, within the United States there were 803,771 persons living with HIV/AIDS at the end of 2010. Expressed another way, the prevalence of HIV/AIDS in the United States was about 262 cases per 100,000 persons in 2010. Thus, *incidence* provides a record of new cases of a disease, whereas *prevalence* indicates the total disease burden in a population. The incidence and prevalence of disease are indicators of the public health of a particular group such as the total global population or the population of a localized region, such as a city, state, or country.

Sporadic cases of a disease occur one at a time in geographically separated areas, suggesting that the cases are not related. A disease **outbreak**, on the other hand, is the appearance of a large number of cases in a short time in an area previously experiencing only sporadic cases. Diseased individuals who show no symptoms or only mild symptoms are said to have *subclinical infections*. Subclinically infected individuals are frequently **carriers** of the particular pathogen, with the pathogen reproducing within them and being shed into the environment. Finally, the term **virulence** is often used in epidemiological parlance, and is a measure of the relative ability of a pathogen to cause disease.

Public health conditions and concerns vary with location and time. That is, assessment of public health at a given time provides only a snapshot of a dynamic situation. Public health policies and laws are evaluated by examining public health statistics over long time periods, with the goal of reducing the incidence and prevalence of disease.

Mortality and Morbidity

Mortality is the incidence of *death* in a population. Infectious diseases were the major causes of death in 1900 in all countries and geographic regions, but they are now less prevalent in developed countries. Noninfectious “lifestyle” diseases such as heart disease and cancer are now much more prevalent and cause higher mortality than do infectious diseases (► Figure 1.8). However, this could change rapidly if public health measures were to break down. Worldwide, and especially in developing countries, infectious diseases are still major causes of mortality (Table 28.1 and Section 28.6).

Morbidity is the incidence of *disease* in a population and includes both fatal and nonfatal diseases. Morbidity statistics indicate the public health of a population more precisely than mortality statistics because many diseases have relatively low mortality. Put another way, the major causes of *illness* are quite different from the major causes of *death*. For example, high-morbidity infectious diseases include acute respiratory diseases such as the common cold and acute digestive disorders. However, seldom do these diseases cause death in developed countries. Thus, both of these diseases have high morbidity, but low mortality. On the other hand, Ebola virus infects only several hundred people worldwide every year, but the mortality in some outbreaks approaches 70%. Thus, Ebola has low morbidity, but high mortality.

Disease Progression

The progression of clinical symptoms for a typical acute infectious disease can be divided into stages:

1. *Infection*: The organism invades, colonizes, and grows in the host.
2. *Incubation period*: Some time always passes between infection and the appearance of disease signs and symptoms. Some

diseases, like influenza, have very short incubation periods, measured in days; others, like AIDS, have longer ones, sometimes extending for years. The incubation period for a given disease is determined by inoculum size, the virulence and life cycle of the pathogen, and resistance of the host. At the end of the incubation period, the first signs and symptoms, for example in the case of an ensuing cold, a mild cough and a feeling of general fatigue, usually appear.

3. *Acute period:* The disease is at its height, with overt symptoms and signs such as fever and chills.
4. *Decline period:* Disease signs and symptoms subside. Any fever subsides, usually following a period of intense sweating, and a feeling of well-being develops. The decline period may be rapid (within one day), in which case decline occurs by *crisis*, or it may be slower, extending over several days, in which case decline occurs by *lysis*.
5. *Convalescent period:* The patient regains strength and returns to normal.

After the acute period, the immune mechanisms of the host become increasingly important for complete recovery from the disease.

28.2 The Host Community

The colonization of a susceptible host population by a pathogen may lead to explosive infections, transmission to uninfected hosts, and an epidemic. As the host population develops resistance, however, the spread of the pathogen is checked, and eventually a balance is reached in which host and pathogen populations reach an equilibrium. In an extreme case, failure to reach equilibrium could result in death and eventual extinction of the host species. If the pathogen has no other host, then the extinction of the host also results in extinction of the pathogen. Thus, the evolutionary success of a pathogen may depend on its ability to establish an equilibrium with the host population rather than destroy the host population. In most cases, the evolution of the host and the pathogen affect one another; that is, the host and pathogen *coevolve*.

Coevolution of a Host and a Pathogen

A striking example of host and pathogen coevolution is a case where myxoma virus was intentionally introduced in Australia to control wild rabbits that were causing massive crop and vegetation damage. The virus, spread by the bite of mosquitoes, is extremely virulent and causes fatal infections in susceptible animals. Within several months, the virus infection had spread over a large area, rising to peak incidence in the summer when the mosquito vectors were present, and then declining in the winter as mosquitoes disappeared. Over 95% of the infected rabbits died during the first

year. However, when virus isolated from infected wild rabbits was used to infect newborn wild and laboratory rabbits, the virus had lost some virulence. Coupled with the loss of virulence, the resistance of the wild rabbits had increased dramatically; wild rabbits were not as susceptible to the virus as laboratory rabbits. Within six years, rabbit mortality dropped to about 84% (Figure 28.3). In time, all wild rabbits acquired resistance. Within 30 years the rabbit population in Australia was nearing pre-myxoma virus levels and again creating widespread environmental damage.

A few years later, Australian authorities released rabbit hemorrhagic disease virus (RHDV), a pathogen that is highly virulent for susceptible rabbits. Because RHDV is spread by direct host-to-host contact and kills animals within days of initial infection, authorities believed the infections would kill all rabbits in a local population, preventing the development of resistance to RHDV. At first RHDV was very effective at reducing local rabbit populations. However, natural infection of some rabbits by an indigenous but nonlethal hemorrhagic fever virus conferred immune cross-resistance to the introduced RHDV. This unanticipated immunity reduced RHDV virulence in some areas. As with the myxoma virus, the host developed resistance to the RHDV control agent, moving the host-pathogen balance toward equilibrium.

For pathogens that do not rely on host-to-host transmission such as *Clostridium tetani*, a common soil bacterium that causes tetanus, there is no selection for decreased virulence to support mutual coexistence. Vectorborne pathogens usually transmitted by the bite of ticks or other arthropods are also under no evolutionary pressure to spare the human host. As long as a vector can obtain its blood meal after infection and before the host dies, the pathogen can maintain a high level of virulence and kill its human host. For example, malaria parasites (*Plasmodium* spp.) show antigenic variations in coat proteins that aid in avoiding the immune response of the host. This ability to avoid the host

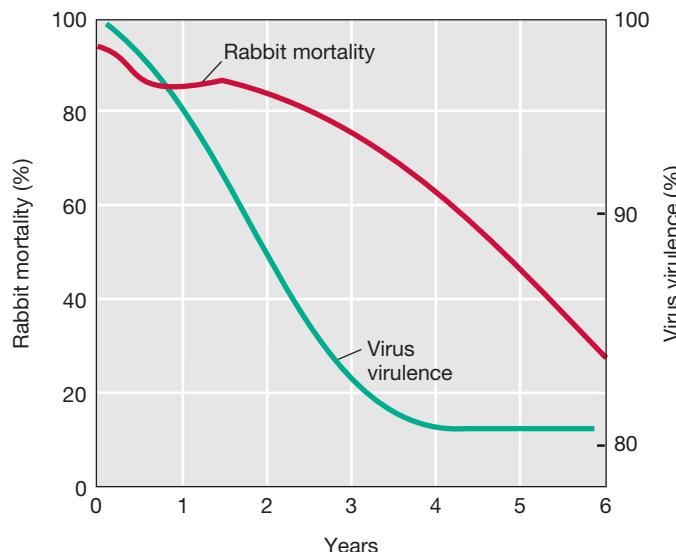

Figure 28.3 Myxoma virus and host coevolution. Myxoma virus was introduced into Australia to control the wild rabbit population. Virus virulence is shown as the average mortality in laboratory rabbits for virus recovered from the field each year. Rabbit mortality was determined by removing young wild rabbits from dens and infecting them with a viral strain that killed 90–95% of control laboratory rabbits.

immunity increases pathogen virulence without regard to the susceptibility of the host.

Other evidence for the phenomenon of unchecked pathogen virulence comes from studies of diarrhea in newborns. In hospital nurseries, *Escherichia coli* can cause severe diarrhea and even death; virulence seems to increase with each passage of the pathogen through a patient. The pathogens replicate in one host and are then inadvertently transferred to another through healthcare providers or objects such as soiled bedding and furniture. Extraordinary efforts such as completely disinfecting the nursery and furniture, coupled with transferring healthcare staff to other services, are sometimes necessary to interrupt the cycle of these highly virulent infections.

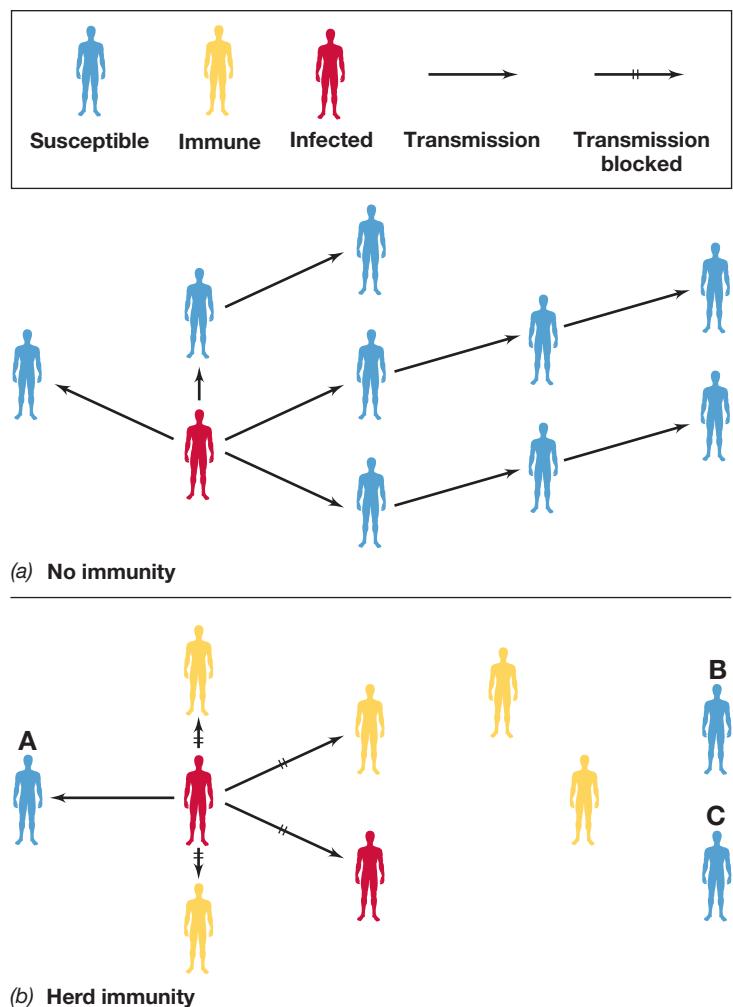

Figure 28.4 Herd immunity and transmission of infection. Immunity in some individuals protects individuals without immunity from infection. (a) In a population with no immunity, transfer of a pathogen from one infected individual can ultimately infect (arrows) all the individuals as newly infected individuals in turn transfer the pathogen to other individuals. (b) In a population that is only moderately dense and that has some immunity against a moderately transmissible pathogen such as influenza, an infected individual cannot transfer the pathogen to all susceptible individuals because resistant individuals, immune from previous exposure or immunization, break the cycle of pathogen transmission: Susceptible individual A becomes infected, but susceptible individuals B and C are protected. The proportion of a population that must be immune for herd immunity to be effective also varies with the disease; highly infectious diseases require a higher proportion of immune individuals for herd immunity to prevent transmission.

Herd Immunity

If a high proportion of the individuals in a group are immune to a pathogen, then the whole population will be protected; this resistance to infection is called **herd immunity** (Figure 28.4). Assessment of herd immunity is important for understanding the development of epidemics. The more highly infectious a pathogen, or the longer its period of infectivity, the greater the proportion of immune individuals necessary to prevent disease spread. For a highly infectious disease such as measles, 90–95% of the population must be immune to confer herd immunity. By contrast, a lower proportion of immune individuals can prevent an epidemic by a less infectious agent or one with a brief period of infectivity. Mumps virus, which is less infectious than measles virus, exhibits this pattern. In the absence of immunity, even poorly infectious agents can be transmitted person-to-person if susceptible hosts have repeated or constant contact with an infected individual. This is the case for the transmission of H5N1 avian influenza among humans (Section 28.11).

28.3 Infectious Disease Transmission

Epidemiologists follow the transmission of a disease by correlating geographic, climatic, social, and demographic data with disease incidence. These correlations are used to identify possible modes of transmission and disease patterns. A disease limited to a restricted geographic location, for example, may suggest a particular vector. This is the case with malaria, a disease of tropical regions that is only transmitted by mosquito species restricted to tropical regions (see Section 32.5).

A marked seasonality or periodicity of a disease often indicates certain modes of transmission. For example, influenza occurs in an annual cyclic pattern, causing epidemics propagated among school children and other populations of susceptible individuals. Influenza infectivity is high in crowded environments such as schools because the virus is transmitted by a respiratory route. Epidemic strains of influenza virus change almost every year, and as a result, most children are susceptible to infection. On the introduction of virus into a school, an explosive propagated epidemic results. Nearly every individual becomes infected and then becomes immune. As the immune population increases, the epidemic subsides, but introduction of a new influenza virus, usually in the following year, will trigger another epidemic.

The mode of pathogen transmission is usually related to the preferred habitat of the pathogen in the body. Respiratory pathogens, for example, are typically transmitted by an airborne route, whereas intestinal pathogens are spread through fecal contamination of food or water. In some cases, environmental factors such as weather patterns may influence the survival of the pathogen. For example, California encephalitis virus and other encephalitis viruses cause disease during the summer and fall months and

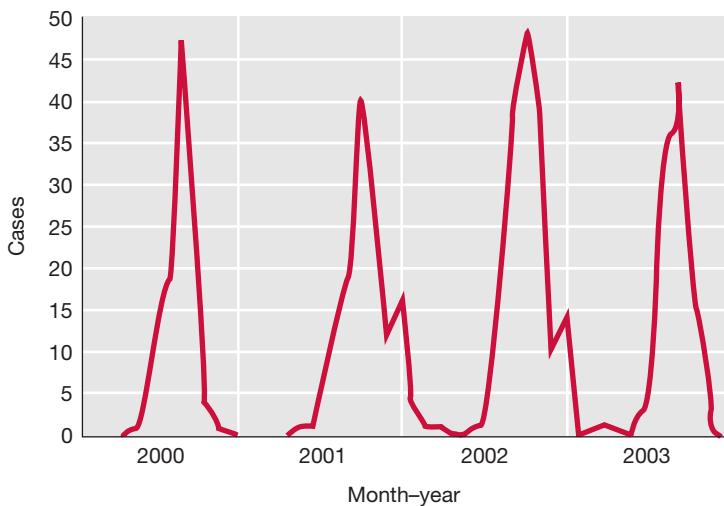

Figure 28.5 California encephalitis in the United States. Disease incidence shows a sharp rise in late summer, followed by a complete decline in winter. The disease cycle follows the yearly cycle of the mosquito vector, which dies out in the winter months. Data are from the CDC, Atlanta, Georgia, USA.

disappear every winter in a cyclical pattern (Figure 28.5). The virus is transmitted from mosquito vectors that die during the winter months, causing the disease to disappear until the insect vector reappears and again transmits the virus in the summer months.

Pathogens can be classified by their mechanism of transmission, but all mechanisms have three stages in common: (1) escape from the host, (2) travel, and (3) entry into a new host. Pathogen transmission can be by direct or indirect mechanisms.

Direct Host-to-Host Transmission

Host-to-host transmission occurs when an infected host transmits a disease directly to a susceptible host without the assistance of an intermediate host or inanimate object. Upper respiratory infections such as the common cold and influenza are most often transmitted host to host by droplets resulting from sneezing or coughing (Figure 29.1). Many of these droplets, however, do not remain airborne for long. Transmission, therefore, requires close, although not necessarily intimate, person-to-person contact.

Some pathogens are extremely sensitive to environmental factors such as drying and heat and are unable to survive for significant periods of time away from the host. These pathogens, transmitted only by intimate person-to-person contact such as exchange of body fluids in sexual intercourse, include those responsible for sexually transmitted diseases including syphilis (*Treponema pallidum*), gonorrhea (*Neisseria gonorrhoeae*), and HIV/AIDS (HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome).

Direct contact also transmits skin pathogens such as staphylococci (boils and pimples) and fungi (ringworm). These pathogens often spread by indirect means as well because they are relatively resistant to environmental conditions such as drying.

Indirect Host-to-Host Transmission

Indirect transmission of an infectious agent can be facilitated by either living or inanimate carriers. Living carriers that transmit

pathogens are called **vectors**. Commonly, arthropods (mites, ticks, or fleas) or vertebrates (dogs, cats, or rodents) act as vectors. Arthropod vectors may not be hosts for the pathogen, but may carry the agent from one host to another. Many arthropods obtain their nourishment by biting and sucking blood, and if the pathogen is present in the blood, the arthropod vector may ingest the pathogen and transmit it when biting another individual. In some cases viral pathogens replicate in the arthropod vector, which is then considered an *alternate host*. Such is the case for West Nile virus (Section 30.6). These replications lead to greater pathogen numbers, increasing the probability that a subsequent bite will lead to infection.

Inanimate agents such as bedding, toys, books, and surgical instruments can also transmit disease. Inanimate objects that, when contaminated with a viable pathogen, can transfer the pathogen to a host are called **fomites**. The term **vehicle** is used to describe nonliving sources of pathogens that transmit disease to large numbers of individuals; common disease vehicles are contaminated food or water. Fomites can also be disease vehicles, but major epidemics originating from a single-vehicle source are typically traced to common sources such as food or water because food and water are shared commodities consumed in large amounts by everyone.

Epidemics

Major epidemics are usually classified as either *common-source epidemics* or *host-to-host epidemics*. These two types of epidemics are contrasted in Figure 28.6. Table 28.2 summarizes the key epidemiological features of some major epidemic diseases.

A **common-source epidemic** results from an infection (or intoxication) of a large number of people from a contaminated common source such as food or water. Such epidemics are often caused by a breakdown in the sanitation of a central food or water distribution system, but they can also be more local, such

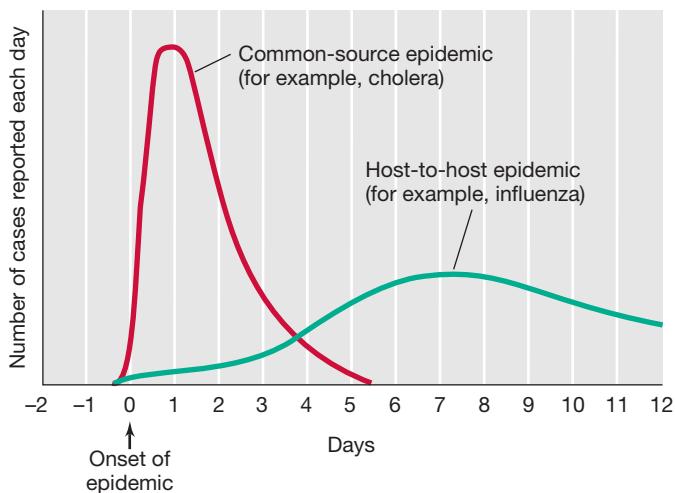

Figure 28.6 Types of epidemics. The shape of the curve that plots incidence of an epidemic disease against time identifies the likely type of the epidemic. For a common-source epidemic such as one resulting from contaminated food or water shared by the people who become infected, the curve rises sharply to a peak and then declines rapidly. Host-to-host infectious disease incidence rises relatively slowly as new cases accumulate.

as contaminated food in a particular restaurant. Foodborne and waterborne common-source epidemics are primarily intestinal diseases; the pathogen leaves the body in fecal material, contaminates food or water supplies due to improper sanitary procedures, and then enters the intestinal tract of the recipient during ingestion of the food or water. Waterborne and foodborne diseases are generally controlled by public health measures, which we discuss further in Chapter 31. A classic common-source epidemic is cholera. In 1855 the British physician John Snow correlated cholera incidence with fecal contamination of the water distribution systems in London. Snow clearly showed that the infectious agent, the bacterium *Vibrio cholerae*, was transmitted through consumption of the contaminated common-source vehicle, water (Section 28.10 and  Section 31.3).

The disease incidence for a common-source outbreak is characterized by a rapid rise to a peak incidence because a large number of individuals become ill within a relatively brief period of time (Figure 28.6). Assuming that the pathogen-contaminated common source is discovered and sanitized, the incidence of a common-source illness also declines rapidly, although the decline is less rapid than the rise. Cases continue to be reported for a period of time approximately equal to the duration of one incubation period for the disease.

In a **host-to-host epidemic**, the disease incidence shows a relatively slow, progressive rise (Figure 28.6) and a gradual decline. Cases continue to be reported over a period of time equivalent to several incubation periods of the disease. A host-to-host epidemic can be initiated by the introduction of a single infected individual into a susceptible population, with this individual infecting one or more people. The pathogen then replicates in susceptible individuals, reaches a communicable stage, is transferred to other susceptible individuals, and again replicates and becomes communicable. Influenza and chicken pox are examples of diseases

that are typically spread in host-to-host epidemics. Chapter 29 discusses these and a number of other diseases propagated by host-to-host transmission.

Basic Reproduction Number (R_0)

The infectivity of a pathogen can be predicted using mathematical models that estimate the **basic reproduction number** (R_0), defined as the number of expected secondary transmissions from each single case of a disease in an entirely susceptible population. Table 28.3 shows the R_0 values for selected infectious diseases.

SARS—A Model of Epidemiological Success

Handling of the severe acute respiratory syndrome (SARS) epidemic early in this decade is an excellent example of the successful application of the principles of epidemiology. Like many other rapidly emerging diseases, SARS was viral and originated in animals. Such characteristics have the potential to trigger explosive disease in humans when the infectious agents cross host species barriers.

The SARS epidemic began in late 2002 in Guangdong Province, China. By the following February, the virus had spread to 28 countries. Global travel provided the major vehicle for SARS dissemination. The cause of SARS was quickly traced to a coronavirus derived from an animal source. The coronavirus entered the human food chain through an exotic food animal such as a civet (a small, catlike, nocturnal animal). The SARS coronavirus (SARS-CoV) (**Figure 1**) most probably originated in bats. Civets apparently acquired the virus by consuming fruit contaminated by bat feces. SARS-CoV likely evolved over an extended period of time in bats and developed, quite by accident, the ability to infect civets and then humans.

Much like common cold viruses, SARS-CoV is a relatively hardy, very infectious RNA virus that is difficult to contain (R_0 of 3.6). Once in humans, SARS-CoV quickly spreads from person to person by sneezing and coughing or by contact with contaminated fomites or feces. Ordinarily, a new coldlike virus would be of little concern, but SARS-CoV caused infections with significant mortality. From the 8500 known SARS-CoV infections, there were over 800 deaths, for an overall mortality rate approaching 10%. In persons over 65 years of age, the mortality rate approached 50%, attesting to the virulence of SARS-CoV as a human pathogen.

About 20% of all SARS cases were in healthcare workers, demonstrating the high infectivity of the virus. Standard containment

and infection control methods practiced by healthcare personnel were not effective in controlling spread of the disease. As a result, SARS patients were confined for the course of the disease in strict isolation in negative-pressure rooms. To prevent infection, healthcare staff caring for SARS patients wore respirators when working with patients or when handling fomites (bed linens, eating utensils, and so on).

The recognition and containment of the SARS outbreak was the start of an international response involving clinicians, scientists, and public officials. Almost immediately, travel to and from the endemic area was restricted,

limiting further outbreaks. SARS-CoV was quickly isolated and cultured, and its genome was rapidly sequenced. This information was used to develop PCR tests to detect the virus in samples. As laboratory work progressed, epidemiologists traced the virus back to the civet food source in China and stopped further transmission to humans by restricting the sale of civets and other foods from wild sources. These actions collectively stopped the outbreak.

SARS is an example of a serious infection that emerged very rapidly from a unique source. However, rapid identification and characterization of the SARS pathogen, nearly instant development of worldwide notification procedures and diagnostic tests, and a concerted effort to understand the biology and genetics of this novel pathogen controlled the disease; there have been no cases of SARS since early 2004. The rapid emergence of SARS, and the equally rapid and successful international effort to identify and control the outbreak, provide a model for the control of emerging epidemics.

As international travel and trade expand, the chances for propagation and rapid dissemination of new exotic diseases will increase. For example, in early 2013, a SARS-like viral illness rapidly emerged in Saudi Arabia and nearby countries that caused severe (and in some cases fatal) symptoms similar to those of SARS. This virus, nicknamed MERS-CoV (Middle East respiratory syndrome—coronavirus) (see opening page of this chapter) is a novel coronavirus that suddenly appeared in healthcare settings and can be rapidly transmitted from person to person. Because of these challenges, epidemiologists and healthcare workers must prepare for the emergence of other serious infectious diseases, including pandemic influenza in particular. However, it is likely that the lessons learned from the SARS epidemic will pay dividends when other emerging diseases appear.

The R_0 value predicts the risk of disease spread in a population. An R_0 of 1 means that each infected person will pass the disease to one susceptible person, maintaining the disease in the population. An R_0 that is greater than 1 indicates that each infected person will pass the disease to *more than one* susceptible person, propagating the outbreak and leading to a possible epidemic or even

pandemic. In contrast, an R_0 that is less than 1 indicates that each infected person will pass the disease to *fewer than one* susceptible person, and the disease will die out under these circumstances.

R_0 directly correlates with the herd immunity necessary to prevent spread of infection; the higher the R_0 value, the greater the herd immunity required to stop infection. For example, under ideal

circumstances, to stop the spread of the highly infectious measles virus ($R_0 = 18$), 94% of the population must be immune, while only 29% of the population must be immune to stop the spread of influenza ($R_0 = 1.6$) (Table 28.3). Unfortunately, conditions are not always ideal and the mathematical models that predict R_0 may not take into account such factors as numbers of recovered individuals, population density (close contact), length of contact time, populations of high-risk individuals, and other variables that may affect disease spread. As a result, R_0 can only estimate theoretical infectivity, but it is still useful as a comparative gauge of the relative infectivity of a pathogen and helps to establish goals for immunization coverage to prevent disease spread.

The *observed reproduction number*, R , calculated from studies of actual disease spread, is a more useful term because it takes into account observed transmissions from infected to susceptible individuals. For most disease outbreaks, R cannot be reliably obtained because precise information about disease spread is not available; too many individuals are involved to accurately track the source of each infection. However, for the SARS outbreak of 2003 (see Explore the Microbial World, “SARS—A Model of Epidemiological Success”), the observed R was 3.6. Public health officials, recognizing the potential for a serious epidemic, instituted infection controls such as isolation of infected individuals and strict barrier protection for healthcare personnel. These measures reduced the SARS R value to 0.7, ending the threat of further disease spread. Likewise in one Ebola filovirus outbreak (Table 28.5), the reproduction number was reduced from a theoretical R_0 of 1.8 to an R of 0.7, again by using strict infection control measures that stopped the spread of the infection, thus averting a potential epidemic.

28.4 Disease Reservoirs and Epidemics

Reservoirs are sites at which infectious agents remain viable and from which individuals may become infected. Reservoirs may be either animate or inanimate. Some pathogens whose reservoirs are not in animals only incidentally infect humans and cause disease. For example, organisms in the genus *Clostridium*, common soil bacteria, occasionally infect humans, causing life-threatening diseases such as tetanus, botulism, gangrene, and certain gastrointestinal diseases. Host damage and even death cause no harm to those pathogen populations because they are normal inhabitants of the soil; the pathogen is not dependent on the host for survival, so host–pathogen balance is not required for pathogen survival. Such a pathogen can cause devastatingly acute disease with no consequences for the pathogen.

For many pathogens, however, living organisms are the only reservoirs. In these cases, the reservoir host is essential for the life cycle of the infectious agent; maintenance of human pathogens of this kind requires person-to-person transmission. Many

viral and bacterial respiratory pathogens and sexually transmitted pathogens require human hosts; certain staphylococci and streptococci are examples of human-restricted pathogens, as are the agents that cause diphtheria, gonorrhea, and mumps. As we shall see, many pathogens that live their entire life cycle dependent on a single host species, especially humans, can be eradicated or at least controlled. Table 28.2 lists some human infectious diseases with epidemic potential and their reservoirs.

Zoonosis

Some infectious diseases are caused by pathogens that reproduce in both humans and animals. A disease that primarily infects animals but is occasionally transmitted to humans is called a **zoonosis**. Animal-to-animal transmission of veterinary diseases can be high because public health measures are less developed, especially for wild animal populations. Occasionally, transmission of a zoonotic disease is from animal to human; person-to-person transfer of these pathogens is rare, but does occur. Factors leading to the emergence of zoonotic disease include the existence and propagation of the infectious agent in an animal host, the proper environment for propagation and transfer of the agent, and the presence of the new susceptible host species. When there is animal-to-human transmission, a new and highly virulent infectious disease may suddenly emerge in the exposed human population. This was the case, for example, with SARS (see the Explore the Microbial World feature).

Control of a zoonotic disease in the human population does not usually eliminate the disease as a potential public health problem. Eradication of the human form of a zoonotic disease can generally be achieved only through elimination of the disease in the animal reservoir. This is because the essential maintenance of the pathogen depends on animal-to-animal transfer; humans are incidental, nonessential hosts. As one example, plague is primarily a disease of rodents. Effective control of human cases of plague is achieved by control of the infected rodent population and the insect (flea) vector that carries the pathogen to humans. Control of the zoonotic reservoir and vector are more effective in preventing plague transmission than interventions such as vaccines in the incidental human host (☞ Section 30.7). As another example, zoonotic bovine tuberculosis is easily spread to humans and is clinically indistinguishable from human tuberculosis. The disease was brought under control in developed countries primarily by identifying and destroying infected animals. Pasteurization of milk was also important because milk was the main vehicle for transmission of bovine tuberculosis to humans (☞ Section 29.4).

Certain infectious diseases are caused by organisms such as protists that have more complex life cycles including an obligate transfer from a nonhuman host to a human host, followed by an obligate transfer back to the nonhuman host (for example, malaria, ☞ Section 32.5). In such cases, the disease may potentially be controlled in either humans or the nonhuman host.

Carriers

A living *carrier* is a pathogen-infected individual who has a sub-clinical infection and shows no symptoms or only mild symptoms of clinical disease. Carriers are potential sources of infection for

others. Carriers may be in the incubation period of the disease, in which case the carrier state precedes the development of actual symptoms. Respiratory infections such as colds and influenza, for example, are often spread via carriers who are unaware of their infection and so are not taking any precautions against infecting others. The carrier state lasts only a short time for carriers who develop acute disease. However, chronic carriers may spread disease for extended periods of time. Chronic carriers usually appear healthy. They may have recovered from a clinical disease but still harbor viable pathogens, or their infections may not be apparent.

Carriers can be identified using diagnostic techniques; culture or immunoassay surveys are conducted in populations to identify carriers. For example, skin testing with *Mycobacterium tuberculosis* antigens tests for delayed hypersensitivity. The test reveals previous or current infection and is widely used to identify carriers of *M. tuberculosis* (🔗 Section 24.3). Other diseases in which carriers contribute to the spread of infection include hepatitis, typhoid fever, and HIV/AIDS. Culture or immunoassay surveys of food handlers and healthcare workers are sometimes used to identify individuals who are carriers and pose a risk as sources of infection.

A famous example of a chronic carrier was the woman known as Typhoid Mary, a cook in New York City in the early part of the twentieth century. Typhoid Mary (her real name was Mary Mallon) was employed as a cook during a typhoid fever epidemic in 1906. Investigations revealed that Mary was associated with a number of the typhoid outbreaks. She was the likely source of infection because her feces contained large numbers of the typhoid bacterium, *Salmonella enterica* serovar Typhi. She remained a carrier throughout her life, probably because her gallbladder was infected and continuously secreted the pathogen into her intestine. She refused to have her gallbladder removed and was imprisoned. Released on the pledge that she would not cook or handle food for others, Mary disappeared, changed her name, and continued to cook in restaurants and public institutions, leaving behind epidemic outbreaks of typhoid fever. After several years, she was again arrested and imprisoned and remained in custody until her death in 1938.

II • Epidemiology and Public Health

Here we identify some of the methods used to identify, track, contain, and eradicate infectious diseases within populations. We also identify some important current and potential future threats from infectious diseases.

28.5 Public Health and Infectious Disease

Public health refers to the health of the general population and to the activities of public health authorities in the control of disease. The incidence and prevalence of many infectious diseases dropped dramatically during the twentieth century, especially in developed countries, because of universal improvements in public health from advances in basic living conditions. Access to safe water and food, improved public sewage treatment, less crowded living conditions, and lighter workloads have contributed immeasurably to disease control, primarily by reducing exposure to infectious agents. Several historically important diseases, including smallpox, typhoid fever, diphtheria, brucellosis, and poliomyelitis, have been controlled and in some cases eliminated (for example, smallpox) by active, disease-specific public health measures such as quarantine and vaccination.

Controls Directed against Common Vehicles

Common vehicles for pathogen dispersal include food, water and air. The transmission of pathogens in food or water can be eliminated by preventing contamination (Chapter 31). For example, water purification methods have dramatically reduced the incidence of typhoid fever (Figure 28.7). Laws controlling food purity and preparation have greatly decreased the probability of transmission of foodborne pathogens to humans. As we mentioned previously, the destruction of infected cattle and pasteurization

of milk have virtually eliminated the spread of bovine tuberculosis to humans.

Transmission of respiratory pathogens carried in the air is difficult to prevent. Attempts at chemical disinfection of air have been unsuccessful. Air filtration is a viable method but is limited to small, enclosed areas. In Japan, many people wear face masks when they have upper respiratory infections to prevent transmission to others, but such methods, although effective, are voluntary and are difficult to institute as public health measures.

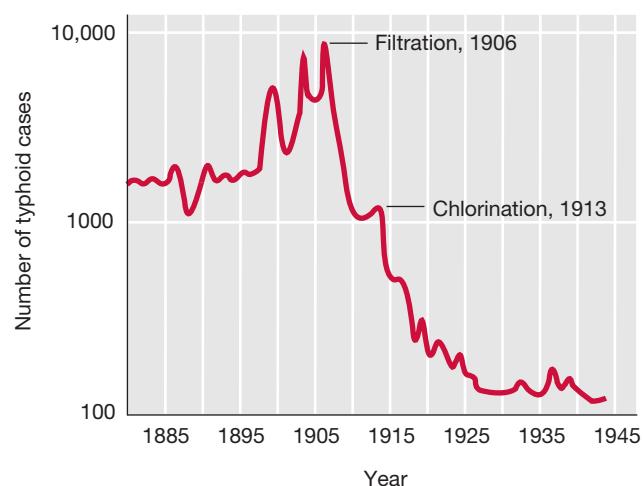

Figure 28.7 Typhoid fever in Philadelphia. The introduction of filtration and chlorination eliminated typhoid fever in Philadelphia and other cities with well-regulated water supplies.

Controls Directed against the Reservoir

When the disease reservoir is primarily domestic animals, the infection of humans can be prevented if the disease is eliminated from the infected animal population. Immunization or destruction of infected animals may eliminate the disease in animals and, consequently, in humans. These procedures have nearly eliminated brucellosis and bovine tuberculosis in humans and have controlled bovine spongiform encephalitis (mad cow disease), caused by a prion (Sections 9.13 and 31.14) in cattle in the United Kingdom, Canada, and the United States. In the process, the health of the domestic animal population is also improved.

When the disease reservoir is a wild animal, eradication is much more difficult. Rabies, for example, is a disease of both wild and domestic animals that is transmitted to domestic animals primarily from wild animals. Thus, control of rabies in domestic animals and in humans can be achieved by immunization of domestic animals. However, because the majority of rabies cases in the United States are in wild animals (Section 30.1), eradication of rabies would require the immunization or destruction of all wild animal reservoirs, including such diverse species as raccoons, bats, skunks, and foxes. Although oral rabies immunization is practical and recommended for rabies control in restricted wild animal populations, its efficacy is untested in large, diverse animal populations such as the wild animal reservoir in the United States.

When insects such as the mosquito vectors that transmit malaria are also required hosts, effective control of the disease can be accomplished by eliminating the vector–host with insecticides or other agents. The use of toxic or carcinogenic chemicals, however, must be balanced with environmental concerns, because in some cases, the elimination of one public health problem only creates another. For example, the insecticide dichlorodiphenyltrichloroethane (DDT) is very effective against mosquitoes and is credited with eradicating yellow fever and malaria in North America. DDT use, however, was banned in the United States in 1972 because of serious environmental and wildlife concerns. DDT is still used in many developing countries to control mosquito-borne diseases, but its use is declining worldwide.

When humans are the disease reservoir (as, for example, in HIV/AIDS), control and eradication can be difficult, especially if there are asymptomatic carriers. By contrast, certain diseases that are limited to humans have no asymptomatic phase. If these can be prevented through immunization or treatment with antimicrobial drugs, the disease can be eradicated if those who have contracted the disease and all possible contacts are strictly quarantined, immunized, and treated. Such a strategy was successfully employed by the World Health Organization to eradicate smallpox and is currently being used to eradicate polio, as we discuss later.

Immunization

Smallpox, diphtheria, tetanus, pertussis (whooping cough), measles, mumps, rubella, and poliomyelitis have been controlled primarily by immunization. Diphtheria, for example, is no longer considered an endemic disease in the United States. Vaccines are available for a number of other infectious diseases (Table 24.4). As we discussed in Section 28.2, 100% immunization is not necessary for disease control in a population because of herd immunity,

although the percentage needed to ensure disease control varies with the infectivity and virulence of the pathogen and with the living conditions of the population (for example, crowding).

Measles epidemics offer an example of the effects of herd immunity. The occasional resurgence of the highly contagious measles virus ($R_0 = 18$, Table 28.3) emphasizes the importance of maintaining appropriate immunization levels for a given pathogen. Until 1963, the year an effective measles vaccine was licensed, nearly every child in the United States acquired measles through natural infections, resulting in over 300,000 annual cases. After introduction of the vaccine, the number of annual measles infections decreased rapidly (Figure 28.8). Case numbers reached a low of 1497 by 1983. However, by 1990, the percentage of children immunized against measles fell to 70%, and the number of new cases rose to 27,786. A concerted effort to increase measles immunization levels to above 90% virtually eliminated indigenous measles transmission in the United States, and a total of only 312 measles cases were reported in 1993. Currently, about 100 cases of measles are reported each year in the United States, most due to infections imported by visitors from other countries.

Most children in the United States are now adequately immunized, but up to 80% of adults lack effective immunity to important infectious diseases because immunity from childhood vaccinations declines with time. When childhood diseases occur in adults, they can have devastating effects. For example, if a woman contracts rubella (a vaccine-preventable viral disease) (Section 29.6) during pregnancy, the fetus may develop serious developmental and neurological disorders. Measles, mumps, and chicken pox are also more serious diseases in adults than in children.

All adults are advised to review their immunization status and check their medical records to ascertain dates of immunizations. This is particularly true for individuals who are traveling abroad. Tetanus immunizations, for example, must be renewed at least every 10 years to provide effective immunity. Surveys of adult populations indicate that more than 10% of adults under the

Figure 28.8 Measles immunization in the United States. The introduction of a measles vaccine eliminated measles as a common childhood infection within 20 years.

age of 40 and more than 50% of those over 60 are not adequately immunized. General recommendations for immunization were discussed in Section 24.6 and those for specific infections will be discussed in Chapters 29 through 32.

Isolation, Quarantine, and Surveillance

Isolation is the separation of persons who have an infectious disease from those who are healthy. **Quarantine** is the separation and restriction of well persons who may have been exposed to an infectious disease to see if they develop the disease. The length of isolation or quarantine for a given disease is the longest period of communicability for that disease. To be effective, these measures must prevent infected or potentially infected individuals from contacting uninfected susceptible individuals.

By international agreement, six diseases require isolation and quarantine: *smallpox*, *cholera*, *plague*, *yellow fever*, *typhoid fever*, and *relapsing fever*. Each is a very serious, particularly communicable disease. Spread of certain other highly contagious diseases such as *Ebola* hemorrhagic fever, SARS, H5N1 influenza, and meningitis may also be controlled by quarantine or isolation as outbreaks occur.

Surveillance is the observation, recognition, and reporting of diseases as they occur. Table 28.4 lists the diseases currently under surveillance in the United States. Some of the epidemic diseases (listed in Table 28.2) and emerging diseases (see Table 28.5) are not on the surveillance list. However, many of these diseases such as seasonal influenza are surveyed through regional laboratories that identify *index cases*—those cases of disease that exhibit unusually high incidence, new syndromes or characteristics, or are linked to new or evolving pathogens that have high potential for causing new epidemics.

The **Centers for Disease Control and Prevention (CDC)** in the United States is the agency of the United States Public Health Service that tracks disease trends, provides disease information to the public and to healthcare professionals, and forms public policy regarding disease prevention and intervention. The CDC operates a number of infectious disease surveillance programs. For a few examples, diseases listed in Table 28.4 are reported to the CDC through the National Notifiable Diseases Surveillance System, providing a database that spots nationwide trends and allows for national healthcare planning; healthcare-associated infections are reported to the National Healthcare Safety Network (NHSN) (🔗 Section 27.2); the Select Agents Program handles reports of potential bioterror incidents (Section 28.8); emerging worldwide infectious disease outbreaks are reported to the Global Emerging Infections Sentinel Network (GeoSentinel). The overall goal of surveillance is to formulate and implement plans for diagnosis and treatment of infections.

Pathogen Eradication

A concerted disease eradication program was responsible for the eradication of naturally occurring smallpox. Smallpox was a disease with a reservoir consisting solely of the individuals with acute smallpox infections, and transmission was exclusively person-to-person. Infected individuals transmitted the disease through direct contact with previously unexposed individuals. Although smallpox, a viral disease, cannot be treated once

acquired, immunization practices were very effective; vaccination with the related vaccinia virus conferred complete immunity.

The World Health Organization (WHO) implemented a smallpox eradication plan in 1967. Because of the success of vaccination programs worldwide, endemic smallpox had already been

confined to Africa, the Middle East, and the Indian subcontinent. WHO workers then vaccinated everyone in remaining endemic areas, with the goal of providing direct and herd immunity to all potential contacts. Each subsequent outbreak or suspected outbreak was targeted by WHO teams that traveled to the outbreak site, quarantined individuals with active disease, and vaccinated all contacts. To break the chain of possible infection, they then immunized everyone who had contact with the contacts. This aggressive policy to provide vaccinations eliminated the active natural disease within a decade, and WHO announced the eradication of smallpox in 1980.

Poliomyelitis, another viral disease with a human-only reservoir, is also preventable with an effective vaccine and is targeted for eradication (endemic polio has been eradicated from the Western Hemisphere). Using much the same strategy to target polio as was used for smallpox, WHO undertook a widespread immunization program in 1988, concentrating efforts in remaining endemic areas. In all, over 2 billion individuals, mostly children, have been immunized, preventing an estimated 5 million cases of paralytic polio. By 2012 endemic polio was restricted to Nigeria, Pakistan, and Afghanistan. Only 650 polio cases were reported in 2011. Individual outbreaks are treated by immunization of all susceptible persons in the region of the outbreak.

Hansen's disease (leprosy), another disease restricted to humans, is also targeted for eradication. Active cases of Hansen's disease can now be effectively treated with a multidrug therapy that cures the patient and also prevents spread of *Mycobacterium leprae*, the causal agent (Section 29.4).

Other communicable diseases are candidates for eradication. These include Chagas' disease (by treating active cases and destroying the insect vector of the *Trypanosoma cruzi* parasite in the American tropics) (Section 32.6) and dracunculiasis (by treating drinking water in Africa, Saudi Arabia, Pakistan, and other places in Asia to prevent transmission of *Dracunculus medinensis*, the Guinea helminth parasite). Eradication of syphilis may be possible because the disease is found only in humans and is treatable. Diphtheria, caused by *Corynebacterium diphtheriae*, is no longer endemic in North America. The disease could be globally eradicated by application of the strict immunization protocols that have virtually eliminated it from North America.

28.6 Global Health Comparisons

The World Health Organization has divided the world into six geographic regions for the purpose of collecting and reporting health information such as causes of morbidity and mortality. These geographic regions are Africa, the Americas (North America, the Caribbean, Central America, and South America), the eastern Mediterranean, Europe, Southeast Asia, and the Western Pacific. Here we compare mortality data from a relatively developed region, the Americas, to those from a developing region, Africa.

Infectious Disease in the Americas and Africa: A Comparison

Mortality statistics in developed and developing countries are significantly different, as illustrated by a comparison of data from the Americas and from Africa in 2008 when the worldwide population was nearly 6.9 billion. Worldwide, 60.8 million individuals died, giving a mortality rate of 8.8 deaths per 1000 inhabitants per year. About 15.8 million (26%) of these deaths were attributable to infectious diseases. There were 924 million people in the Americas in 2008 and there were 5.6 million deaths, or 6.1 deaths per 1000 inhabitants per year. In Africa, there were 837 million people in 2008 and 14.1 million deaths, or 16.8 deaths per 1000 inhabitants per year. These statistics clearly show differences in overall mortality between developed and developing countries, but a comparative examination of the *causes* of mortality is even more instructive.

Figure 28.9 indicates that infectious diseases caused the most deaths in Africa, whereas in the Americas, noninfectious diseases such as cancer, cardiovascular disease, and diabetes were the leading causes of mortality. In Africa, there were about 6.6 million

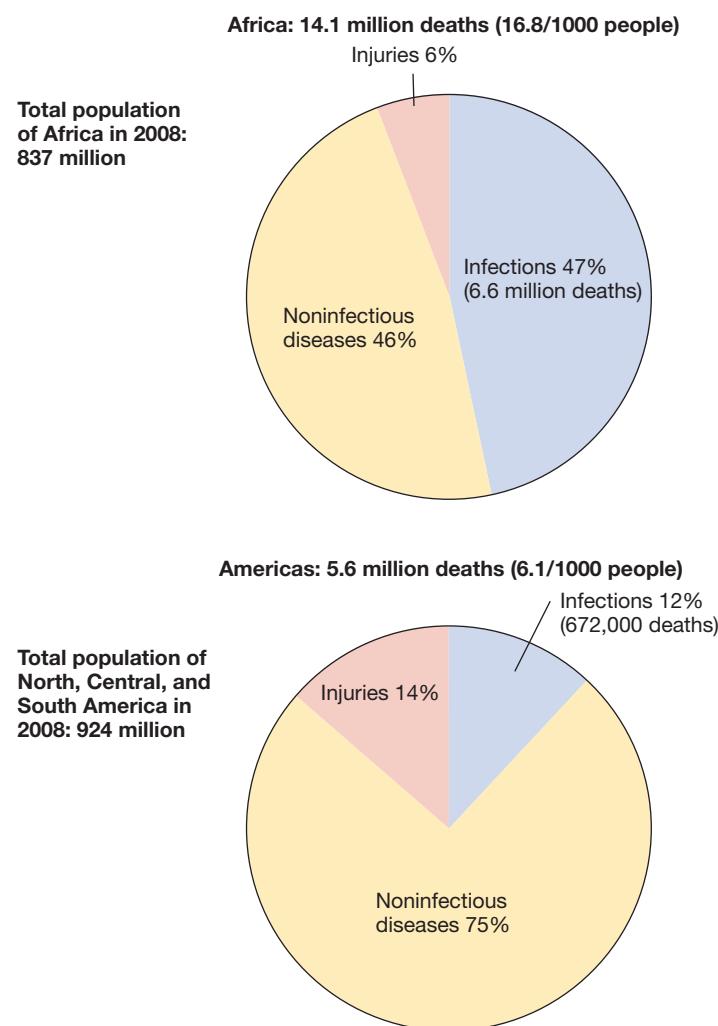

Figure 28.9 Causes of death in Africa and the Americas, 2008. Noninfectious diseases include cancer, cardiovascular diseases, and diabetes. Injuries include accidents, murder, suicide, and war. Data are from the World Health Organization.

deaths due to infectious diseases and the life expectancy was 54 years of age. The African death toll due to infectious diseases was 10% of the total deaths in the world. In stark contrast, only 672,000 died of infectious disease in the Americas and the life expectancy was 76 years of age. In developed countries, the increased life expectancy is a direct consequence of the reduction in death rates from infection over the last century (Figure 1.8). Most of these gains are due to the advances in public health. By contrast, lack of resources in developing countries limits access to adequate sanitation, safe food and water, immunizations, healthcare, and medicines, leading to increases in infectious diseases and, by extension, to dramatically shorter life expectancy.

Travel to Endemic Areas

The high incidence of disease in many parts of the world is a concern for people traveling to such areas. However, travelers can be immunized against many of the diseases that are endemic in foreign countries. Specific recommendations for immunization for those traveling abroad are updated biannually and published by the Centers for Disease Control and Prevention (<http://www.cdc.gov/>).

For many countries, immunization certificates for yellow fever are required for entry from areas with endemic yellow fever. These

areas include much of equatorial South America and Africa. Most other nonstandard immunizations such as those for rabies and plague are recommended only for people who are expected to be at high risk, such as veterinary healthcare providers. The CDC summarizes current information for the potential for infectious disease transmission throughout the world, including diseases for which there are no effective immunizations (for example, HIV/AIDS, malaria, Ebola hemorrhagic fever, dengue fever, amebiasis, encephalitis, and typhus). Travelers should take precautions such as avoiding unprotected sex, avoiding insect and animal bites, drinking only water that has been properly treated to kill all microorganisms, eating properly stored and prepared food, and undergoing antibiotic and chemotherapeutic programs for prophylaxis or for suspected exposure. Although these precautions do not guarantee that one will remain disease-free, adhering to them greatly reduces the risk of infection.

III • Emerging Infectious Diseases

New infectious diseases are constantly emerging and established diseases are reemerging with alarming frequency. Here we discuss some of these diseases and the reasons for their sudden emergence or reemergence. We also investigate the potential for the purposeful use of infectious microorganisms as agents of war and terror.

28.7 Emerging and Reemerging Infectious Diseases

Infectious diseases are global, dynamic health problems. In this section we examine some recent patterns of infectious disease, some reasons for the changing patterns, and the methods used by epidemiologists to identify and deal with new threats to public health.

Emerging and Reemerging Diseases

The worldwide distribution of diseases can change dramatically and rapidly. Alterations in the pathogen, the environment, or the host population contribute to the spread of new diseases, with potential for high morbidity and mortality. Diseases that suddenly become prevalent are called **emerging diseases**, infectious diseases whose incidence recently increased or whose incidence threatens to increase in the near future. Emerging diseases are not limited to “new” diseases; they also include **reemerging diseases**, diseases that were previously under control but suddenly appear as a new epidemic.

Examples of global emerging and reemerging disease were shown in Figure 28.1, and recent examples are shown in Figure 28.10.

Select diseases with high potential for emergence or reemergence are described in Table 28.5. The epidemic diseases listed in Table 28.2 also have the potential to emerge or reemerge in epidemic or pandemic forms.

Emerging epidemic diseases are not a new phenomenon. Among the diseases that rapidly and sometimes catastrophically emerged in the past are syphilis (caused by *Treponema pallidum*) and plague (caused by *Yersinia pestis*). In the Middle Ages, up to one-third of all humans were killed by the plague epidemics that swept Europe, Asia, and Africa (Chapter 1 Explore the Microbial World, “The Black Death Decoded” and Section 30.7). Influenza caused a devastating worldwide pandemic in 1918–1919, claiming up to 100 million lives. In the 1980s, HIV/AIDS and Lyme disease emerged as new diseases. Important emerging pathogens in the last decade include West Nile virus (Section 30.6) and pandemic (H1N1) 2009 influenza, the strain that emerged in spring 2009 in Mexico and rapidly spread throughout the world (Section 28.11). Health officials worldwide are particularly concerned about the potential for rapid emergence of pandemic influenza developing from H5N1 avian influenza (Section 29.8).

Emergence Factors: Demographics, Land Use, and Transportation

Some factors responsible for the emergence of new pathogens, some current examples, and some epidemics attributable at least in part to these emergence factors are outlined in Table 28.6. Human demographics and behavior can affect disease spread. In 1800, less than 2% of the world’s population lived in urban areas.

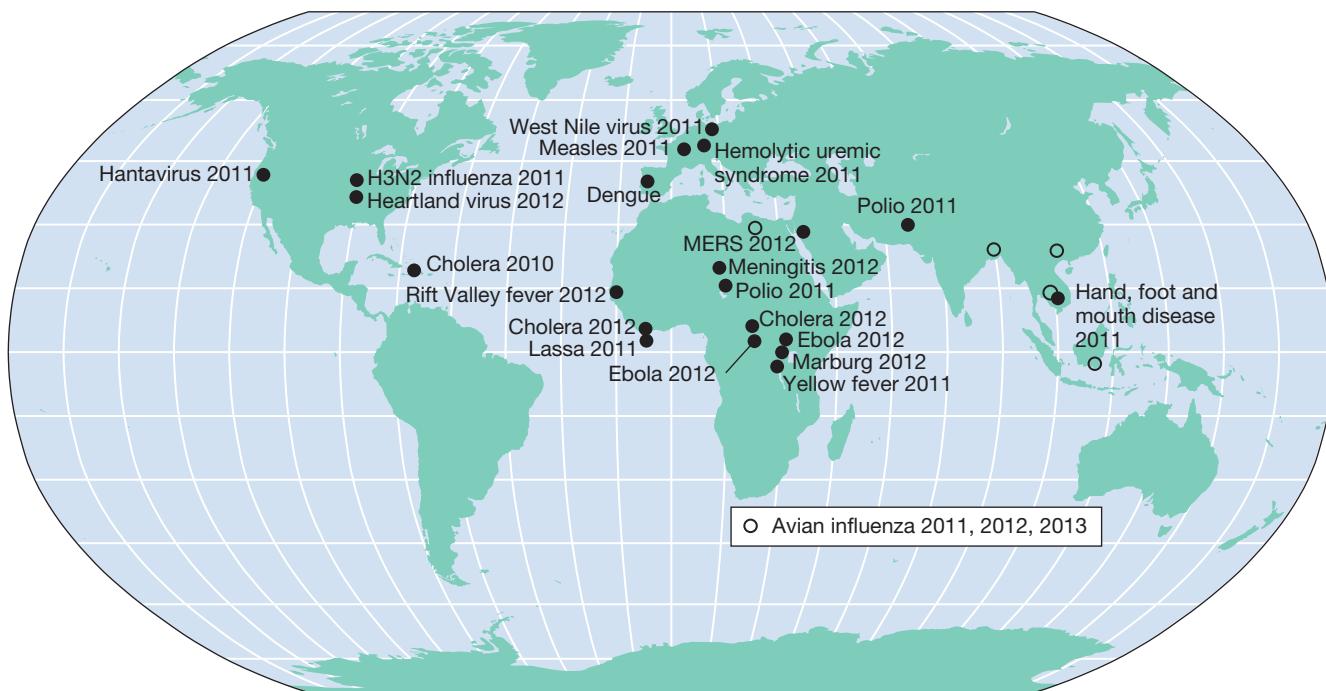

Figure 28.10 Recent outbreaks of emerging and reemerging infectious diseases. The diseases shown are local outbreaks capable of producing widespread epidemics and pandemics. Not shown are established pandemic diseases such as HIV/AIDS and cholera, and predictable annual epidemic diseases such as seasonal epidemic human influenza.

Today nearly one-half of the world's population lives in cities. The high density of human hosts in cities can facilitate disease transmission. For example, dengue fever (Table 28.4) is a serious disease now concentrated in tropical and subtropical urban areas, with up to 100 million infections due to the spread of dengue virus

in the mosquito *Aedes aegypti* (Figure 28.11). Prior to 1981, dengue fever was unknown in the Americas as the mosquito vector *Aedes aegypti* was not present (➡ Section 30.5). However, by 2003 both the mosquito and dengue virus were present in all Central American and tropical South American countries, possibly

imported into tropical population centers from Africa via cargo ships that transported infected mosquitoes along with trade goods. Human behavior, especially in large population centers, also contributes to disease spread. For example, sexually promiscuous practices in population centers contribute to the spread of hepatitis and HIV/AIDS.

Technological advances and industrial development have a generally positive impact on living standards worldwide, but in some cases these advances have contributed to the spread of diseases. For example, the number and kind of healthcare-associated infections have increased dramatically in recent years (Section 27.2). Antibiotic resistance in microorganisms is another negative outcome of modern healthcare practices. For instance, vancomycin-resistant enterococci and staphylococci and drug-resistant *Streptococcus pneumoniae* and *Mycobacterium tuberculosis* are emerging pathogens in developed countries.

Economic development and changes in land also promote disease spread. For example, Rift Valley fever, another mosquito-borne viral infection, has been on the increase since the completion of the Aswan High Dam on the Nile River in Egypt

in 1970. An epidemic of Rift Valley fever first developed in Egypt in 1977, when an estimated 200,000 people became ill and 598 died; the disease is now endemic near the dammed reservoir. Lyme disease, the most common vectorborne disease in the United States, is on the rise largely due to changes in land use patterns (Section 30.4). Reforestation and the resulting increase in populations of deer and mice (the natural reservoirs for the disease-producing *Borrelia burgdorferi*) have resulted in greater numbers of the arthropod tick vector. New homes and recreational areas in and near forests increase contact between the infected ticks and humans, consequently increasing disease incidence.

Transportation, bulk processing, and central distribution methods have become increasingly important for quality assurance and economy in the food industry. However, these same factors can increase the potential for common-source epidemics when sanitation measures fail. For example, a single U.S. meat-processing plant spread *Escherichia coli* O157:H7 to people in eight states in 2009. The contaminated food source, ground beef, was recalled and the epidemic was eventually stopped, but not before several people died.

International travel and commerce also affect the spread of pathogens. For example, filoviruses (*Filoviridae*), a group of RNA viruses, cause fevers culminating in hemorrhagic disease in infected hosts (Explore the Microbial World, “Handling Viral Hemorrhagic Fever Viruses,” in Chapter 30). These untreatable viral diseases typically have a mortality rate above 20%. Most outbreaks have been restricted to equatorial central Africa, where the natural primate hosts and other vectors live (Figure 28.10), but travel of potential hosts to or from endemic areas can result in disease transmission. For example, one of the filoviruses was imported into Marburg, Germany, in 1967 with a shipment of African green monkeys used for laboratory work. The virus spread from the primate host to some of the human handlers. Seven of 31 infected people died in this outbreak of what became known as the *Marburg virus*. In 1989, another shipment of laboratory monkeys brought a different filovirus to Reston, Virginia, in the United States. The virus, now called Ebola-Reston, did not cause overt disease in any humans but, having an effective respiratory

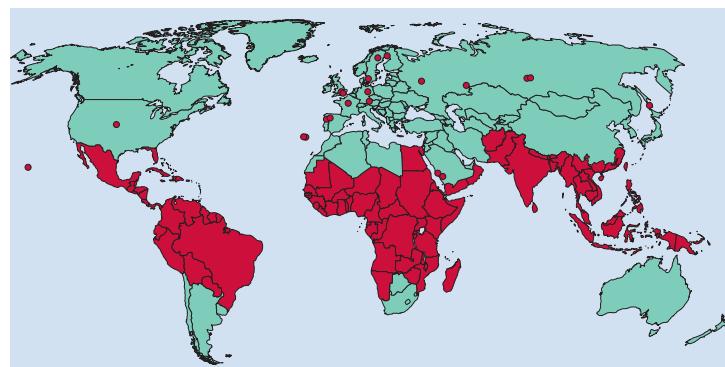

Figure 28.11 Dengue virus 2013. Dengue virus is now found in all tropical and subtropical countries due to the spread of its *Aedes aegypti* mosquito vector. The red areas are now endemic for the virus and mosquito vector. The red dots indicate outbreaks outside the known endemic areas. Prior to 1981, dengue virus was unknown in the Americas. Data are from the CDC, Atlanta, Georgia, USA.

transmission mode, Ebola-Reston infected and killed most of the monkeys at the Reston facility within days. The high mortality potential of filovirus infections, especially one with respiratory transmission, could devastate population centers worldwide in a matter of weeks.

Emergence Factors: Pathogen Variation, Public Health Breakdowns, and Climate Change

Pathogen adaptation and change can contribute to disease emergence. For example, nearly all RNA viruses, including influenza (Section 29.8), HIV, and the hemorrhagic fever viruses, mutate rapidly. Because RNA viruses lack correction mechanisms for mutations during RNA replication, they incorporate mutations at an extremely high rate compared with most DNA viruses. These mutant RNA viruses present major epidemiological problems because their altered genomes may affect their antigens, making immunity to old viruses ineffective for neutralizing the mutants (see an example with influenza in Figure 29.27). Bacterial genetic mechanisms are capable of enhancing virulence and promoting emergence of new epidemics. Virulence-enhancing factors are often carried by bacteriophages, plasmids, and transposons as mobile genetic elements that can be transferred between and among members of the same species, and sometimes to other species and genera. **Table 28.7** lists some mobile virulence factors that can contribute to pathogen emergence.

A breakdown of public health measures is sometimes responsible for the emergence or reemergence of diseases. For instance, cholera (caused by *Vibrio cholerae*) can be adequately controlled, even in endemic areas, by providing proper sewage disposal and water treatment. In 2010 contaminated water supplies probably caused by inadequate sanitation measures by United Nations peacekeeping forces brought cholera to Haiti for the first time in over 100 years (Section 28.10). In 1993, the municipal water supply of Milwaukee, Wisconsin, was contaminated with the chlorine-resistant protist *Cryptosporidium*, resulting in over 400,000 cases of intestinal disease.

Inadequate public vaccination programs can lead to the resurgence of previously controlled diseases. For example, pertussis, a

vaccine-preventable childhood respiratory disease, has increased recently in Eastern Europe and in the United States partly due to inadequate immunization among adults and children.

Finally, abnormal natural occurrences sometimes upset the usual host-pathogen balance. For example, hantavirus is a human pathogen that is endemic in some rodent populations (Section 30.2). An abnormally high number of cases of human hantavirus infections leading to several deaths were reported in 1993 in the American Southwest and were linked to exposure to wild mice and their urine and droppings. The likelihood of exposure to mice and their waste products was increased due to a larger than normal wild mouse population resulting from near-record rainfall, a long growing season, and a mild winter, leading to a dramatic increase in the zoonotic host and pathogen density and enhanced exposure for susceptible human hosts. Similar factors led to a hantavirus outbreak in Yosemite National Park (California, USA) in 2011 (Figure 28.10). As global warming progresses, we are likely to see permanent alterations in climate that significantly alter the range of hosts, vectors, and pathogens.

Addressing Emerging Diseases

Emerging diseases have, at least at first, low incidence and are usually absent from the official notifiable disease list for the United States (Table 28.4). The keys for addressing emerging diseases are recognition of the disease and intervention to prevent pathogen transmission.

Emerging diseases are first recognized from their unique epidemic incidence, clusterings and other epidemiological patterns, and clinical symptoms unrelated to known pathogens. These diseases warrant intensive public health surveillance, followed by specific interventions designed to control further outbreaks. Methods such as isolation, quarantine, immunization, and drug treatment can be applied to contain outbreaks. For vectorborne and zoonotic diseases, the nonhuman host or vector must be identified to intervene in the life cycle of the pathogen and stop human infection.

International public health surveillance and intervention programs were instrumental in controlling the emergence of severe

acute respiratory syndrome (SARS), a disease that emerged rapidly, explosively, and unpredictably from a zoonotic source. On the other hand, even a rapid and focused response was unsuccessful in containing the spread of pandemic (H1N1) 2009 influenza (Section 28.11).

28.8 Biological Warfare and Biological Weapons

Biological warfare is the use of biological agents to incapacitate or kill a military or civilian population in an act of war or terrorism. The use and development of biological weapons are forbidden by international law. Nevertheless, biological weapons have been used against targets in the United States, and biological weapon-making facilities may be in the hands of several governments as well as avowed terrorist groups.

Characteristics of Biological Weapons

Effective biological weapons are pathogens or toxins that are (1) easy to produce and deliver, (2) safe for use by the offensive forces, and (3) able to incapacitate or kill people in a systematic and consistent manner. Although biological weapons are potentially useful in the hands of conventional military forces, the greatest likelihood of biological weapons use is probably by terrorists. This is in part due to the availability and low cost of producing and propagating many of the organisms useful for biological warfare.

Virtually all pathogenic bacteria or viruses are potentially useful for biological warfare, and several of the most likely candidate organisms are relatively simple to grow and disseminate. *Select agents* that have significant potential for use as biological weapons are listed in **Table 28.8**. The most frequently mentioned candidates for use as biological weapons are smallpox virus and *Bacillus anthracis*, the cause of anthrax.

Select agents are classified according to their potential as bio-weapons into three categories by the Centers for Disease Control and Prevention. The highest level of threat comes from Category A agents. These can be easily disseminated by, for example, aerosols, or are easily transmissible from person to person. These agents characteristically cause high mortality and consequently have high impact on public health. Preparations for attacks by such agents require a specific plan for each agent. Category B agents are moderately easy to spread, result in moderate morbidity and low mortality, and require specialized diagnostic and surveillance capabilities. Category C agents are emerging pathogens for which no specific control and containment plans can be anticipated.

Smallpox

Smallpox virus has intimidating potential as a Category A biological warfare agent because it can be easily spread by contact or aerosol spray and it has a mortality rate of 30% or more. Its

Table 28.8 Select agents and diseases by bioweapons threat category^a

Category A

Highest-priority agents that pose a risk to national security. These agents are easily disseminated or transmitted and result in high mortality rates. They require special action for public health preparedness.

Disease/Pathogen

- Anthrax (*Bacillus anthracis*)
- Botulism (*Clostridium botulinum* toxin)
- Plague (*Yersinia pestis*)
- Smallpox (*Variola major*)
- Tularemia (*Francisella tularensis*)
- Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])

Category B

Second-highest-priority agents. These agents are moderately easy to disseminate, result in moderate morbidity and low mortality, and require specific enhancements of public health diagnostic capacity and disease surveillance.

Disease/Pathogen

- Brucellosis (*Brucella* species)
- Epsilon toxin of *Clostridium perfringens*
- Food safety threats (e.g., *Salmonella* spp., *Escherichia coli* O157:H7, *Shigella*)
- Glanders (*Burkholderia mallei*)
- Melioidosis (*Burkholderia pseudomallei*)
- Psittacosis (*Chlamydophila psittaci*)
- Q fever (*Coxiella burnetii*)
- Ricin toxin from *Ricinus communis* (castor beans)
- Staphylococcal enterotoxin B (*Staphylococcus aureus*)
- Typhus fever (*Rickettsia prowazekii*)
- Viral encephalitis (alphaviruses such as Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis)
- Water safety threats (*Vibrio cholerae*, *Cryptosporidium parvum*, and others)

Category C

Third-highest-priority agents are emerging pathogens that are available, easily produced and disseminated, with high potential for high morbidity and mortality.

potential for use as a military biological weapon is considered low, however, because the only known stocks of smallpox virus are in guarded repositories in the United States and Russia and military personnel are routinely vaccinated. A possibility remains, however, for terrorist groups or military forces to gain access to the smallpox virus and spread it among the public at large. Because of this, the United States government has made provisions to immunize frontline healthcare and public safety personnel for smallpox.

Although there is an extremely effective smallpox vaccine that uses the closely related vaccinia virus as the immunogen, this

vaccine has not been in general use for almost 40 years because wild smallpox was eradicated worldwide over 35 years ago. Vaccinia immunization is very effective, but it carries significant risk; about one to two people per million who receive the vaccine will likely die from a vaccinia virus complication. Consequently the vaccine is no longer recommended and over 90% of the world population is inadequately immune and susceptible to the disease. Preparations for a potential smallpox attack in the United States have included recommendations for immunization of certain individuals: persons having close contact with smallpox patients; workers evaluating, caring for, or transporting smallpox patients; laboratory personnel handling clinical specimens from smallpox patients; and other persons such as housekeeping personnel who might come into contact with infectious materials from smallpox patients.

Anthrax

Bacillus anthracis, a ubiquitous saprophytic soil bacterium, is a Category A biowarfare and bioterrorism agent. Its unique properties make it particularly useful as a bioweapon. It grows as an aerobic gram-positive rod and produces endospores resistant to heat and drying, and it forms distinctive colonies on blood agar plates (Figure 28.12). Endospore formation enhances the ability to disseminate *B. anthracis* in aerosols.

B. anthracis endospores are the normal means of acquiring anthrax; we discuss the pathology of anthrax in detail in Section 30.8. Animals and humans occasionally acquire the spores by contact with contaminated plants or soil. There are three forms of the disease. *Cutaneous anthrax* (Figure 28.13a) is contracted when abraded skin is contaminated by *B. anthracis* endospores produced by a toxigenic poly-D-glutamic acid-encapsulated strain. Cutaneous anthrax cases in humans are rare in the United States. *Gastrointestinal anthrax* is contracted from consumption of endospore-contaminated plants or meat from animals infected with anthrax. Human gastrointestinal anthrax is also rare in the United States. *Inhalation anthrax* (also called pulmonary anthrax) is contracted when the endospores are inhaled. Inhalation of the endospores or the live bacteria results in pulmonary infections characterized by pulmonary and cerebral hemorrhage

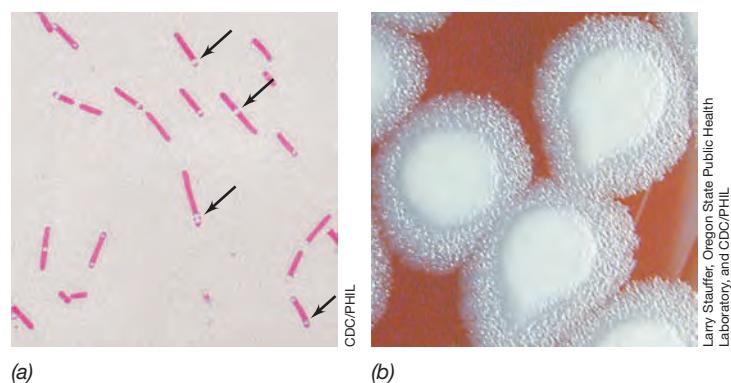

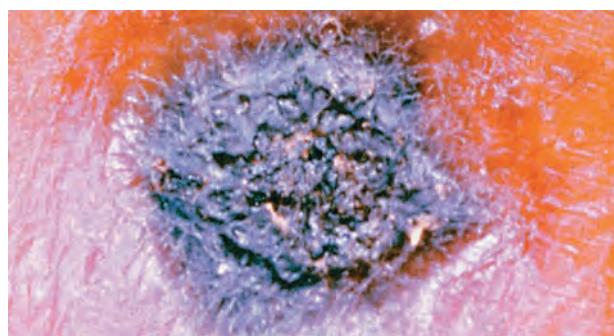

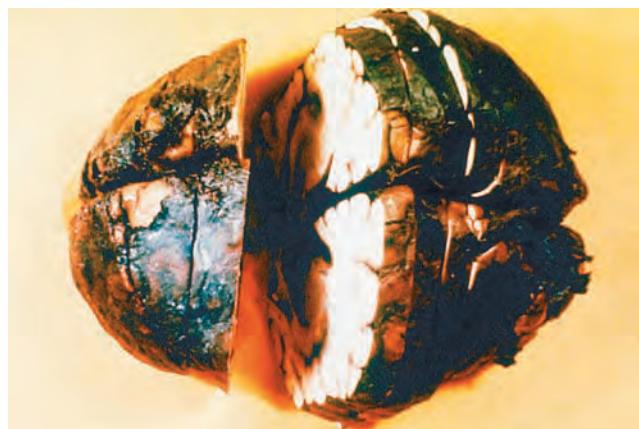

Figure 28.12 *Bacillus anthracis*. (a) *Bacillus anthracis* is a gram-positive endospore-forming rod approximately 1 μm in diameter and 3–4 μm in length. Note the developing endospores (arrows). (b) Characteristic “ground glass” appearance of colonies of *B. anthracis* on blood agar plates.

(Figure 28.13b). Untreated inhalation anthrax has a mortality rate of nearly 100%. Fortunately, inhalation anthrax cases, even in agricultural workers, are extremely rare. The most recent naturally acquired inhalation anthrax infection in the United States occurred in 1976. However, several cases of inhalation anthrax identified in 2001 in the United States were caused by a bioterrorism attack.

Pathogenesis results from inhalation of endospores from toxigenic *B. anthracis*. Pathogenic strains produce three key virulence proteins—protective antigen (PA), lethal factor (LF), and edema factor (EF). PA and LF form *lethal toxin*. PA and EF form *edema toxin* (Table 23.5). Growth of *B. anthracis* in the lymph nodes and lymphatic tissues leads to sore throat, fever, and muscle aches. Symptoms from the growing toxemia escalate in several days to include difficulty in breathing and systemic shock. Fatality rates can approach 90% even when exposure is recognized and treatment is started, and is nearly 100% in cases for which treatment is not started until after the onset of symptoms.

Weaponized anthrax strains are usually endospore preparations that have properties that enhance dissemination. Such strains and preparations were developed in several countries in the post-World War II era, but development of new biological weapons was halted by international treaty in 1972. The physical characteristics of weaponized anthrax preparations typically include a

small particle size interspersed with a very fine particulate agent such as talc. This powdered form ensures that the endospores will spread easily by air currents. Thus, opening an envelope containing endospores or releasing the powder–endospore mixture into a ventilation system or other air current can contaminate surrounding areas and personnel.

In 2001 anthrax attacks were carried out in the United States by mailing envelopes or packages containing weaponized anthrax spores. In all, the attacks were responsible for 22 cases of anthrax, 11 of which were cutaneous anthrax, and 11 were inhalation anthrax; five deaths resulted from the attacks. These incidents in the United States were not the first or the most serious anthrax biological weapons infections. In 1979, *B. anthracis* spores were inadvertently released into the atmosphere from a biological weapons facility in Sverdlovsk, Russia. Less than 1 g of endospores was released, and everyone in the area surrounding the facility was immunized and given prophylactic antibiotic therapy as soon as the first anthrax case was diagnosed. However, even with these quick reactive measures, 77 persons outside the facility contracted inhalation anthrax and 66 died.

Vaccination for anthrax is restricted to individuals who are considered at risk. This includes agricultural animal workers and military personnel.

Delivery of Biological Weapons

As for anthrax, organisms most suitable for use as biological weapons can be spread as an aerosol, providing simple, rapid, widespread dissemination leading to infection. Examples of several other aerosol exposures are instructive.

In 1962, one of the last outbreaks of smallpox in a developed country occurred in Germany. A German worker developed smallpox after returning from Pakistan, where smallpox was still endemic. The patient, who had a cough, was immediately hospitalized and quarantined; the cough aerosolized the virus and caused 19 cases of smallpox and one death, even though every individual who became infected had been immunized.

There have been planned bioterrorist attacks in the United States and other countries before the anthrax attacks of 2001. In 1984 in The Dalles, Oregon (USA), terrorists sprayed salad bars in ten restaurants with a culture of *Salmonella enterica* serovar

Typhimurium, causing 751 cases of foodborne salmonellosis in a region that usually has fewer than 10 cases per year. In 1995, a terrorist group released sarin nerve gas, a chemical weapon, into a Tokyo subway, killing several people and injuring many more. This incident is relevant to a discussion of biological weapons because this group also possessed anthrax cultures, bacteriological media, drone airplanes, and spray tanks. They attempted at least one biological attack, but were unsuccessful.

Delivery of preformed bacterial toxins such as botulinum toxin or staphylococcal enterotoxin to large populations may be impractical because most exotoxins are proteins that lose effectiveness as they are diluted or denatured, and are destroyed in common sources such as drinking water. However, delivery of toxins could be aimed at selected individuals and small groups, or delivered randomly to instigate panic.

Prevention and Response to Biological Weapons

Proactive measures against the deployment of biological weapons have already begun with periodic updating of the international agreements of the 1972 Biological and Toxic Weapons Convention. The fifth and most recent update was in 2002. At the practical level, governments are now supporting the large-scale production and distribution of vaccines along with the development of strategic and tactical plans to prevent and contain biological weapons.

The United States government, through the Centers for Disease Control and Prevention (CDC), has developed the Select Agent Program surveillance system to monitor possession and use of potential bioterrorism agents. The CDC Laboratory Response Network and the Health Alert Network have been upgraded to enhance their diagnostic capabilities and increase the reporting abilities of local and regional healthcare centers to rapidly identify bioterrorism events as well as emerging diseases (Table 28.5).

IV • Current Pandemics

Here we examine data collected by national and worldwide disease-surveillance programs that provide a picture of current and emerging disease patterns for three major pandemic diseases: HIV/AIDS, cholera, and influenza.

28.9 The HIV/AIDS Pandemic

HIV/AIDS is a continuum of disease, starting with the infection of an individual with the human immunodeficiency virus (HIV), leading to the clinical disease, acquired immunodeficiency syndrome (AIDS), a disease that attacks the immune system (Section 29.14).

HIV/AIDS Numbers

The first reported cases of AIDS were diagnosed in the United States in 1981. Since then, more than 1 million cases have been reported in the United States with over 500,000 deaths. A total of 36,870 persons in 2009 and 35,741 persons in 2010 acquired new HIV infections. Over 33,000 new AIDS cases have been diagnosed and reported every year since 1989 (Figure 28.14); 800,000 to 1.3 million persons are living with HIV/AIDS in the United States.

Worldwide, from 1981 through 2010, over 80 million people have been infected with HIV. About 46 million people have already died from AIDS, and about 34 million are currently infected with HIV (Table 28.9), with most—23.5 million—living in sub-Saharan Africa.

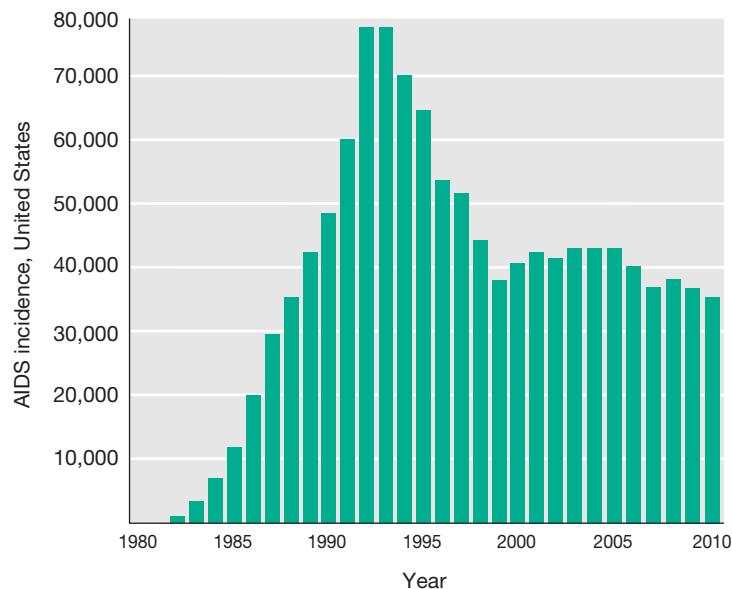

Figure 28.14 Annual new cases of human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) in the United States. Cumulatively, there were about 1.1 million cases of HIV/AIDS through 2010. In 2009, the HIV/AIDS case definition changed to include all new HIV infections and AIDS diagnoses. Data are from the HIV/AIDS Surveillance Report and Division of HIV/AIDS Prevention—Surveillance and Epidemiology, CDC, Atlanta, Georgia, USA.

Globally, 2.5 million individuals are newly infected with HIV and about 1.7 million deaths occur each year, with 1.2 million deaths occurring in sub-Saharan Africa.

HIV/AIDS Epidemiology

Case studies in the United States in the 1980s initially suggested a high AIDS prevalence among men who have sex with men and intravenous drug abusers. This indicated a transmissible agent, presumably transferred during sexual activity or by blood-contaminated needles. Individuals receiving blood or blood products were also at high risk: Hemophiliacs who required infusions of blood products, usually pooled from multiple donors, acquired AIDS, as did a small number of individuals who received blood transfusions or tissue transplants before 1982 (when blood-screening procedures were implemented). Today the incidence of HIV in hemophiliacs and in blood transfusion and organ

recipients has been virtually eliminated through rigorous screening of blood and biological products.

Soon after the discovery of HIV, laboratory immunosorbent assays and immunoblot tests (► Section 27.9) were developed to detect antibodies to the virus in a blood sample. Extensive surveys of HIV incidence and prevalence defined the spread of HIV and ensured that new cases would not be transmitted by blood transfusions. The pattern illustrated in Figure 28.15 is typical of an agent transmissible by blood or other body fluids. The identification of defined high-risk groups implied that HIV was not transmitted from person to person by casual contact, such as the respiratory route, or by contaminated food or water. Instead, body fluids, primarily blood and semen, were identified as the vehicles for transmission of HIV.

Figure 28.15 shows that in the United States the number of AIDS cases is disproportionately high in men who have sex with men, but the patterns in women and in certain racial and ethnic groups indicate that male-to-male sex is not the only risk factor for acquiring AIDS. Among women, for example, heterosexuals are the largest risk group, whereas in African American and Hispanic men, intravenous drug use as well as sexual activity is linked to HIV infection.

Racial differences in HIV incidence rates in the United States indicate that social and economic factors also contribute to infection risk. African Americans acquired 44% of all new HIV infections in 2010, but made up only about 14% of the U.S. population. Black men accounted for 70% of these infections; the incidence of new HIV infections for black men was seven times as high as that for white men.

The study of individuals who are at high risk for acquiring AIDS indicates that virtually all who acquire HIV today share two specific behavior patterns. First, they engage in activities (sex or drug use) in which body fluids, usually semen or blood, are transferred. Second, they exchange body fluids with multiple partners through sexual activity, needle-sharing drug activity, or both. With each

encounter they have a probability of receiving body fluids from an HIV-infected individual and therefore a chance of being infected with HIV.

HIV can be transmitted to the fetus by infected mothers and also in mothers' milk; in 2010, there were 162 new cases of perinatal HIV infection in the United States. Infants born to HIV-infected mothers have maternally derived antibodies to HIV in their blood. However, a positive diagnosis of HIV infection in infants must wait a year or more after birth because about 70% of infants showing maternal HIV antibodies at birth show no signs of being infected later on.

Heterosexual transmission of HIV is the norm in Africa. In some regions, fewer men than women are infected with HIV. The identification of high-risk groups such as prostitutes has led to the development of health education campaigns that inform the public of HIV transmission methods and define high-risk behaviors. Because no cure or proven immunization for AIDS is available, public health education remains the most effective approach to the control of HIV/AIDS. We discuss the pathology and therapy of HIV/AIDS in Section 29.14.

28.10 Cholera Pandemics

Cholera is a severe diarrheal disease that is now largely restricted to the developing world. Cholera is an example of a major waterborne disease that can be controlled by application of appropriate public health measures for water treatment. Global incidence estimates range from 3 to 5 million cases per year, mostly unreported, causing an estimated 100,000–120,000 deaths. We discuss the biology, pathogenesis, and treatment of cholera in Section 31.3. Here we concentrate on the epidemiology of cholera pandemics, including the recent outbreak in Haiti.

Epidemiology

Cholera is typically caused by ingestion of contaminated water containing *Vibrio cholerae*, a gram-negative, curved rod-shaped species of *Proteobacteria*. As with many waterborne diseases, cholera can also be acquired by consumption of contaminated food (☞ Section 31.3).

Cholera is endemic in Africa, Southeast Asia, the Indian subcontinent, and Central and South America. Epidemic cholera occurs frequently in areas where sewage treatment is either inadequate or altogether absent. Worldwide in 2008, there were 190,130 reported cases and 5143 reported deaths from cholera, with over 98% of all reported cases occurring in Africa. About 100,000 cases or more have been reported annually since 2000, with a low of 95,560 cases in 2004, and a high of 589,854 cases in 2011 (Figure 28.16).

The World Health Organization estimates that only 5–10% of cholera cases are reported, so the total incidence of cholera exceeds 1 million cases per year. Even in developed countries, the

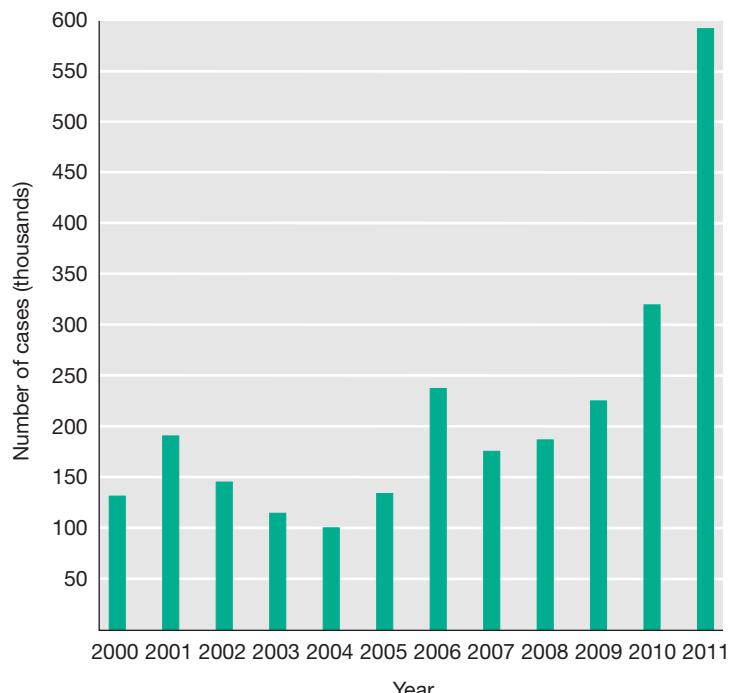

Figure 28.16 Cholera cases. The reported cholera cases from 2000 to 2011 show an increasing trend indicating a continuation of the seventh pandemic (or the beginning of an eighth pandemic). Up to 95% of cholera cases are unreported. Data were provided by the World Health Organization.

disease is a threat. A handful of cases are reported each year in the United States, but rarely from drinking water sources. Most of these cases are imported, often in food. A few cases are possibly from endemic sources; raw shellfish seems to be the most common vehicle, presumably because *V. cholerae* can be free-living in coastal waters in endemic areas where the pathogen adheres to marine microflora ingested by the shellfish (☞ Section 31.3).

Epidemic cholera may develop into pandemics when travelers from endemic areas carry the pathogen to new locations with susceptible populations. Since 1817, cholera has swept the world in seven major, and nearly contiguous, pandemics (Figure 28.17). All cholera pandemics have originated from the Indian subcontinent, where cholera is endemic. Two distinct pandemic strains of *V. cholerae* are recognized, known as the *classic* and the *El Tor* biotypes. The *V. cholerae* O1 El Tor biotype started the seventh pandemic in Indonesia in 1961, and its spread continues to the present. This pandemic has caused over 5 million cases of cholera and at least 250,000 deaths and continues to be a major cause of morbidity and mortality, especially in developing countries. In 1992, a genetic variant of the El Tor biotype known as *V. cholerae* O139 Bengal arose in Bangladesh and caused an extensive epidemic. *V. cholerae* O139 Bengal has continued to spread since 1992, causing several major epidemics, and may be the agent of an eighth pandemic.

Haitian Outbreak

In October 2010 Haiti experienced its first cholera in over 100 years. Through July 2012, Haiti experienced 581,952 cases and 7455 deaths due to cholera, with no end in sight. The outbreak began in the aftermath of a catastrophic 2010 earthquake. There were two possible triggers of the cholera outbreak, the first being

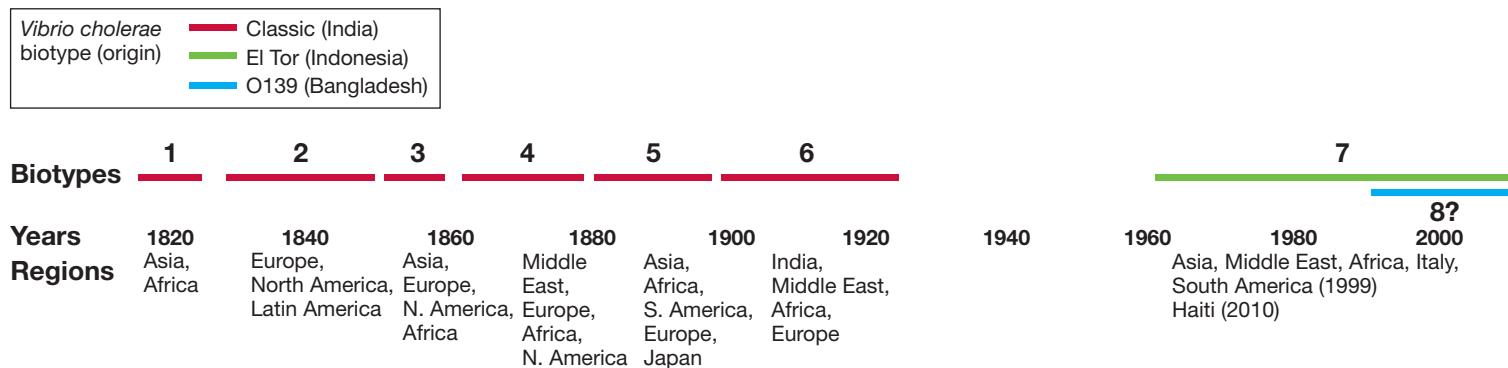

Figure 28.17 Cholera pandemic timeline. Seven cholera pandemics have been nearly contiguous for over 200 years. The seventh pandemic started in 1961 and is ongoing. The O139 strain that appeared in 1991 is endemic to Bangladesh and the Bay of Bengal and is causing epidemics that may be the prelude to an eighth pandemic.

a classic scenario of poor sanitation and the second an accidental importation from an outside source.

Based on climatic data and the possibility of the earthquake disturbing coastal waters where *Vibrio cholerae* is endemic in local microflora, some scientists hypothesized that the vibrios had grown explosively offshore and been washed into coastal freshwater, where they contaminated drinking water sources. The poor sanitary conditions following the earthquake included the breakdown of water and sewage treatment infrastructure that, they reasoned, provided the perfect scenario for an outbreak.

The second possibility was that the outbreak was the result of poor sanitation and disposal of waste from a battalion of United Nations (UN) peacekeeping troops. The troops had arrived from Nepal where there had been a recent cholera outbreak. Sewage from their camp ran into the Artibonite River, a major water source for much of Haiti. The first cases were from towns near the Artibonite River and the UN camp, inland from the coastal areas that would be the likely initial sites of an outbreak due to an offshore source. Whole genome sequence typing confirmed that the strain responsible for the Haiti outbreak was nearly identical to *V. cholerae* serogroup O1, serotype Ogawa, the strain that had caused a recent outbreak in Nepal. This serotype had never before been seen in the Western Hemisphere.

Though scientists were not permitted to take samples from the Nepalese soldiers, the molecular and classical epidemiology data lead to the almost certain conclusion that the Nepalese troops had introduced cholera to Haiti. Cholera has since spread to the Dominican Republic, Haiti's sister country on the island of Hispaniola, to other areas of the Caribbean, and to Mexico.

Swine Flu—Pandemic (H1N1) 2009 Influenza

An influenza pandemic began in March 2009 with the outbreak of epidemics in Mexico. Typical year-to-year antigenic variation, called *antigenic drift*, is caused by point mutations in the RNA of the influenza genome. These mutations seldom cause pandemics, but do cause annual influenza outbreaks. Pandemic influenza strains arise from a much larger change in the viral genome termed *antigenic shift*. In the “swine flu” pandemic—officially, pandemic (H1N1) 2009—swine in Mexico were simultaneously infected with swine influenza, bird influenza, and human influenza (Figure 29.27). During viral maturation, viral genomic RNA segments, in this case from three sources, are mixed together and packaged to form genetically unique viruses, a process called *reassortment*. Such *reassortant viruses* cause new pandemics as new strains are mixed in susceptible animals and spread to susceptible human populations (Section 29.8).

A virus that results from antigenic shift has the potential to contain antigens to which no human has had prior exposure. This means that immunity to a new virus is nonexistent; the only way humans can obtain immunity to a new strain is to become infected (or artificially immunized) and produce an immune response. For the virus of pandemic (H1N1) 2009, almost no one less than 50 years old had any immunity because they were never exposed to similar H1N1 viral strains. As a result, many of the deaths in this pandemic were of people younger than 50 who were healthy until they were infected by the virus. However, pandemic (H1N1) 2009 is related to the 1957 influenza pandemic nicknamed the “Asian flu,” and, farther back, to the 1918 influenza pandemic that killed over 2 million people worldwide. Hence, most people 50 or older had probably been infected with a strain of influenza virus related to the pandemic (H1N1) 2009 virus and had immune cells and antibodies (immune memory) that responded to control this pandemic virus. For younger people, unfortunately, immune memory to pandemic (H1N1) 2009 was nonexistent.

Within six months of its emergence, pandemic (H1N1) 2009 had spread to almost every country in the world, causing significant mortality in most of those. The pattern of spread was similar to that of seasonal influenza, but had one major difference. The virus began its spread from an initial focus of infection in Mexico and the southwestern United States in March, at the very end of the traditional winter flu season. Instead of dying out, as

28.11 Influenza Pandemics

The influenza pandemic of 2009–2010 began with an outbreak in Mexico. Influenza pandemics occur every 10 to 40 years due to major genetic changes in the influenza A virus genome (Table 29.2). We discuss the disease influenza in detail in Section 29.8.

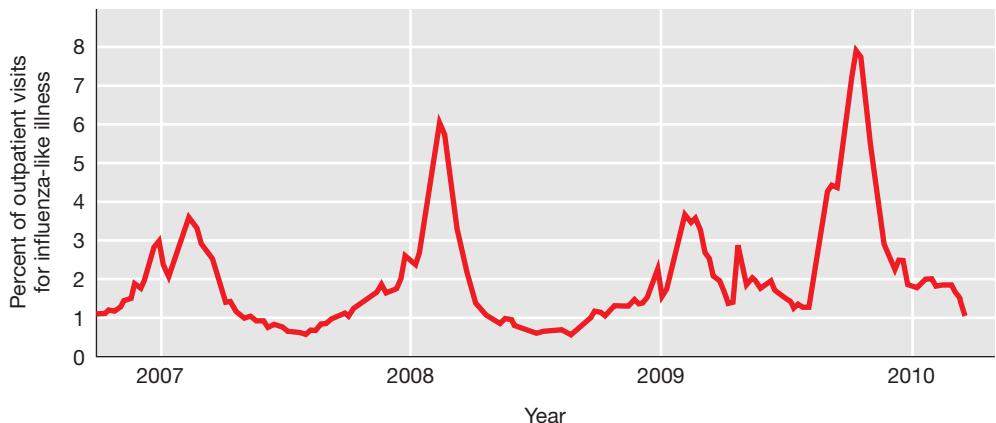

Figure 28.18 Influenza incidence in the United States. Pandemic (H1N1) 2009 influenza virus caused a higher than normal incidence of influenza from the middle of 2009 through 2010. In the 2009–2010 flu season the peak incidence of disease was higher than in the three previous seasons and occurred 3–4 months earlier than usual. Data are adapted from the CDC, Atlanta, Georgia, USA.

most seasonal flu outbreaks do at the end of the winter season, pandemic (H1N1) 2009 continued to spread through the summer months in the United States, especially in susceptible populations such as children at youth group camps. The 2009–2010 flu season in the United States thus differed from the typical seasonal influenza infection pattern; the highest incidence occurred in October and November and tapered off during the usual peak flu season in January through March (**Figure 28.18**). In the Southern Hemisphere, where the flu season runs from about April to September, the pandemic strain spread with all of the characteristics of seasonal flu.

Future Influenza Pandemics

Perhaps the greatest threat to biosecurity worldwide is another influenza pandemic that has the virulence and infectivity of the 1918

pandemic. Public health officials worldwide are watching for the emergence of a potentially devastating avian influenza designated influenza A H5N1, also called *avian influenza*. H5N1 first appeared in Hong Kong in 1997, jumping directly from the avian host to humans. The H5N1 virus has reemerged several times over the last decade, with the most recent outbreaks occurring in Egypt, Indonesia, Cambodia, Bangladesh, and China (Figure 28.10). Through 2012, 610 cases of human H5N1 infections have been confirmed, resulting in 360 deaths, for a mortality rate of almost 60%.

The H5N1 virus is spread directly from birds such as domestic chickens or ducks to humans through prolonged contact or consumption of infected meat; avian influenza is spread human to human only after

prolonged close contact, but some reports indicate that H5N1 has infected swine. If further reassortment with human influenza strains occurs, a new reassortant virus for which there is no immunity in humans could trigger an influenza pandemic with the potential for unprecedented mortality. Plans are in place nationally and internationally to provide appropriate vaccines and support for potential pandemics initiated by this and other emergent influenza strains. A recombinant vaccine for the H5N1 virus is available on a limited basis.

BIG IDEAS

28.1 • Epidemiology is the study of the occurrence, distribution, and determinants of health and disease in populations. An endemic disease is continually present at low incidence in a population, whereas an epidemic disease is one that has increased to unusually high incidence in a population. Incidence is a record of new cases of a disease, whereas prevalence is a record of total cases of a disease in a population. Infectious diseases cause morbidity (illness) and may cause mortality (death). An infectious disease follows a predictable clinical pattern in the host.

28.2 • Effects on both populations and individuals must be studied to understand infectious disease. The interactions of pathogens with hosts can be dynamic, affecting the long-term evolution and survival of all species involved. Herd immunity provides disease protection for uninfected or unimmunized hosts.

28.3 • Infectious diseases can be transmitted directly from one host to another host, indirectly from living vectors or inanimate objects (fomites), or from common-source vehicles such as food and water. Epidemics may be of host-to-host origin or originate from a common source.

28.4 • Many pathogens exist only in humans and are maintained only by transmission from person to person. Many other human pathogens, however, have reservoirs in soil, water, or animals. An understanding of disease reservoirs, carriers, and pathogen life cycles is critical for controlling disease epidemics.

28.5 • Food and water purity regulations, vector control, immunization, quarantine, isolation, and disease surveillance are public health measures that reduce the incidence of communicable diseases.

28.6 • Infectious diseases account for almost 25% of all mortality worldwide. Most cases of infectious diseases are in developing countries. Control of infectious diseases can be accomplished by public health measures.

28.7 • Changes in host, vector, or pathogen conditions, whether natural or artificial, can encourage the explosive emergence or reemergence of infectious diseases. Global surveillance and intervention programs must be in place to prevent new epidemics and pandemics.

28.8 • Bioterrorism is a threat in a world of rapid international travel and easily accessible technical information. Biological agents can be used as weapons by military forces or by terrorist groups. Aerosols or common sources such as food and water are the most likely modes of delivery. Prevention and containment measures rely on a well-prepared public health infrastructure.

28.9 • HIV/AIDS is a major worldwide public health problem that affects individuals who exchange bodily fluids. Those who engage in promiscuous unprotected sex or intravenous drug use are particularly at risk.

28.10 • Cholera pandemics have occurred nearly constantly over the last 200 years. Cholera control can be achieved by maintaining adequate clean water and waste sanitation measures.

28.11 • Influenza pandemics occur cyclically. New pandemic influenza strains resulting from bird–swine–human influenza reassortments present the biggest predictable infectious disease threat worldwide.

REVIEW OF KEY TERMS

Acute infection a short-term infection, usually characterized by dramatic onset

Basic reproduction number (R_0) the number of expected secondary transmissions from each single case of a disease in an entirely susceptible population

Biological warfare the use of biological agents to incapacitate or kill a military or civilian population in an act of war or terrorism

Carrier a subclinically infected individual who may spread a disease

Centers for Disease Control and Prevention (CDC) the agency of the United States Public Health Service that tracks disease trends, provides disease information to the public and to healthcare professionals, and forms public policy regarding disease prevention and intervention

Chronic infection a long-term infection

Common-source epidemic an infection (or intoxication) of a large number of people from a contaminated common source such as food or water

Emerging disease an infectious disease whose incidence recently increased or whose incidence threatens to increase in the near future

Endemic disease a disease that is constantly present, usually in low numbers, in a population

Epidemic the occurrence of a disease in unusually high numbers in a localized population

Epidemiology the study of the occurrence, distribution, and determinants of health and disease in a population

Fomite an inanimate object that when contaminated with a viable pathogen can transfer the pathogen to a host

Herd immunity the resistance of a population to a pathogen as a result of the immunity of a large portion of the population

Host-to-host epidemic an epidemic resulting from person-to-person contact, characterized by a gradual rise and fall in number of new cases

Incidence the number of new disease cases reported in a population in a given time period

Isolation in the context of infectious disease, the separation of persons who have an infectious disease from those who are healthy

Morbidity the incidence of disease in a population

Mortality the incidence of death in a population

Outbreak the occurrence of a large number of cases of a disease in a short period of time

Pandemic a worldwide epidemic

Prevalence the total number of new and existing disease cases reported in a population in a given time period

Public health the health of the population as a whole

Quarantine the separation and restriction of well persons who may have been exposed to an infectious disease to see if they develop the disease

Reemerging disease an infectious disease previously under control but that produces a new epidemic

Reservoir a source of infectious agents from which susceptible individuals may be infected

Surveillance the observation, recognition, and reporting of diseases as they occur

Vector a living agent that transfers a pathogen (differs from genetic vector, discussed in Chapter 11)

Vehicle a nonliving source of pathogens that transmits the pathogens to large numbers of individuals; common vehicles are food and water

Virulence the relative ability of a pathogen to cause disease

Zoonosis any disease that occurs primarily in animals but can be transmitted to humans

REVIEW QUESTIONS

- Distinguish between *acute* and *chronic*, *mortality* and *morbidity*, *prevalence* and *incidence*, and *epidemic* and *pandemic*, as these terms relate to infectious disease. (Section 28.1)
- How does herd immunity protect the nonimmune members of the population from acquiring a disease? Will herd immunity work for diseases that have a common source, such as water? Why or why not? (Section 28.2)
- Give examples of host-to-host transmission of disease via direct contact. Also give examples of indirect host-to-host transmission of disease via vector agents and fomites. (Section 28.3)
- Identify the disease reservoirs for the diseases botulism, gonorrhea, and plague. How do the reservoirs influence our ability to control or eradicate the disease? (Section 28.4)
- Describe the major medical and public health measures developed in the twentieth century that were instrumental in controlling the spread of infectious diseases in developed countries. (Section 28.5)
- Compare the contribution of infectious diseases to mortality in developed and developing countries. (Section 28.6)
- Review the major reasons for the emergence of new infectious diseases. What methods are available for identifying and controlling the emergence of new infectious diseases? (Section 28.7)
- Describe the general properties of an effective biological warfare agent. How do smallpox and *Bacillus anthracis* meet these criteria? Identify other organisms that meet the basic requirements for a bioweapon. (Section 28.8)
- Identify the major risk factors for acquiring human immunodeficiency virus (HIV) infection in the United States. Does this pattern hold for other geographic regions? (Section 28.9)
- Review the current cholera pandemic. Where and when did the pandemic start? (Section 28.10)
- Why is influenza H5N1 considered a very important biological threat? (Section 28.11)

APPLICATION QUESTIONS

- Smallpox, a disease that was limited to humans, was eradicated. Plague, a disease with a zoonotic reservoir in rodents (see Section 30.7), can never be eradicated. Explain this statement and why you agree or disagree with the possibility of eradicating plague on a global scale. Devise a plan to eradicate plague in a limited environment such as a town or city. Be sure to use methods that involve the reservoir, the pathogen, and the host.
- Identify a pathogen that would be a suitable agent for biological warfare and is not listed as a Category A or B agent (Table 28.8). Describe the properties of the pathogen in the context of its use as a biological weapon. Describe equipment and other resources necessary for growing large amounts of the pathogen. Identify a suitable delivery method. As you will propagate, weaponize, and deliver the pathogen, describe the precautions you will take to protect yourself. Now reverse your role. As a public health official in your community, describe how you would recognize and diagnose the disease caused by the agent. Indicate the measures you would take to treat the illnesses caused by the agent. How could you best limit the damage? Would quarantine and isolation methods be useful? What about immunization and antibiotics?
- Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) is a disease that can be eliminated because

it is propagated by person-to-person contact and there are no known animal reservoirs. Do you agree or disagree with this statement? Explain your answer. Design a program for eliminating HIV/AIDS in a developed country and in a developing country. How would these programs differ? What factors would work against the success of your program, both in terms of human behavior and in terms of HIV/AIDS disease progression? Why are the numbers of HIV/AIDS patients continuing to grow, especially in developing countries? HIV/AIDS incidence (new cases) in developed countries has been virtually unchanged in this century (Figure 28.14). The numbers of individuals living with HIV/AIDS, however, is increasing. Explain this contradiction.

- H5N1 avian influenza has high potential for causing an influenza pandemic under certain circumstances. Discuss conditions in which avian influenza may spread in humans as an epidemic. If such a human–avian strain were to evolve in Asia, from the perspective of a national public health official, what measures would you employ to stop the spread of the new influenza to the United States? If you fail to contain the new virus, based on the known mortality figures for the current avian influenza strain, and assuming that 10% of the population became infected, predict the overall number of deaths in the United States.

Is Another Influenza Pandemic on the Way?

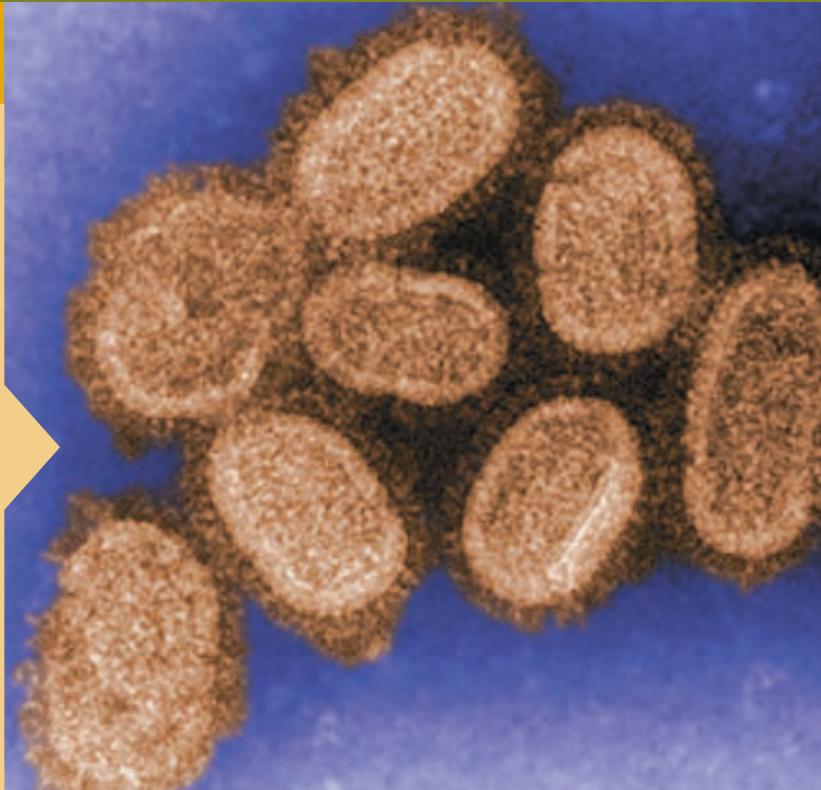

In 1918 a pandemic (worldwide epidemic) of influenza swept across the world infecting 500 million people and killing nearly a fifth of them. The pandemic strain of influenza virus was particularly virulent, killing many otherwise healthy people. In 2005, scientists revived the 1918 killer strain of influenza (photo) from tissues of one of its victims in order to determine why this strain was so virulent.

Health officials today are concerned that new highly virulent influenza viruses may be formed from the exchange of genes between different strains. It is well known that influenza viruses that infect humans can also infect birds and swine. When an animal is infected by more than one strain, their genes can mix—a process called reassortment—to form viruses with new properties. A major worry today is that influenza virus strain H5N1, which has caused large influenza outbreaks in poultry and wild birds but does not transmit well to or between people, could reassort and trigger a new human influenza pandemic.

Scientists are focused on how H5N1 gains transmissibility in a new host. In a major study,¹ researchers were surprised to find that either one of two different genes transferred to the H5N1 virus from a recent human influenza strain (H1N1) allowed H5N1 to be spread by the airborne route between guinea pigs, a new phenomenon for this virus. Changes in the transmission pattern of influenza virus can thus occur very quickly and from a minimal amount of genetic exchange.

Influenza viruses are particularly dangerous pathogens because they are easily spread in infectious droplets and their genetics allow them to rapidly become transmissible in new hosts. Is a new human influenza pandemic in the making? Stay tuned.

- II Airborne Viral Diseases 862
- III Direct-Contact Diseases 868
- IV Sexually Transmitted Infections 872

As many as several million species of microorganisms may exist in nature, but only a few hundred of them cause disease. In this and the next three chapters we focus on this vitally important subset of the microbial world. We investigate the biology of the pathogens as well as the diseases they cause, including disease diagnosis, treatment, and prevention.

Our infectious disease coverage is organized around each pathogen's *mode of transmission*. In this chapter we explore diseases

transmitted from person to person, whether through the air, by direct contact, or through intimate contact. Using this approach, we will establish the ecological connections between biologically diverse pathogens. In Chapters 30 and 31 we focus on diseases transmitted by animal and arthropod vectors and diseases from common sources such as water or food, respectively. In Chapter 32 we examine fungal and parasitic infections, diseases caused by microbial *Eukarya*.

I • Airborne Bacterial Diseases

Worldwide, acute respiratory infections kill more than 4 million people a year, mainly in developing countries. Children and the elderly make up most of the fatalities, but in general, respiratory infections are the most common of all human diseases. Aerosols, such as those generated by a sneeze (Figure 29.1), as well as by coughing, talking, or breathing, are major vehicles for person-to-person transmission of respiratory diseases. Besides directly infecting a new host, infectious mucus from an aerosol can also contaminate objects, such as a door handle, and transmit infection well after the aerosol event. In these ways, respiratory diseases spread quickly, especially in congested areas, as airborne pathogens exploit a simple yet highly effective means of infecting new hosts.

29.1 Airborne Pathogens

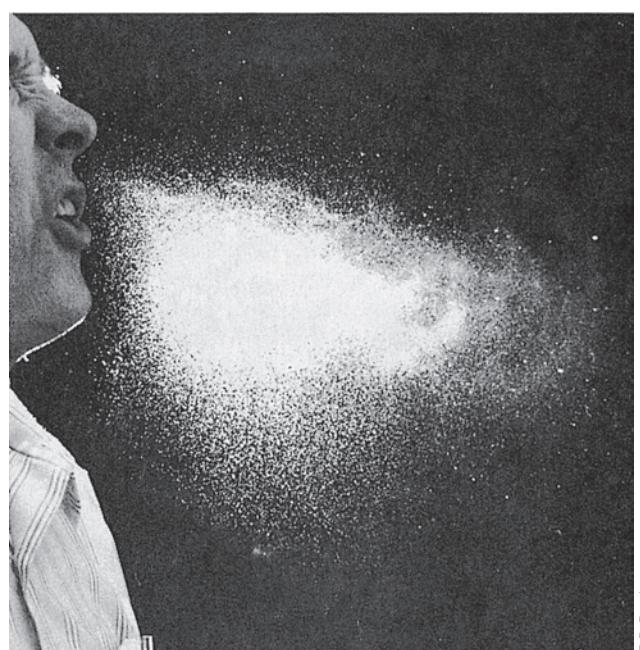

Microorganisms found in air are derived from soil, water, plants, animals, people, surfaces, and other sources. Most microorganisms survive poorly in air. As a result, airborne pathogens are effectively transmitted between people only over short distances. Certain pathogens, however, survive drying well and can remain alive in dust or on fomites for long periods of time. For example, because of their thick, rigid cell walls, gram-positive bacteria (*Staphylococcus*, *Streptococcus*) are generally more resistant to drying than are gram-negative bacteria. Likewise, the waxy layer of *Mycobacterium* cell walls resists drying and promotes survival of pathogens such as *Mycobacterium tuberculosis*.

Large numbers of droplets can be expelled during a sneeze (Figure 29.1). Infectious droplets are about 10 µm in diameter and each droplet can contain one or more microbial cells or virus virions. The initial speed of the droplet movement is about 100 m/s (more than 325 km/h) in a violent sneeze and ranges from 15 to 50 m/s during coughing or shouting. The number of bacteria in a single sneeze varies from 10^4 to 10^6 , and viral numbers can be much higher than this. Because of their small size, the droplets evaporate quickly in the air, leaving behind dried mucus in which the airborne pathogens remain embedded.

The human respiratory tract is divided into upper and lower regions and specific airborne pathogens tend to exploit one region or the other, or sometimes both (Figure 29.2). The speed at which air moves through the human respiratory tract varies, and in the lower respiratory tract the rate is quite slow. As air slows down, particles in it stop moving and settle. Large particles settle first and the smaller ones later; only particles smaller than about 3 µm travel as far as the bronchioles in the lower respiratory tract (Figure 29.2).

Upper respiratory infections such as the common cold are typically acute and non-life-threatening. By contrast, *lower* respiratory infections, such as bacterial or viral pneumonia, are often chronic and can be quite serious, especially in the elderly or an immune-compromised person. Also, although most common respiratory infections are not serious in an otherwise healthy host, they can set the stage for *secondary infections* that can be life-threatening. For example, death of an elderly person from pneumonia following a severe case of influenza is not an uncommon event.

Most human respiratory pathogens are transmitted from person to person because humans are the only reservoir for the pathogens. However, many airborne pathogens, such as *Streptococcus* spp., cold viruses, and influenza, can also be transmitted by direct contact (for example, by a handshake) or on fomites. Accurate and rapid diagnosis and treatment of respiratory infections are well developed in the clinical setting and if practiced effectively, can limit host damage. Many bacterial and viral pathogens transmitted by an airborne route can be controlled by immunization, and most respiratory bacterial pathogens respond readily

to antibiotic therapy. Antiviral therapies, on the other hand, are rather limited, and recovery from viral infections is often due solely to the immune response.

29.2 Streptococcal Diseases

The bacteria *Streptococcus pyogenes* (Figure 29.3) and *Streptococcus pneumoniae* are important human respiratory pathogens. Streptococci are nonsporulating, homofermentative but aerotolerant gram-positive cocci (► Section 15.6). Cells of *S. pyogenes* (Figure 29.3) typically grow in elongated chains, as do many other species of the genus. Pathogenic strains of *S. pneumoniae* typically grow in pairs or in short chains, and virulent strains produce an extensive polysaccharide capsule (see Figure 29.11). Virulent strains of *Streptococcus* can form vicious pus-forming wounds in humans and other warm-blooded animals (Figure 29.4 and see Figure 29.10). But in addition, many other serious conditions whose symptoms are less dramatic than these are also associated with streptococcal infections.

Streptococcus pyogenes

Streptococcus pyogenes (Figure 29.3), also called *group A streptococci*, is frequently isolated from the upper respiratory tract

of healthy adults. Although numbers are typically low, if host defenses are weakened or a new, highly virulent strain is introduced, serious infections are possible.

S. pyogenes is the cause of *streptococcal pharyngitis*, better known as *strep throat* (Figure 29.5). Most clinical isolates of *S. pyogenes* produce an exotoxin (► Section 23.9) that lyses red blood cells in culture media, a condition called β -hemolysis (Figure 29.4b and see Figure 29.8). Streptococcal pharyngitis is characterized by a severe sore throat with enlarged tonsils and red spots on the soft palate (Figure 29.5); tender cervical lymph nodes; and a mild fever and feeling of general malaise. *S. pyogenes* can also

cause infections of the middle ear (*otitis media*) and of the mammary glands (*mastitis*); infections of the superficial layers of the skin called *impetigo* (Figure 29.6); *erysipelas*, an acute streptococcal skin infection (Figure 29.7); and other conditions linked to the aftereffects of streptococcal infections.

About half of the clinical cases of severe sore throat are due to *S. pyogenes*; most others are due to viral infections. Because of this, an accurate and rapid diagnosis of a severe sore throat is important. If the sore throat is due to *S. pyogenes*, immediate treatment

Figure 29.5 A case of strep throat caused by *Streptococcus pyogenes*. The back of the throat is inflamed and shows small red spots, typical of streptococcal pharyngitis.

is important because untreated group A streptococcal infections can lead to serious secondary diseases such as scarlet fever, rheumatic fever, acute glomerulonephritis, and streptococcal toxic shock syndrome. On the other hand, if the sore throat is due to a virus, treatment with antibiotics will be useless and will only promote drug resistance on the part of the normal microflora.

Clinical tools for quickly diagnosing strep throat are widely available and in routine use in primary care clinics. These tools include, in particular, rapid antigen detection systems that contain antibodies specific for cell surface proteins of *S. pyogenes*

Figure 29.7 Erysipelas. Erysipelas is a *Streptococcus pyogenes* infection of the skin, shown here on the nose and cheeks, characterized by redness and distinct margins of infection. Other commonly infected body sites include the ears and the legs.

([Section 27.9](#)). A more sensitive and accurate confirmation is possible by obtaining an actual culture of *S. pyogenes* from the throat or other suspected lesion on a blood agar plate ([Figure 29.8](#)). In contrast to rapid tests, however, results of a throat culture may take up to 48 h to process and such a delay in treatment can have adverse effects, as we consider now.

Scarlet and Rheumatic Fevers and Other Group A Strep Syndromes

Certain strains of group A streptococci carry a lysogenic bacteriophage that encodes streptococcal pyrogenic exotoxin A (SpeA), SpeB, SpeC, and SpeF. These exotoxins are responsible for most of the symptoms of *streptococcal toxic shock syndrome* and **scarlet fever** ([Figure 29.9](#)). Streptococcal pyrogenic exotoxins are superantigens that recruit large numbers of T cells to the infected tissues ([Sections 23.9 and 23.9](#)). Toxic shock results when the activated T cells secrete cytokines, which in turn activate large numbers of macrophages and neutrophils, causing severe inflammation and tissue destruction.

Scarlet fever, signaled by a severe sore throat, fever, and characteristic rash (Figure 29.9), is readily treatable with antibiotics or may be self-limiting. But treatment is always advisable since several undesirable conditions can emerge from a case of scarlet fever. Occasionally group A streptococcal infections cause fulminant (sudden and severe) invasive systemic infections, such as cellulitis, a skin infection in subcutaneous layers; or *necrotizing fasciitis*, a rapid and progressive disease resulting in extensive destruction of subcutaneous tissue, muscle, and fat ([Figure 29.10](#)). Necrotizing fasciitis is a clinical term for the condition caused by “flesh-eating bacteria.” In these cases, SpeA, SpeB, SpeC, and SpeF exotoxins and the bacterial cell surface M protein function as superantigens; the associated inflammation results in extensive tissue destruction and can be fatal (Figure 29.10).

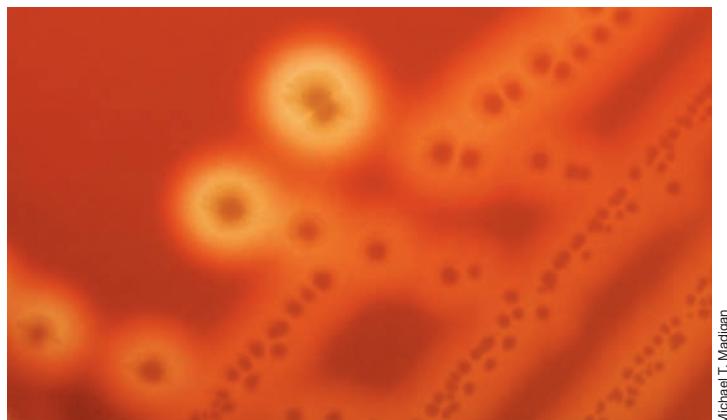

Untreated or insufficiently treated *S. pyogenes* infections may lead to other severe conditions 1 to 4 weeks after the onset of infection. For example, the immune response to the invading pathogen can produce antibodies that cross-react with host tissue

Franklin H. Top

Figure 29.9 Scarlet fever. The typical rash of scarlet fever results from the activity of the pyrogenic exotoxins produced by *Streptococcus pyogenes*.

antigens of the heart, joints, and kidneys, resulting in damage to these tissues. The most serious of these syndromes is **rheumatic fever** caused by rheumatogenic strains of *S. pyogenes*. These strains contain cell surface antigens that are similar in structure to heart valve and joint proteins. Thus rheumatic fever is, in effect, an *autoimmune disease* ([Section 24.8](#)), because antibodies directed against streptococcal antigens cross-react with heart valve and joint antigens, causing host inflammation and tissue destruction. Damage to host tissues may be permanent, and is often exacerbated by subsequent streptococcal infections that lead to recurring bouts of rheumatic fever. Another streptococcal syndrome is *acute poststreptococcal glomerulonephritis*, a painful kidney disease. This “immune complex” disease develops transiently due to streptococcal antigen–antibody complexes in the blood that lodge in the glomeruli (filtration membranes of the kidney) and cause inflammation, a condition called *nephritis*.

Figure 29.11 *Streptococcus pneumoniae*. India ink negative stain of cells of *Streptococcus pneumoniae*. An extensive capsule surrounds the cells, which are 1.0–1.2 μm in diameter.

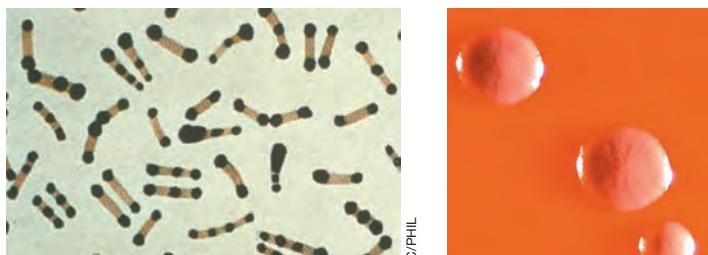

Streptococcus pneumoniae

A second major human streptococcal pathogen is *Streptococcus pneumoniae* (Figure 29.11), a species that can cause invasive lung infections, typically as secondary infections to other respiratory disorders. Encapsulated strains of *S. pneumoniae* (Figure 29.11) are particularly pathogenic because they are very invasive. Cells invade the lower respiratory tract where the capsule enables the cells to resist phagocytosis yet generate a strong host inflammatory response. Reduced lung function, called *pneumonia*, results from the accumulation of recruited phagocytic cells and fluid. Cells of *S. pneumoniae* can then spread from the focus of infection as a bacteremia, sometimes infecting the bones, middle ear, and heart valves (endocarditis). *S. pneumoniae* infection is often the cause of death in elderly persons who die from “respiratory failure.”

Unlike the case with *S. pyogenes*, effective vaccines are available for preventing infection by the most common strains of *S. pneumoniae*. A vaccine for adults consists of a mixture of 23 capsular polysaccharides (Figure 29.11) from the most prevalent pathogenic strains. The vaccine is recommended for those over age 60, health-care providers, individuals with compromised immunity, and any other high-risk population. *S. pneumoniae* infections typically respond quickly to penicillin therapy, but up to 30% of pathogenic isolates now exhibit resistance to this drug. Resistance to the antibiotics erythromycin and cefotaxime is also found in some strains but thus far, all strains have been found sensitive to vancomycin, an antibiotic held in reserve for treating pneumonia and several other bacterial diseases where antibiotic resistance is widespread.

29.3 Diphtheria and Pertussis

Diphtheria is a severe respiratory disease that typically infects young children. Diphtheria is caused by *Corynebacterium diphtheriae*, a gram-positive, nonmotile, and aerobic club-shaped bacterium that forms small, smooth colonies on blood agar plates (Figure 29.12). *Pertussis*, also known as **whooping cough**, is a serious respiratory disease caused by infection with *Bordetella pertussis*, a small, gram-negative, aerobic coccobacillus (see Figure 29.14a). Pertussis mostly affects children but can cause serious respiratory disease in adults as well. Both diphtheria and pertussis can be prevented by vaccination and cured with antibiotics.

Diphtheria

Cells of *C. diphtheriae* (Figure 29.12a) enter the host from airborne droplets, infecting the tissues of the throat and tonsils. Throat tissues respond to *C. diphtheriae* infection by forming a characteristic lesion called a *pseudomembrane* (Figure 29.13), which consists of damaged host cells and cells of *C. diphtheriae*. Pathogenic strains of *C. diphtheriae* carry a lysogenic bacteriophage whose genome

Franklin H. Top

Figure 29.13 The pseudomembrane in diphtheria. The pseudomembrane (arrows) in an active case of diphtheria restricts airflow and swallowing and is associated with a severe sore throat.

encodes a powerful exotoxin called *diphtheria toxin*. This toxin inhibits protein synthesis in the host, leading to cell death (Figure 23.20). Death from diphtheria is typically due to a combination of partial suffocation by the pseudomembrane and tissue destruction by diphtheria exotoxin. *C. diphtheriae* isolated from the throat is diagnostic for diphtheria. Nasal or throat swabs are used to inoculate blood agar containing tellurite (Figure 29.12b) or Loeffler's medium, a selective medium that inhibits the growth of most other respiratory pathogens.

Prevention of diphtheria is accomplished with a highly effective toxoid vaccine, part of the *DTaP* (diphtheria toxoid, tetanus toxoid, and acellular pertussis) vaccine (Section 24.6). Diphtheria is all but absent from developed countries where this vaccine is widely used. Penicillin, erythromycin, and gentamicin are generally effective treatments for diphtheria, but in life-threatening cases, diphtheria antitoxin (an antiserum to diphtheria toxoid produced in horses) may be administered in addition to antibiotic therapy.

Pertussis

Pertussis (whooping cough) is an acute, highly infectious respiratory disease. Infants less than 6 months old, who are too young to be effectively vaccinated, have the highest incidence of disease and also have the most severe symptoms. Cells of *B. pertussis* (Figure 29.14a) attach to host cells of the upper respiratory tract and excrete *pertussis exotoxin*. This potent toxin induces synthesis of cyclic adenosine monophosphate (cyclic AMP, Figure 7.14), which is at least partially responsible for the events that lead to host tissue damage. *B. pertussis* also produces an endotoxin (Section 23.10), which may induce some of the symptoms of whooping cough. Clinically, whooping cough is characterized by a recurrent, violent cough that can last up to 6 weeks. The spasmodic coughing gives the disease its name; a whooping sound results from the patient inhaling deep breaths to obtain sufficient air.

Worldwide, up to 50 million cases and over 250,000 deaths occur each year from pertussis, most in developing countries. *B. pertussis* is endemic worldwide and pertussis remains a problem, even in developed countries, usually due to inadequate immunization.

(a) Gram-stained cells of *Bordetella pertussis*, the cause of whooping cough

In the United States there has been a gradual upward trend of pertussis since the 1980s, with spikes in reported cases in 2005, 2010, and 2012 (Figure 29.14b); many of these have been in young adults under age 20. In the United States, pertussis causes fewer than 20 deaths per year. But pertussis is a classic endemic disease; incidence rises cyclically as populations become susceptible and are exposed to the pathogen. A combination of lax vaccination protocols and the fact that pertussis is a much more common disease than diphtheria have probably fueled the overall higher incidence of pertussis in recent years.

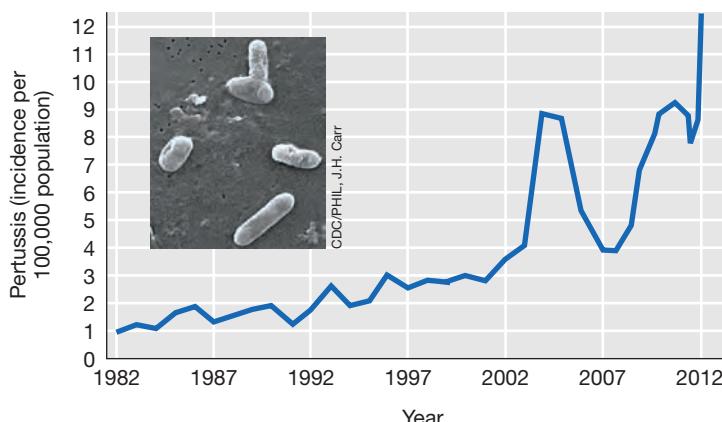

Whooping cough can be treated with ampicillin, tetracycline, or erythromycin, although antibiotics alone do not seem to effect a complete cure, as patients continue to show symptoms and remain infectious for up to 2 weeks after beginning antibiotic therapy. This indicates that the immune response may be as important as antibiotics in ridding the pathogen from the body.

29.4 Tuberculosis and Leprosy

The famous pioneering microbiologist Robert Koch, the founder of the field of medical microbiology, isolated and described the causative agent of tuberculosis, *Mycobacterium tuberculosis*, in 1882 (Section 1.8). A related species, *Mycobacterium leprae*, causes leprosy (Hansen's disease). Mycobacteria are gram-positive bacteria and share the property of being *acid-fast* due to the waxy mycolic acid constituent of their cell walls (Section 15.11). Mycolic acid allows these organisms to retain the red dye carbol-fuchsin after washing a mycobacterial smear on a slide in 3% hydrochloric acid in alcohol. Colonies of *M. tuberculosis* grow slowly on plates and have a characteristically wrinkled morphology (Figure 29.15).

(b) Colonies of *Mycobacterium tuberculosis*. The rough wrinkled surface is typical of mycobacterial colonies.

Tuberculosis

Tuberculosis (TB) is easily transmitted by the respiratory route, and at one time it was the most important infectious disease of humans. Worldwide, TB still accounts for nearly 1.5 million deaths per year. About one-third of the world's population has been infected with *M. tuberculosis*, though most do not show active disease because cell-mediated immunity (Sections 24.3, 24.8, and 25.1) plays a critical role in the prevention of active disease after infection.

Tuberculosis can take several forms. TB can be a *primary* infection (initial infection) or *postprimary* infection (reinfection). Primary infection typically results from inhalation of droplets containing *M. tuberculosis*, after which the bacteria settle in the lungs and grow. The host mounts an immune response to *M. tuberculosis*, resulting in the formation of aggregates of activated macrophages, called *tubercles*. Bacteria are found in the sputum of individuals with active disease, and areas of destroyed tissue can be seen in chest X-rays (Figure 29.16). Mycobacteria survive and grow within macrophages in the tubercles, forming granulomas, and if the disease is not controlled, extensive destruction of lung tissue can occur. If the disease reaches this stage, the pulmonary infection is often fatal.

In most individuals infected with *M. tuberculosis*, however, acute disease does not occur; instead, the infection is inapparent. Nevertheless, the infection hypersensitizes the individual to *M. tuberculosis* or its products and typically protects the individual against postprimary infections. A diagnostic skin test, called the **tuberculin test**, can detect this hypersensitivity (Figure 24.6), and many healthy adults are *tuberculin-positive* as a result of previous or current inapparent infections. In most cases, the cell-mediated immune response to *M. tuberculosis* is protective and lifelong. However, some tuberculin-positive patients develop postprimary tuberculosis through reinfection from bacteria that have remained dormant in lung macrophages for years. Because

of this, individuals who have a positive tuberculin test are typically treated with anti-tuberculosis drugs for extended periods to ensure that all mycobacteria have been killed.

Antimicrobial therapy of TB has been a major means of controlling the disease. Streptomycin was the first effective anti-tuberculosis antibiotic, but the real revolution in tuberculosis treatment came with the discovery of isonicotinic acid hydrazide, called *isoniazid* (INH) (Figure 29.17). This drug is highly effective and readily absorbed when given orally. Isoniazid is a growth factor analog (Section 27.11) of the structurally related molecule nicotinamide; in mycobacteria the drug inhibits mycolic acid synthesis and this compromises cell wall integrity. Following treatment with isoniazid, mycobacteria lose their acid-fast properties, in keeping with the role of mycolic acid in this staining property.

Treatment of tuberculin-positive individuals is typically achieved with daily doses of isoniazid and the antibiotic rifampin for 2 months, followed by biweekly doses for a total of 9 months. This treatment eradicates pockets of *M. tuberculosis* cells and prevents emergence of antibiotic-resistant derivatives. Multiple drug therapy reduces the possibility that strains having resistance to more than one drug will emerge. Resistance of *M. tuberculosis* to isoniazid and other drugs, however, is increasing, especially in HIV/AIDS patients, in whom TB is a common infection (see Figure 29.45g). Treatment of these strains, called *multi-drug-resistant tuberculosis strains*, requires the use of second-line tuberculosis drugs that are generally more toxic, less effective, and more costly than rifampin and isoniazid.

Leprosy

Mycobacterium leprae, a relative of *M. tuberculosis*, causes the disease *leprosy*, more formally known as *Hansen's disease*. The most serious form of Hansen's disease is *lepromatous leprosy*, characterized by folded, bulblike lesions on the body, especially on cooler parts of the body such as the face and extremities (Figure 29.18). The lesions are due to the growth of *M. leprae* cells in the skin and contain large numbers of bacterial cells. Like cells of other mycobacteria (Figure 29.15a), cells of *M. leprae* from the lesions stain deep red with carbol-fuchsin in the acid-fast staining procedure, providing a definitive demonstration of active infection.

In severe untreated cases of leprosy, the disfiguring lesions lead to destruction of peripheral nerves; muscles then atrophy and motor function is impaired. The loss of sensation in the extremities leads to inapparent injuries, such as burns and cuts. Loss of

bone calcium leads to a slow shrinking of the digits and their transition to clawlike forms in late-stage leprosy. Pathogenicity in the disease is due to a combination of delayed-type hypersensitivity (Section 24.8) and the highly invasive activities of *M. leprae*, which can grow within macrophages and lead to the characteristic lesions (Figure 29.18). Leprosy is transmitted by direct contact as well as by an airborne route, but is not as highly contagious as TB. Historically, leprosy has been associated with poverty, malnutrition, and poor sanitation and hygiene. Among other things, these factors undoubtedly affect an individual's ability to resist infection.

Many Hansen's disease patients exhibit less-pronounced lesions from which *M. leprae* cells cannot be obtained; these individuals have the *tuberculoid* form of the disease. Tuberculoid leprosy is characterized by a vigorous immune response and a good prognosis for spontaneous recovery. Hansen's disease of either form, and the continuum of intermediate forms, is treated using a multiple drug therapy protocol, which includes some combination of extended therapy of up to 1 year with *dapsone* (4,4'-sulfonylbis-benzeneamine, an inhibitor of folic acid synthesis), *rifampin*, a bacterial RNA polymerase inhibitor, and *clofazimine*, a drug that targets bacterial respiration and ion transport.

Nearly 250,000 new cases of leprosy were reported in 2009, with most cases occurring in Africa, the Indian subcontinent, and Brazil. In the United States only about 200 cases occur per year, mainly in immigrants. Until recently, a leprosy diagnosis relied on the identification of *M. leprae* cells from lesions. However, a quick, inexpensive, and specific blood test is now available that should greatly assist in identifying early stage leprosy, the most treatable form.

In addition to *M. tuberculosis* and *M. leprae*, several other mycobacteria are human pathogens. These include in particular *M. bovis*, a close relative of *M. tuberculosis* and a common pathogen of dairy cattle. *M. bovis* can initiate classic symptoms of TB in humans; however, a combination of the pasteurization of milk

and the culling of infected cattle has greatly reduced the incidence of bovine-to-human transmission of this form of TB.

- Describe three common characteristics of pathogenic mycobacteria.

29.5 Meningitis and Meningococcemia

Meningitis is an inflammation of the meninges, the membranes that are the protective covering of the central nervous system, that is, the spinal cord and brain. Several different microorganisms, including certain viruses, bacteria, fungi, and protists, can cause meningitis. Here we focus on the severe bacterial form of the disease called *infectious meningitis*, caused by the bacterium *Neisseria meningitidis*.

Pathogen and Disease Syndromes

Neisseria meningitidis, often called the *meningococcus*, is a gram-negative and obligately aerobic coccus about 0.6–1.0 µm in diameter (Figure 29.19a); it is a relative of the bacterium that causes gonorrhea, *Neisseria gonorrhoeae*. The bacterium is transmitted to a new host, usually via the airborne route from an infected individual, and attaches to the cells of the nasopharynx. Once there, the organism quickly gains access to the bloodstream, causing widespread dissemination (bacteremia) and upper respiratory tract symptoms. Meningitis is characterized by the sudden onset of a headache accompanied by vomiting and a stiff neck, and can progress to coma and death in less than a day. Instead of or in addition to full-blown meningitis, *N. meningitidis* bacteremia sometimes leads to fulminant **meningococcemia**, a condition characterized by intravascular coagulation and tissue destruction (gangrene, Figure 29.19b), shock, and death in over 10% of cases.

Meningococcal meningitis often occurs in epidemics, usually in populations living in close proximity such as in military barracks or college dormitories. Anyone can get meningococcal disease, but the incidence is much higher in infants, school-age children, and young adults. Up to 30% of people carry *N. meningitidis* in their nasopharynx with no apparent harmful effects, and the trigger for conversion from the asymptomatic carrier state to the disease state is unknown.

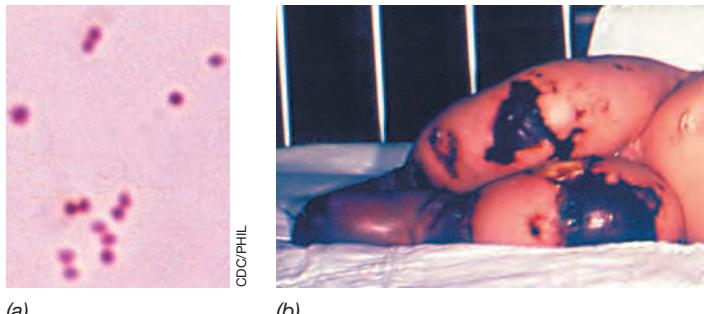

Figure 29.19 *Neisseria meningitidis*. The organism causes meningitis and meningococcemia. (a) Gram stain of cells of *N. meningitidis*; cocci are about 0.6–1.0 µm in diameter. (b) Four-month old infant with gangrene on legs from meningococcemia.

Diagnosis, Treatment, and Vaccines

Meningococcal meningitis is definitively diagnosed from cultures of *N. meningitidis* isolated from nasopharyngeal swabs, blood, or cerebrospinal fluid. Thayer–Martin medium (► Figure 27.5), a selective medium for the growth of pathogenic *Neisseria*, including both *N. meningitidis* and *N. gonorrhoeae*, is used to isolate *N. meningitidis*, and colonies containing gram-negative diplococci (Figure 29.19a) are further tested. However, due to the rapid onset of life-threatening symptoms in infectious meningitis, preliminary diagnosis is often based on clinical symptoms and treatment is started before culture tests confirm infection with *N. meningitidis*. Treatment is typically with penicillin, and intravenous application is often needed to speed antibiotic infusion.

Naturally occurring antibodies acquired by subclinical infections with *N. meningitidis* are effective for preventing infectious meningitis in most adults. Vaccines consisting of purified polysaccharides or polysaccharides from the most prevalent pathogenic strains are available to immunize certain susceptible populations such as military recruits and students living in dormitories, especially if an outbreak has already occurred. In addition, the antibiotic rifampin is often used to eradicate the carrier state and prevent meningococcal disease in close contacts of infected individuals.

II • Airborne Viral Diseases

29.6 Viruses and Respiratory Infections

The most prevalent and difficult to treat of all human infectious diseases are those caused by viruses. This is because viruses can often remain infectious for long periods in dried mucus (Figure 29.1) or on fomites, and because viruses require host cells for replication. Hence, killing the virus often means killing the cell as well.

Most viral diseases are acute, self-limiting infections, but some can be problematic in healthy adults. We begin with measles, rubella, mumps, and chicken pox, all common, endemic viral diseases transmitted in infectious droplets by an airborne route.

Measles and Rubella

Measles (*rubeola* or *7-day measles*) affects susceptible children as an acute, highly infectious, often epidemic disease. The measles

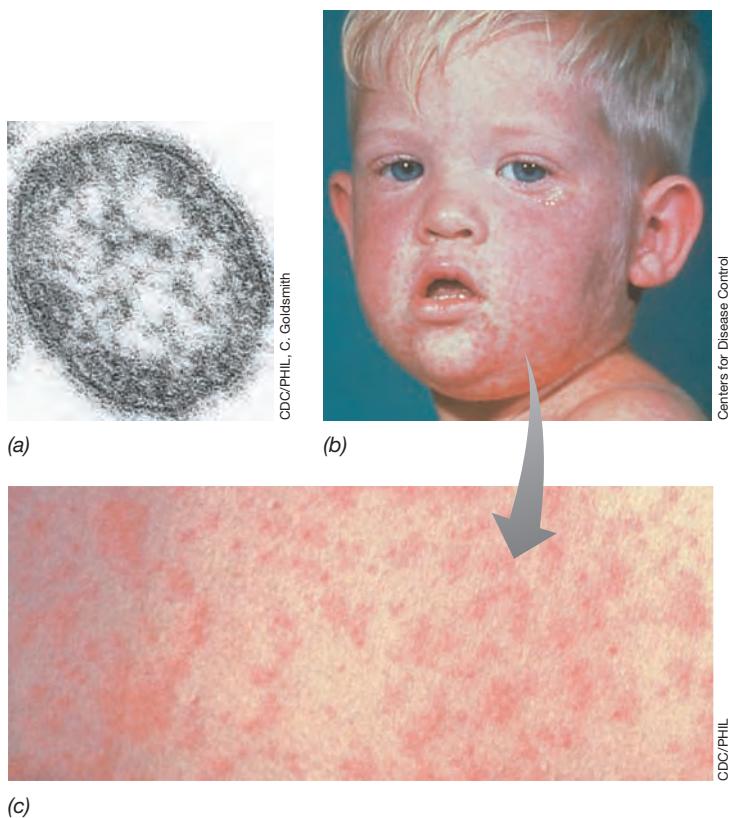

Figure 29.20 Measles in children. (a) Transmission electron micrograph of a measles virus virion; a virion is about 150 nm in diameter. (b, c) Measles rash. The light pink rash starts on the head and neck, and can spread to the chest, trunk, and limbs. Discrete papules coalesce into blotches as the rash progresses for several days.

virus (Figure 29.20a) is a *paramyxovirus*, a single-stranded, minus-sense RNA virus (Section 9.9) that enters the nose and throat by airborne transmission, quickly leading to a systemic viremia. Symptoms start with nasal discharge and redness of the eyes. As the disease progresses, fever and cough appear and rapidly intensify, followed by a characteristic rash (Figure 29.20b, c).

Symptoms of measles generally persist for 7–10 days, and no drugs are available that will eliminate symptoms. However, the measles virus generates a strong immune response. Circulating antibodies to measles virus are measurable within 5 days of infection; these serum antibodies along with T-cytotoxic lymphocytes combine to eliminate the virus from the host. Possible postinfection complications include middle ear infection, pneumonia, and, in rare cases, measles encephalomyelitis.

Although once a common childhood illness, measles is limited to rare isolated outbreaks in the United States because of widespread immunization programs begun in the 1960s. Those outbreaks that have occurred have been in populations that were either not immunized or inadequately immunized. Worldwide, measles remains endemic, however, and still causes over 400,000 annual deaths, mostly in children. Active immunity to measles is conferred with an attenuated virus preparation as part of the MMR (measles, mumps, rubella) vaccine (Figure 24.15). Because the disease is highly infectious, all public school systems in the United States require proof of measles immunization

before a child can enroll. A childhood case of measles generally confers lifelong immunity.

Rubella (sometimes called *German measles* or *3-day measles*) is caused by a single-stranded, positive-sense RNA virus (Section 9.8). Symptoms of rubella resemble those of measles (Figure 29.21) but are often restricted to just the upper torso. Rubella is less contagious than measles, and thus a significant proportion of the population has never been infected. However, during the first three months of pregnancy, rubella virus can infect the fetus by placental transmission and cause serious fetal abnormalities including stillbirth, deafness, heart and eye defects, and brain damage, events called *congenital rubella syndrome*. Thus, women should not be immunized with the rubella vaccine or contract a rubella infection during pregnancy. Also for this reason, routine childhood immunization against rubella should be practiced. An attenuated rubella virus is administered as part of the MMR vaccine. The low incidence of rubella since 2001, coupled with the high degree of protection by the vaccine and the relatively low infectivity of the virus, combine to make rubella very rare in the United States. An active rubella vaccination program worldwide is also decreasing case numbers significantly, as total reported active cases in 2009 were fewer than 125,000 and cases of congenital rubella syndrome were 165.

Mumps

Mumps, like measles, is caused by a paramyxovirus and is also highly infectious by the airborne route. Mumps is spread by airborne droplets, and the disease is characterized by inflammation of the salivary glands, typically the parotid gland, the largest of the salivary glands, leading to swelling of the jaws and neck (Figure 29.22). The virus spreads through the bloodstream and may infect other organs, including the testes and pancreas, and may cause encephalitis in rare severe cases. As for measles, the immune response rather than drug treatment is what cures a case of mumps. The host immune response produces antibodies to mumps virus surface proteins, and this generally leads to a quick recovery and lifelong immunity to reinfection.

An attenuated mumps vaccine (part of the MMR) is highly effective in preventing disease. Hence, the prevalence of mumps in developed countries is low, with disease generally restricted to individuals who did not receive the vaccine. However, an outbreak of mumps in the midwestern United States in 2006 involved more than 5000 cases, which is significantly up from the typical

number of fewer than 300 cases per year since 2001. The outbreak affected mainly young adults (18–34). As a result, recommendations for immunizations were revised to target school-age children, healthcare workers, and adults who had not previously had mumps.

Chicken Pox and Shingles

Chicken pox (*varicella*) is a common childhood disease caused by the varicella-zoster virus (VZV), a double-stranded DNA herpesvirus (🔗 Section 9.7). VZV is a mild but highly contagious disease and is transmitted by infectious droplets, especially when susceptible individuals are in close contact. In schoolchildren, for example, close confinement during the winter months leads to the spread of VZV through airborne droplets from infected classmates and through direct contact with chicken pox blisters of other children or contaminated fomites. The virus enters the respiratory tract, multiplies, and is quickly disseminated via the bloodstream, resulting in a systemic papular rash (Figure 29.23) that heals quickly without scarring. An attenuated chicken pox virus vaccine (Varivax) is used in the United States but not as

Figure 29.23 Chicken pox. Papular rash on the foot of an adult. The papules are due to infection by varicella-zoster virus, the herpesvirus that causes chicken pox.

widely as the MMR vaccine for measles, rubella, and mumps. Consequently, the reported annual incidence of chicken pox is about 40,000 cases per year, but this is only about 25% of the number of cases reported prior to 1995, the year the vaccine was first licensed.

VZV establishes a lifelong latent (permanent) infection in nerve cells. The virus can remain dormant there indefinitely, but in some individuals the virus migrates from this reservoir to the skin surface, often years or decades later, causing a painful skin eruption called *shingles* (*zoster*). Shingles most commonly strikes immunosuppressed individuals or the elderly, and often causes severe blisters and a rash on the head, neck, or upper torso. A fairly effective shingles vaccine containing concentrated attenuated virus (Zostavax) is available for individuals over 50 years of age. The vaccine stimulates antibody and cell-mediated immunity to VZV, keeping VZV from migrating out of nerve ganglia to skin cells and triggering shingles.

29.7 Colds

Colds are the most common of infectious diseases. Colds are typically upper respiratory tract viral infections that are transmitted via droplets spread from coughs, sneezes, and respiratory secretions. Colds are usually of short duration, lasting a week or so, and the symptoms are milder than other respiratory diseases such as influenza. Table 29.1 contrasts the usually distinct symptoms and incidence of colds and influenza.

Cold symptoms include *rhinitis* (inflammation of the nasal region, especially the mucous membranes), nasal obstruction, watery nasal discharges, muscle aches, and a general feeling of malaise, usually without fever. *Rhinoviruses* are single-stranded

plus-sense RNA viruses of the picornavirus group (Figure 29.24a) and are the most common causes of colds. Over 100 different rhinoviruses have been identified. About one-quarter of all colds are due to infections with other viruses. These include in particular the *coronaviruses* (Figure 29.24b). Adenoviruses, coxsackie viruses, respiratory syncytial viruses (RSV), and orthomyxoviruses are collectively responsible for only a small percentage of common colds.

Aerosol transmission is a major means of spreading colds, although experiments with volunteers suggest that direct contact and indirect contact involving fomites are also important means of transmission, perhaps even more important than aerosols. Incidence of the common cold rises when people are indoors in the winter months, although it is possible to “catch a cold” at any time of year. Most antiviral drugs are ineffective against common cold viruses, although some have shown promise for preventing the onset of symptoms following rhinovirus exposure. Moreover, new antiviral drugs are being designed based on knowledge of the three-dimensional structure of cold viruses. For example, antirhinovirus drugs that bind to the virus and change its surface properties in such a way as to prevent it from attaching to host cells have been developed. But thus far, most “cold drugs” on the market simply help to reduce the severity of symptoms—the cough, nasal discharges, headache, and the like.

Because colds are generally self-limiting and not serious diseases, treatment is aimed at controlling symptoms, especially nasal discharges, with antihistamine and decongestant drugs. Cold viruses also induce an antibody-mediated immune response. However, the number of immunologically unique strains of each type of cold virus makes immunity to the common cold from previous exposure unlikely. Thus, the common cold is a recurrent

event, with the severity of symptoms a function of both the type of cold virus involved and the overall health and well-being of the person at the time of infection.

29.8 Influenza

Influenza is a highly infectious airborne disease of viral origin. Influenza viruses contain a single-stranded, negative-sense, segmented RNA genome surrounded by an envelope composed of protein, a lipid bilayer, and external glycoproteins (Figure 29.25) (Section 9.9). There are three classes of influenza viruses: influenza A, B, and C. Here we consider only influenza A because it is the most important human pathogen.

Antigenic Drift and Antigenic Shift

Each strain of influenza A virus can be identified by a unique set of surface glycoproteins. These glycoproteins are *hemagglutinin* (HA or H antigen) and *neuraminidase* (NA or N antigen). Each virus has one type of HA and one type of NA on its viral capsid. The HA antigen is important in *attaching* the influenza virus to host cells while the NA antigen is instrumental in *releasing* the virus from host cells; each antigen is composed of several individual proteins (Figure 29.26).

Infection or immunization with influenza virus results in the production of antibodies that react with the HA and NA glycoproteins. When these antibodies bind to HA or NA, the virus is blocked from either attaching or releasing and is effectively neutralized, stopping the infection process. However, over time,

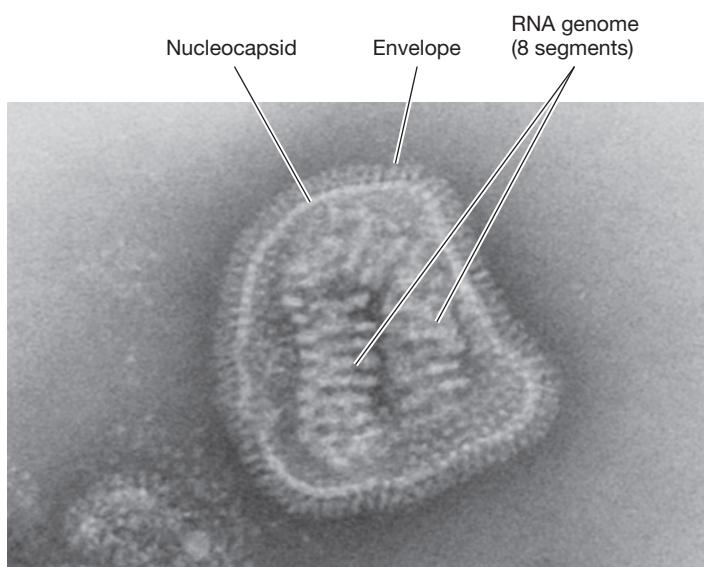

Figure 29.25 Influenza A virus. The virus contains a single-stranded negative-sense RNA genome in eight segments; a virion is about 100 nm in diameter. Major factors in the success of influenza virus as a pathogen are antigenic drift and antigenic shift (see Figure 29.27).

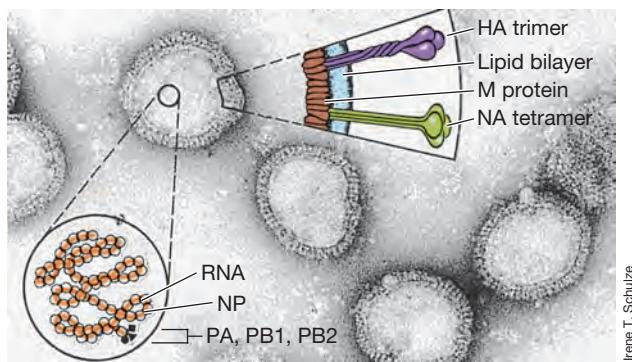

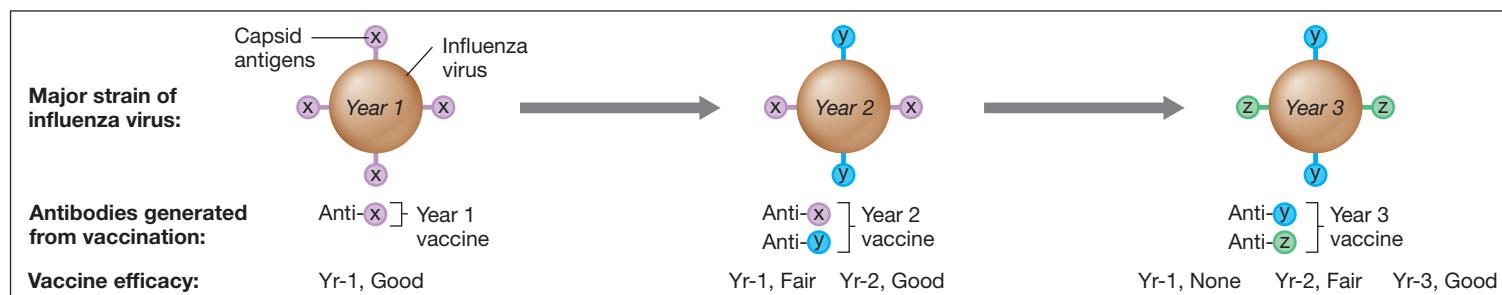

Figure 29.26 Influenza virus structure. Major viral coat proteins are: HA, hemagglutinin (three copies make up the HA coat spike); NA, neuraminidase (four copies make up the NA coat spike); M, coat protein; NP, nucleoprotein; PA, PB1, PB2, and other internal proteins, some of which have enzymatic functions.

the viral genes encoding the HA and NA glycoprotein antigens mutate, rendering minor changes to their amino acid sequence and hence antigenic structure. Mutations that alter as few as one amino acid in the glycoprotein can affect how an antibody binds to these antigens. This slight variation in the structure of influenza viral surface antigens is at the heart of a phenomenon

in influenza biology called **antigenic drift**. As a result of these subtle yet important changes, host immunity to a given virus strain diminishes as the strain mutates, and reinfection with the mutated strain can occur. This phenomenon is why last year's influenza vaccine may work only poorly against this year's crop of influenza viruses (Figure 29.27a).

In addition to antigenic drift, there is a second feature of influenza virus biology that aids virulence. The single-stranded RNA genome of influenza viruses is *segmented*, with genes found on each of eight distinct segments (Figure 9.19b). During virus maturation in the host cell, the viral RNA segments are packaged randomly. To be infective, a virus must be packaged so it contains one copy of each of the eight gene segments. Occasionally, however, more than one strain of influenza virus infects a single animal at one time. In such cases, if the two strains infect the same cell, both viral genomes are replicated; when genome packaging occurs, the segments from the two strains may intermix. The result is a genetically unique virus that is now a *new virus strain*. This mixing of gene fragments between different strains of influenza virus is called **reassortment**.

Unique reassortant viruses trigger the phenomenon known as **antigenic shift** (Figure 29.27b), a major change in a surface antigen resulting from the total replacement of the RNA that encoded it.

(a) Antigenic drift

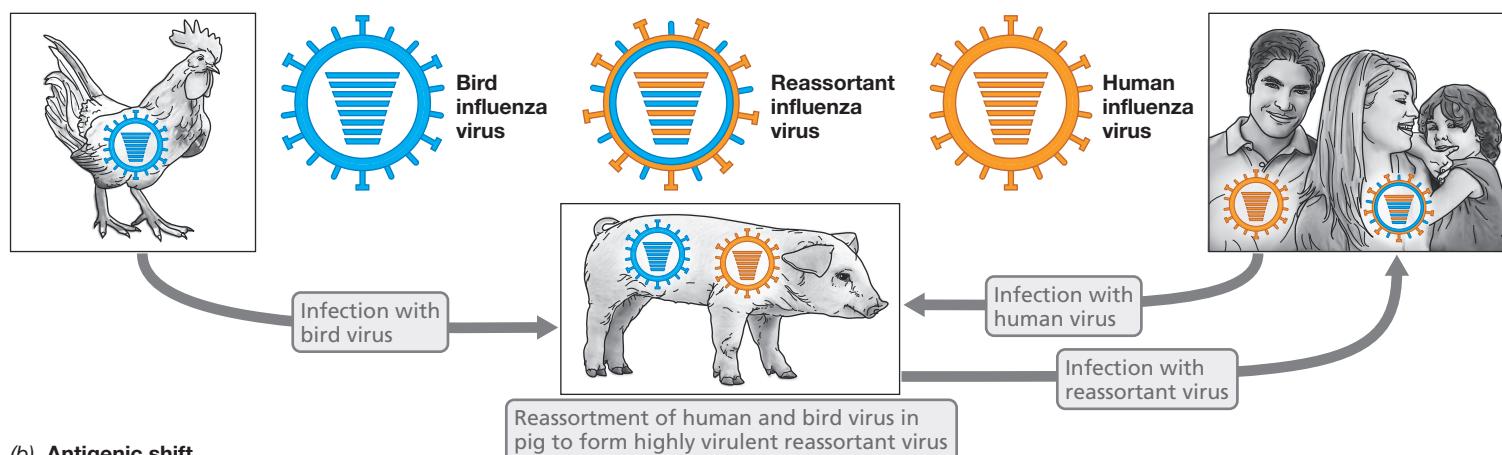

Figure 29.27 Antigenic drift and antigenic shift in influenza virus biology. (a) Antigenic drift. A new vaccine is prepared each year against the major strain of influenza circulating among the population. However, vaccine efficacy wanes with time as immunologically new surface antigens appear from mutations in genes encoding viral surface proteins. (b) Antigenic shift. Influenza strains that originate in birds and humans can also infect swine. If a pig becomes infected with both bird and human viruses simultaneously, the viral genomes can be mixed, forming reassortant viruses. If such viruses, which now contain several unique antigens, infect humans, influenza pandemics can be triggered (see page 853).

Antigenic shift can immediately and completely change one or both of the major HA and NA viral glycoproteins in a major way. As a result, reassortant viruses are essentially unrecognized by immune responses to previous influenza infections. Reassortant viruses also frequently display one or more unique virulence properties that help to trigger unusually strong clinical symptoms and are the usual catalysts of influenza *pandemics*, which we consider shortly.

Symptoms and Treatment of Influenza

Human influenza virus is transmitted from person to person through the air, primarily in droplets expelled during coughing and sneezing (Figure 29.1). The virus infects the mucous membranes of the upper respiratory tract and occasionally invades the lungs. Symptoms include a low-grade fever lasting up to a week, chills, fatigue, head and muscle aches, a cough and/or a sore throat, and general malaise (Table 29.1). Most of the serious consequences of seasonal influenza occur not from the disease itself but from bacterial secondary infections, especially in persons whose resistance has been lowered by the influenza infection. For example, in infants and the elderly, influenza can be followed by bacterial pneumonia (Section 29.2), sometimes in fatal form.

Most individuals develop protective immunity to the infecting strain of influenza virus, making it impossible for that strain or a very closely related strain to cause widespread infection (epidemic) until the virus encounters another susceptible population. Immunity occurs from both antibody- and cell-mediated immune responses directed at HA and NA glycoproteins. Influenza epidemics can be controlled by immunization. Developing an effective vaccine, however, is complicated by the large number of existing influenza viral strains resulting from antigenic drift and antigenic shift (Figure 29.27). Through careful worldwide surveillance, samples of the major emerging strains of influenza virus are obtained each year before the onset of seasonal epidemics and used to prepare that year's vaccine.

In most years, this approach confers adequate protective immunity.

Most human influenza viruses respond to anti-viral drugs. The adamantanes—*amantadine* and *rimantadine*—are synthetic amines that inhibit viral replication, and the neuraminidase inhibitors *oseltamivir* (Tamiflu) and *zanamivir* (Relenza) (Table 27.6) block release of newly replicated human influenza virions. These drugs are often used early on to shorten the course and severity of infection, especially in immune-compromised people or the elderly.

Influenza Pandemics

Influenza pandemics—worldwide epidemics—are much less frequent than outbreaks and epidemics, occurring from 10 to 40 years apart (Table 29.2). Flu pandemics result from antigenic shift, and virtually all have been due to avian and human influenza viruses reassorting in swine (Figure 29.27b) since swine can propagate both avian and human influenza viruses. This results in a highly virulent

Table 29.2 Influenza pandemics

influenza strain for which there is no preexisting immunity in humans.

The “Spanish flu” pandemic of 1918 was the most catastrophic in recorded history, killing somewhere between 20 and 50 million people worldwide, 2 million in the United States. The extreme virulence of the 1918 H1N1 virus is thought to have triggered host production and release of unusually large amounts of inflammatory substances, resulting in systemic inflammation and more severe symptoms than those typical of yearly flu epidemics. The 1957 Asian flu was also a memorable pandemic (Figure 29.28), beginning in China and spreading to the United States and shortly thereafter to Europe and South America. In this case, the pandemic influenza strain was a highly virulent H2N2 virus, differing antigenically from all previous strains. Immunity to this strain was thus absent, allowing the virus to spread rapidly throughout the world, killing nearly 2 million people. However, early detection of the Asian flu virus and more sophisticated vaccine manufacturing capabilities kept this influenza pandemic under better control than the 1918 pandemic where an effective vaccine was unavailable.

Pandemic influenza A (H1N1) 2009 virus, nicknamed the “swine flu,” spread much more rapidly in 2009 than even the 1957

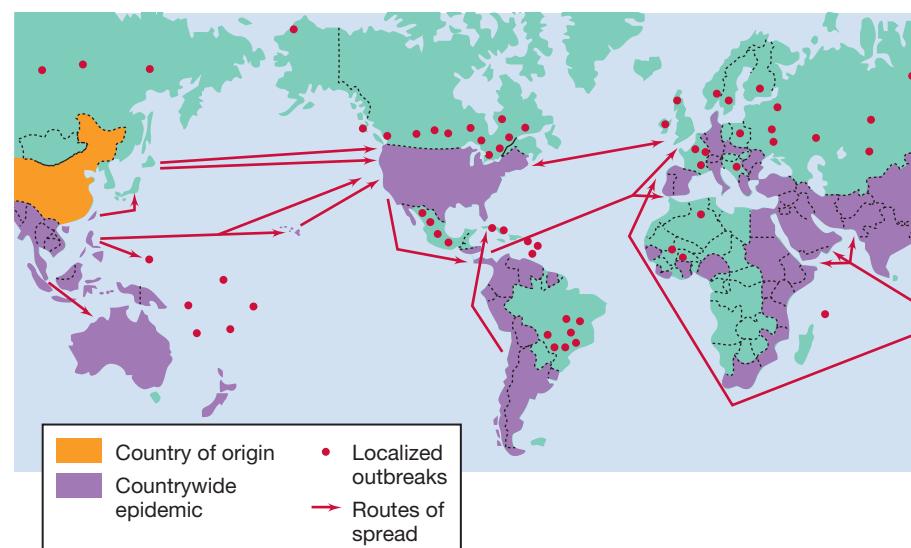

Figure 29.28 An influenza pandemic. Map of the Asian influenza pandemic of 1957. Lax agricultural practices with poultry and swine coupled with human interactions with these animals allowed the reassortment of influenza viral genomes from the three host species, producing a new strain for which there was no immune memory in humans. (see Figure 29.27b and page 853).

Asian flu, starting in Mexico and spreading quickly to the United States, Europe, and Central and South America. H1N1 was a classic case of influenza virus genome reassortment in swine (Figure 29.27b), and from the swine reservoir, a highly virulent virus emerged to infect humans. Although the H1N1 virus spread quickly, the overall mortality rate was much lower than in the Spanish H1N1 pandemic, an estimated 0.1–0.2%, which is only slightly higher than seasonal influenza mortality.

Influenza A H5N1, nicknamed the “bird flu,” appeared in Hong Kong in 1997, jumping directly from its avian host to humans without a reassortment step. H5N1 has now been detected in birds throughout Asia, Europe, the Middle East, and North Africa. Effective human-to-human spread of H5N1 apparently only occurs following prolonged close contact, and so this strain has not yet triggered a pandemic. However, if this virus were to

infect swine and yield an easily transmissible reassortant virus that subsequently jumps to humans (Figure 29.27b), such a virus could initiate a major new influenza pandemic. Health organizations worldwide have recognized this potential and have plans in place to provide appropriate vaccines and support for potential pandemics initiated by this and other emergent influenza viruses (see this chapter’s opening page).

III • Direct-Contact Diseases

Some pathogens are spread primarily by direct contact with an infected person or by direct contact with blood or excretions from an infected person. Many of the respiratory diseases we have just discussed can also be spread by direct contact, but here we consider diseases spread primarily through direct contact with infected individuals rather than by an airborne route. These include staphylococcal infections, ulcers, and certain types of hepatitis.

29.9 *Staphylococcus aureus* Infections

The genus *Staphylococcus* contains pathogens of humans and other animals. Staphylococci commonly infect skin and wounds and may also cause pneumonia. Most staphylococcal infections result from the transfer of staphylococci in the normal flora of an infected, asymptomatic individual, to a susceptible individual. Others result from toxemia following the ingestion of contaminated food (“staph food poisoning,” ↗ Section 31.8).

Staphylococci are nonsporulating, gram-positive cocci about 0.5–1.5 µm in diameter that divide in multiple planes to form irregular clumps of cells (Figure 29.29). They are resistant to drying and tolerate high concentrations of salt (up to 10% NaCl) when grown on artificial media. Staphylococci are readily dispersed in dust particles through the air and on surfaces. In humans, two species are important: *Staphylococcus epidermidis*, a nonpigmented species usually found on the skin or mucous membranes, and *Staphylococcus aureus*, a yellow-pigmented species (see Figure 29.31). Both species are potential pathogens, but *S. aureus* is more commonly associated with human disease. Both species are frequently present in the normal microbial flora of the upper respiratory tract and the skin (Figure 29.2 and see Figure 29.31b), making many people potential carriers.

Epidemiology and Pathogenesis

Staphylococcal diseases include acne, boils, pimples, impetigo, pneumonia, osteomyelitis, carditis, meningitis, and arthritis. Many of these diseases are *pyogenic* (pus-forming) (Figure 29.30a). Those strains of *S. aureus* that cause human disease produce a

variety of virulence factors (↗ Table 23.5). At least four different *hemolysins* (proteins that lyse red blood cells, see Figure 29.8) have been recognized, and a single strain often produces several. A key

Staphylococci initiate a localized skin infection and become walled off by coagulated blood and fibrin through the activity of the enzyme coagulase, a major virulence factor. The ruptured boil releases pus, consisting of dead host cells and bacteria. See also Figure 29.30.

(b)

(b) Abscess on the hand caused by a methicillin-resistant strain of *Staphylococcus aureus* (MRSA strain). If no treatment for a pus-forming wound is sought or if penicillin is administered first, MRSA infections can cause extensive tissue destruction, as shown here.

virulence factor produced by *S. aureus* is *coagulase*, an enzyme that converts fibrin to fibrinogen, forming a localized clot. Clotting induced by coagulase results in the accumulation of fibrin around the bacterial cells, making it difficult for host immune cells to contact the bacteria and initiate phagocytosis. Most *S. aureus* strains also produce *leukocidin*, a protein that destroys white blood cells. Production of leukocidin in skin lesions such as boils and pimples results in host cell destruction and is one of the factors responsible for pus (Figure 29.30). Some strains of *S. aureus* also produce other virulence proteins including *hyaluronidase*, *fibrinolysin*, *lipase*, *ribonuclease*, and *deoxyribonuclease*.

Certain strains of *S. aureus* cause **toxic shock syndrome (TSS)**, a serious outcome of staphylococcal infection, characterized by high fever, rash, vomiting, diarrhea, and death. TSS was first recognized in women and was associated with the use of highly absorbent tampons. However, TSS is now seen in both men and women and is typically initiated by staphylococcal infections following surgery. The symptoms of TSS result from an exotoxin called *toxic shock syndrome toxin-1*. This very potent toxin is a superantigen (Section 24.9) that is released during cell growth and recruits large numbers of T cells to the site of infection. These

then cause a major inflammatory response that is fatal in about 70% of cases. TSS can also be due to superantigens from other pathogens, including *Streptococcus pyogenes* (Section 29.2).

Diagnosis and Treatment

To diagnosis an *S. aureus* infection through laboratory culture, a specimen, typically from a pus-forming wound (Figure 29.30a), is cultured on a selective and differential medium containing 7.5% NaCl, mannitol, and phenol red, a pH indicator (mannitol-salt agar, Figure 29.31). The salt inhibits the growth of nonhalophilic bacteria while allowing staphylococci to grow. In addition, because *S. aureus* ferments mannitol, it generates acidity and changes the medium from red to yellow; other staphylococci, such as *S. epidermidis*, do not (Figure 29.31).

In major clinical laboratories, the polymerase chain reaction (PCR) is used to amplify genes unique to *S. aureus* from DNA isolated from a clinical sample, and this speeds up the diagnosis (results from laboratory culture take 24 h). For specific identification of methicillin-resistant strains of *S. aureus* (MRSA), a special selective and differential medium is available as well as a PCR protocol to identify *mecA*, the gene that encodes methicillin resistance in MRSA strains.

Historically, *S. aureus* infections have been treated with various penicillin and cephalosporin antibiotics. However, extensive use of these antibiotics for many years has selected for resistant strains that now predominate, especially in the clinical environment. Surgical patients, for example, may acquire staphylococci from healthcare personnel who are asymptomatic carriers of drug-resistant strains. As a result, appropriate antimicrobial drug therapy for *S. aureus* infections is a major problem in healthcare environments. The antibiotics clindamycin and various tetracycline drugs are currently used to treat MRSA infections.

MRSA infections (Figure 29.30b) are becoming more common. Over 100,000 cases of MRSA are reported each year in the United States, but actual infections are probably closer to ten times this number. Many of these cases are hospital-acquired (nosocomial) MRSA, but many others are not. Because of the potential severity of MRSA infections, it is important to rapidly identify these

strains in clinical specimens so that an effective treatment is begun as soon as possible. Delayed treatment of a MRSA infection, whether due to hesitation to seek treatment or treatment with an ineffective antibiotic, can lead to extensive tissue damage (Figure 29.30b).

Prevention of staphylococcal infections is virtually impossible because many people are asymptomatic carriers of *S. aureus*, either on their skin or upper respiratory tract (Figure 29.31b). However, identification and treatment or isolation of MRSA-carrying healthcare providers who serve in surgical or nursery units has helped limit transmission of these very aggressive strains. As is true of many direct-contact diseases, MRSA transmission can also be greatly diminished by practicing good basic hygiene, avoiding contact with the personal items (including clothing and towels) of others, and keeping wounds covered.

29.10 *Helicobacter pylori* and Gastric Ulcers

Helicobacter pylori is a gram-negative, highly motile, spiral-shaped bacterium (Figure 29.32) associated with gastritis, ulcers, and gastric cancers. This bacterium colonizes the non-acid-secreting mucosa of the stomach and the upper intestinal tract. Up to 80% of gastric ulcer patients have concomitant *H. pylori* infections, and up to 50% of asymptomatic adults in developing countries are chronically infected. Although there is no known nonhuman reservoir of *H. pylori*, infection occurs in high incidence within families, suggesting person-to-person transmission.

Figure 29.32 *Helicobacter pylori*. Colorized scanning electron micrograph of cells attached to the mucous lining of the stomach. Cells range in size from 3 to 5 μm in length and are about 0.5 μm in diameter. Note the flagella.

H. pylori infections also occasionally occur in clusters, suggesting that transmission from common sources such as food or water is also possible.

H. pylori is only slightly invasive and colonizes the surfaces of the gastric mucosa, where it is protected from the effects of stomach acids by the gastric mucus layer. After mucosal colonization, a combination of virulence factors and host responses cause inflammation, tissue destruction, and ulceration. Pathogen products such as the cytotoxin VacA (an exotoxin), urease, and an autoimmune response triggered by *H. pylori* lipopolysaccharide all contribute to localized tissue destruction and ulceration. Individuals who acquire *H. pylori* tend to have chronic infections unless they are treated with antibiotics. Treatment is both simple and important, as chronic inflammation of the gastroduodenum (gastritis) due to untreated *H. pylori* infection may lead to the development of gastric cancers.

Clinical signs of *H. pylori* infection include belching and stomach (epigastric) pain. Definitive diagnosis requires the isolation or observation of *H. pylori* from a gastric ulcer biopsy. A simple diagnostic test for the *H. pylori* enzyme urease is used for a noninvasive diagnosis. In this test, a small amount of ^{13}C - or ^{14}C -labeled urea ($\text{H}_2\text{N}-\text{CO}-\text{NH}_2$) is ingested; if *H. pylori* is present, the bacterium will hydrolyze the urea, forming labeled CO_2 and ammonia. Hence, the presence of labeled CO_2 in the patient's breath is highly suggestive of *H. pylori* infection.

The best evidence for a causal association between *H. pylori* and gastric ulcers comes from antibiotic treatments for the disease. Long-term treatment with antacids helps alleviate gastric ulcer symptoms temporarily, but most patients relapse within 1 year. However, by treating the *cause* rather than the *effect* of the disease, actual cures can be obtained. *H. pylori* infection is typically treated with a combination of drugs, including the antibacterial compound metronidazole, an antibiotic such as tetracycline or amoxicillin, and a bismuth-containing antacid preparation. The combination treatment, administered for 14 days, abolishes the *H. pylori* infection and provides a long-term cure.

For their contributions to unraveling the connection between *H. pylori* and peptic and duodenal ulcers, the Australian scientists Robin Warren and Barry Marshall were awarded the 2005 Nobel Prize in Physiology or Medicine.

29.11 Hepatitis Viruses

Hepatitis is a liver inflammation commonly caused by an infectious agent. Hepatitis sometimes results in acute illness followed by destruction of functional liver anatomy and cells, a condition known as **cirrhosis**. Hepatitis due to infection can cause chronic or acute disease, and some forms lead to liver cancer.

Although many viruses and a few bacteria can cause hepatitis, a restricted group of viruses is often associated with liver disease. Hepatitis viruses A, B, C, D, and E are phylogenetically diverse viruses

Table 29.3 Hepatitis viruses

Disease	Virus and genome	Vaccine	Clinical illness	Transmission route
Hepatitis A	<i>Hepadovirus (HAV)</i> ssRNA	Yes	Acute	Enteric (food)
Hepatitis B	<i>Orthohepadnavirus (HBV)</i> dsDNA	Yes	Acute, chronic, oncogenic	Parenteral, sexual
Hepatitis C	<i>Hepacivirus (HCV)</i> ssRNA	No	Chronic, oncogenic	Parenteral
Hepatitis D	<i>Deltavirus (HDV)</i> ssRNA	No	Fulminant, only with HBV	Parenteral

but share in common their ability to infect the liver (Table 29.3). Hepatitis A and E viruses, although occasionally transmitted person to person, are more commonly transmitted by food (hepatitis A virus) or water (hepatitis E virus). We cover hepatitis A viral disease in Chapter 31. Here our focus is on hepatitis viruses transmitted by direct contact.

The incidence of hepatitis A and B, the most common forms, has decreased significantly in the past 20 years because of effective vaccines (Figure 29.33) and increases in surveillance. By comparison to hepatitis A and B, hepatitis C infections are of very low incidence (Figure 29.33).

Epidemiology

Infection with *hepatitis B virus* (HBV) is often called *serum hepatitis* because it is transmitted in blood or body fluids in contact with blood. HBV is a hepadnavirus, a partially double-stranded DNA virus (Section 9.11). The mature virus particle containing the viral genome is called a *Dane particle* (Figure 29.34). HBV causes acute, often severe disease that can lead to liver failure and death. Chronic HBV infection can lead to cirrhosis and liver cancer.

HBV is transmitted by a *parenteral route*, which means “outside the gut.” The main means of HBV transmission is from blood transfusions, contact with infected blood in a hypodermic needle, and from mother to child during childbirth. HBV may also be transmitted through exchanges of body fluids during sex. The number of new HBV infections has remained low and more or less constant since the year 2000 (Figure 29.33). Nevertheless, over 100,000 people worldwide and nearly 5000 people in the

United States die yearly from liver failure or liver cancer caused by chronic HBV infection.

Hepatitis D virus (HDV) is a *defective virus* (Section 10.7) that lacks genes encoding its own capsid. HDV is also transmitted by parenteral routes, but because it is a defective virus, it cannot replicate and form an intact virion unless the cell is also infected with HBV. The HDV genome replicates independently but relies on HBV to produce capsid proteins (which are the same as those used by HBV) to form infectious virions. Thus, HDV infections are always coinfections with HBV.

Hepatitis C virus (HCV) is also transmitted parenterally. HCV generally produces a mild or even asymptomatic disease at first, but later on up to 85% of those infected develop chronic hepatitis, with up to 20% proceeding to chronic liver disease and cirrhosis. Chronic infection with HCV leads to hepatocarcinoma (liver cancer) in 3–5% of infected individuals. The latency period for development of cancer can be several decades after the primary infection. Only a fraction of the estimated 25,000 annual new infections with HCV are recognized and reported in the United States (Figure 29.33). Large numbers of HCV-related deaths occur annually due to chronic HCV infections that develop into liver cancer. HCV-induced liver disease accounts for up to 10,000 of the 25,000 annual deaths due to liver cancer, other chronic liver diseases, and cirrhosis.

Other Aspects of Hepatitis Syndromes

Hepatitis is an acute disease of the liver, a vital organ that plays a role in several key metabolic processes, including carbohydrate,

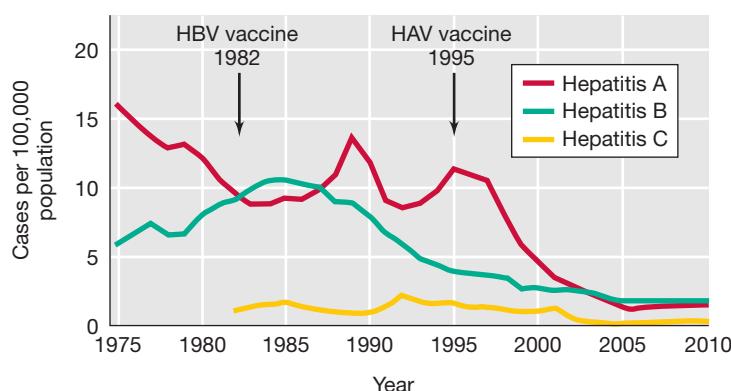

Figure 29.33 Hepatitis A, B, and C in the United States. In 2010 there were 1670 reported cases of hepatitis A, 3350 reported cases of hepatitis B, and 850 reported cases of hepatitis C. Data obtained from the CDC, Atlanta, Georgia, USA.

lipid, and protein syntheses, as well as detoxification and many other functions. Symptoms of hepatitis include fever, jaundice (yellowing of the skin and the whites of the eyes), and liver enlargement and cirrhosis. All hepatitis viruses cause similar acute symptoms and cannot be readily distinguished based on clinical findings alone. Chronic hepatitis infections, usually caused by HBV or HCV, are often asymptomatic or produce very mild symptoms, but nonetheless cause serious liver disease, even in the absence of liver cancer.

Diagnosis of hepatitis is based on a combination of clinical symptoms and laboratory tests that assess liver function, especially key liver enzymes. Cirrhosis is diagnosed by visual examination of biopsied liver tissue. Virus-specific molecular assays are typically used to confirm a diagnosis, positively identify the infectious agent, and determine a course of treatment; isolation and culture of hepatitis viruses is usually not attempted.

Many of the immunological and molecular diagnostic tools discussed in Chapter 27 are used in hepatitis diagnoses. These include enzyme immunoassays that target viral-specific proteins or anti-viral antibodies in a blood sample, immunoblots (Western blots), and immunofluorescence (microscopic) methods. Polymerase

chain reaction (PCR) tests are also used to detect hepatitis viral genomes in blood or in liver tissue obtained by biopsy.

Infection with HAV or HBV can be prevented with effective vaccines. HBV vaccination is recommended and in most cases is required for school-age children in the United States. No effective vaccines are available for the other hepatitis viruses. For those unvaccinated, the practice of *universal precautions* will prevent infection. The precautions prescribe a high level of vigilance and aseptic handling and containment procedures to deal with patients, body fluids, and infected waste materials (🔗 Section 27.1). Most treatment of hepatitis is supportive, providing rest and time for the immune system to attack the infection and allow liver damage to be repaired. In some cases, in particular for HBV infections, some antiviral drugs are available that offer effective treatment.

IV • Sexually Transmitted Infections

Sexually transmitted infections (STIs), also called *sexually transmitted diseases* (STDs), are caused by a wide variety of bacteria, viruses, protists, and even fungi (Table 29.4). Unlike respiratory pathogens that can be shed constantly in large numbers by an infected individual, sexually transmitted pathogens

are typically found only in body fluids from the genitourinary tract (and blood, in the case of HIV). Because they require a protected and moist environment, sexually transmitted pathogens preferentially and sometimes exclusively colonize the genitourinary tract.

^bRecommendations of the U.S. Department of Health and Human Services, Public Health Service.

Since the transmission of STIs is limited to sexual activity, their spread can be controlled by sexual abstinence and minimized by the use of condoms that stop the exchange of body fluids during sex. With the exception of HIV/AIDS, most STIs are curable and many can have only minor symptoms. These realities, combined with the fact that those infected are sometimes reluctant to seek treatment, make treatment of STIs an ongoing public health challenge. However, delaying or forgoing treatment of STIs only serves to maintain lines of transmission and can lead to long-term health problems such as infertility, cancer, heart disease, degenerative nerve disease, birth defects, stillbirth, or destruction of the immune system, any of which can result in death.

29.12 Gonorrhea and Syphilis

Gonorrhea and *syphilis* are ancient STIs, but because of major differences in their symptoms, the overall pattern of disease differs significantly between the two. In the United States, cases of gonorrhea peaked following the introduction of birth control pills in the mid-1960s, and gonorrhea is still quite prevalent today; cases of syphilis, on the other hand, have a much lower incidence (Figure 29.35). This is partly because syphilis exhibits very obvious symptoms in its primary stage and infected individuals usually seek immediate treatment.

Gonorrhea

Neisseria gonorrhoeae, often called the *gonococcus*, causes gonorrhea. *N. gonorrhoeae* is a gram-negative and obligately aerobic diplococcus related biochemically and phylogenetically to *Neisseria meningitidis* (Section 29.5). Cells of *N. gonorrhoeae* are killed rapidly by drying, sunlight, and ultraviolet radiation and thus normally do not survive away from the mucous membranes of the pharynx, conjunctiva, rectum, or genitourinary tract (Figure 29.36). Because of this, gonorrhea can only be transmitted by intimate person-to-person contact. We discussed the clinical microbiology and diagnosis of gonorrhea in Section 27.3.

The symptoms of gonorrhea are quite different in the male and female. In females, gonorrhea may be asymptomatic or cause a mild vaginitis that is difficult to distinguish from vaginal

infections caused by other organisms; hence, the infection may easily go unnoticed. Complications from untreated gonorrhea in females, however, can lead to a chronic condition called *pelvic inflammatory disease (PID)*, which can cause sterility. In men, *N. gonorrhoeae* causes a painful infection of the urethral canal and typical puslike urethral discharge. Complications from untreated gonorrhea affecting both males and females include damage to heart valves and joint tissues due to inflammatory reactions from immune complexes that deposit in these areas. In addition to disease in adults, *N. gonorrhoeae* can also cause eye infections in newborns. Infants born of infected mothers may acquire eye infections during birth. Therefore, prophylactic treatment of the eyes of all newborns with an ointment containing erythromycin is generally mandatory to prevent gonococcal infection in infants.

Treatment of gonorrhea with penicillin was the method of choice until the 1980s when strains of *N. gonorrhoeae* resistant to penicillin arose. The quinolones ciprofloxacin, ofloxacin, or levofloxacin were also used, but by 2006, a significant fraction of *N. gonorrhoeae* strains isolated in the United States had developed resistance to these drugs as well. Strains resistant to penicillin and quinolones respond to alternative antibiotic therapy with a single dose of the β -lactam antibiotics cefixime or ceftriaxone.

Despite the fact that drugs are still effective in treating gonorrhea, incidence of gonorrhea remains relatively high (Figure 29.35) for at least three reasons. First, although anti-gonococcal antibodies are generated by an infection, they are strain-specific and provide no protection from infection by other strains of *N. gonorrhoeae*. As a consequence, gonorrhea reinfection is possible and quite common in high-risk populations. In addition, within a single *N. gonorrhoeae* strain, antigenic switches can thwart the immune response. For example, by mutation *N. gonorrhoeae* can alter the structure of its pilus proteins, thus creating new serotypes to challenge the immune response. Second, oral contraceptives cause a rise in vaginal pH; when this occurs, lactic acid bacteria normally found in the adult vagina (Figure 23.8b) fail to develop, and this reduces competition for colonization by *N. gonorrhoeae*. And finally, and quite importantly, symptoms of gonorrhea in the female are often so mild that the disease may go unrecognized.

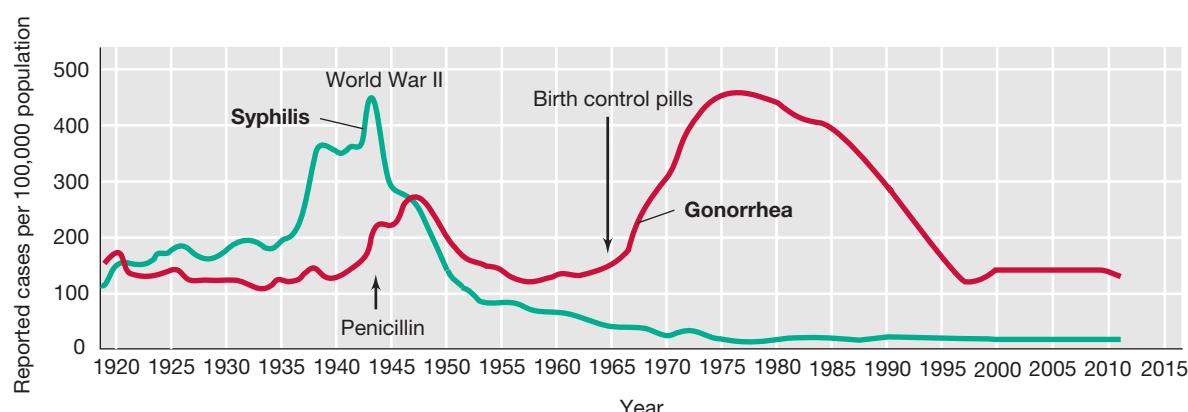

Figure 29.35 Reported cases of gonorrhea and syphilis in the United States. Note the downward trend in disease incidence after the introduction of antibiotics and the upward trend in the incidence of gonorrhea after the introduction of birth control pills. In 2011 there were 321,849 new cases of gonorrhea and 46,042 new cases of primary and secondary syphilis in the United States.

(b) Scanning electron micrograph of the microvilli of human fallopian tube mucosa with cells of *N. gonorrhoeae* attached to the surface of epithelial cells. Cells of *N. gonorrhoeae* are about 0.8 µm in diameter. *Neisseria* species are Betaproteobacteria (Section 15.2).

Syphilis

Syphilis is caused by a spirochete, *Treponema pallidum*, a long and extremely thin coiled cell (Figure 29.37). Like *N. gonorrhoeae*, *T. pallidum* is very sensitive to environmental stress and drying, and thus syphilis is only transmitted through intimate sexual contact or from mother to fetus during pregnancy. The biology of the spirochetes and the genus *Treponema* is discussed in Section 14.20.

Syphilis is often transmitted along with gonorrhea as coinfections. However, syphilis is potentially the more serious disease. For example, syphilis kills about 100,000 people per year worldwide, whereas gonorrhea by itself kills only about 1000 people per year. Nevertheless, largely because of differences in the symptoms and pathobiology of the two diseases, the incidence of syphilis in the United States is much lower than the incidence of gonorrhea. The incidence of syphilis in the United States, however, has increased in recent years, with over 10,000 new infections diagnosed each year, from a low of about 6000 in 1997.

The syphilis spirochete (Figure 29.37) does not pass through unbroken skin, and initial infection takes place through tiny breaks in the epidermal layer. In the male, initial infection is usually on the penis; in the female it is most often in the vagina, cervix, or perineal region. In about 10% of cases, infection is extragenital, usually in the oral region (Figure 29.38). During pregnancy, the organism can be transmitted from an infected woman to the fetus; the disease acquired by the infant is called **congenital syphilis**.

Syphilis is an extremely complex disease and can progress into increasingly serious stages. Syphilis always begins with a localized infection called *primary syphilis*. In primary syphilis, *T. pallidum* multiplies at the initial site of entry, and a characteristic lesion called a *chancre* forms within 2 weeks to 2 months (Figure 29.38a, b). Microscopy of a syphilitic chancre exudate reveals the actively motile spirochetes (Figure 29.37). In most cases the

(b) Silver-stained (Fontana method) preparation of a specimen from a syphilitic chancre. (c) Shadow-cast electron micrograph of a cell of *T. pallidum*. The endoflagella are typical of spirochetes. (Section 14.20).

chancre heals spontaneously and *T. pallidum* disappears from the site. In untreated cases, however, some cells spread from the initial site to various parts of the body, such as the mucous membranes, eyes, joints, bones, or central nervous system, where extensive multiplication occurs. A hypersensitivity reaction to the treponemes often takes place, revealed by the development of a generalized skin rash; this rash is the key symptom of *secondary syphilis* (Figure 29.38c).

In the absence of treatment, the subsequent course of the disease varies from case to case. About one-fourth of infected individuals undergo a spontaneous cure and are free of any further disease symptoms. Another one-fourth exhibit no further symptoms, but maintain a persistent, chronic, syphilitic infection. Roughly half of untreated patients develop *tertiary syphilis*, with symptoms ranging from relatively mild infections of the skin and bone to serious and even fatal infections of the cardiovascular system or central nervous system. This may occur many years after the primary infection. Involvement of the nervous system can cause paralysis or other severe neurological damage. Relatively low numbers of *T. pallidum* are present in individuals with tertiary syphilis; most of the symptoms probably result from inflammation due to delayed-type hypersensitivity reactions (Section 24.8) to the syphilis spirochetes. Tertiary syphilis can still be treated, usually with long-term intravenous antibiotic administration, but prior neurological damage from the syphilitic infection is typically irreversible.

Several tests used in laboratory diagnoses of syphilis were discussed in Chapter 27. However, the single most important physical sign of a primary syphilis infection, the chancre (Figure 29.38a, b), is highly diagnostic for the disease. Infected individuals generally seek treatment for syphilis because of the chancre. Penicillin remains highly effective in syphilis therapy, and the primary and

secondary stages of the disease can typically be cured by a single injection of benzathine penicillin G.

29.13 Chlamydia, Herpes, and Human Papillomavirus

STIs caused by *Chlamydia* (a bacterium) and herpesvirus and human papillomavirus are very prevalent among sexually active adults and are often more difficult to diagnose and treat than are syphilis and gonorrhea.

Chlamydia

A number of sexually transmitted diseases can be ascribed to infection by the obligately intracellular bacterium *Chlamydia trachomatis* (Figure 29.39). This organism is one of a small group of parasitic bacteria that form their own phylum (the *Chlamydiae*) of *Bacteria* (☞ Section 15.15). Because *C. trachomatis* must be grown in host cells (tissue culture), its rapid isolation and identification is not as straightforward as for *Neisseria gonorrhoeae*.

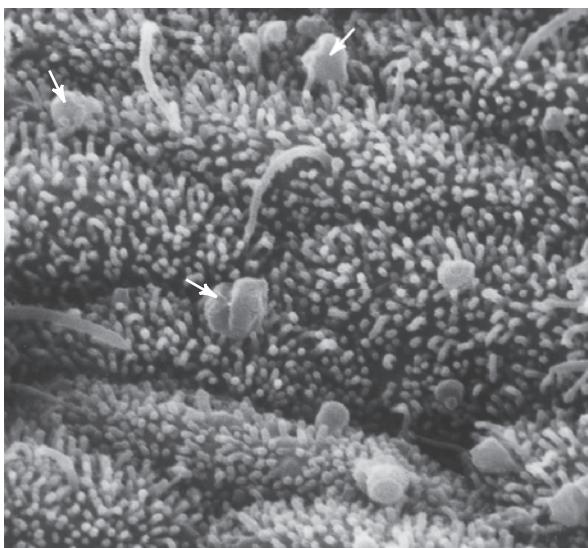

The total incidence of sexually transmitted *C. trachomatis* infections probably greatly outnumbers the incidence of gonorrhea. Over 1 million chlamydial cases are now reported annually in the United States, but because of their often inapparent nature, there may be more than 4 million new sexually transmitted chlamydial infections every year. Because of this, chlamydia is the most prevalent STI and reportable communicable disease in the United States. *C. trachomatis* also causes a serious eye infection called *trachoma*, but the strains of *C. trachomatis* responsible for STIs are distinct from those causing trachoma. Chlamydial

infections may also be transmitted congenitally to the newborn in the birth canal, causing newborn conjunctivitis and pneumonia.

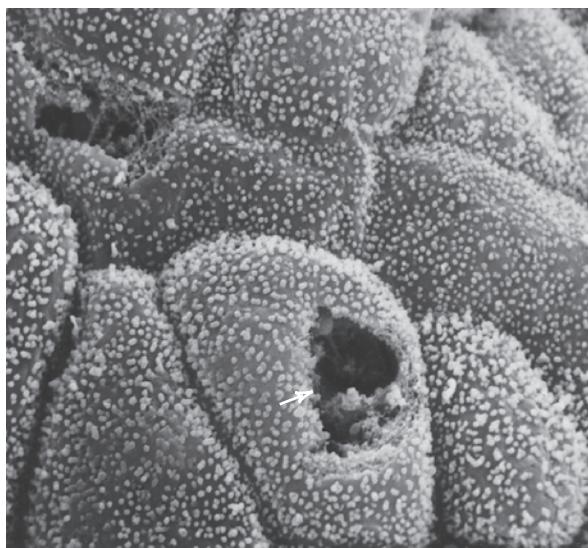

Nongonococcal urethritis (NGU) due to *C. trachomatis* is one of the most frequently observed sexually transmitted diseases in males and females, but the infections are often inapparent. In a small percentage of cases, chlamydial NGU leads to serious acute complications, including testicular swelling and prostate inflammation in men and cervicitis, pelvic inflammatory disease, and fallopian tube damage in women. During NGU, cells of *C. trachomatis* can attach to microvilli of fallopian tube cells, enter, multiply, and eventually lyse the cells (Figure 29.39b). Untreated NGU in a female can thus cause infertility. Infections with the protist *Trichomonas vaginalis* can cause symptoms similar to those of chlamydial NGU, and we consider trichomoniasis along with other parasitic infections in Chapter 32.

Chlamydial NGU is frequently observed as a secondary infection following gonorrhea. Both *Neisseria gonorrhoeae* and *C. trachomatis* are often transmitted to a new host simultaneously. However, treatment of gonorrhea does not eliminate the chlamydia. Although cured of gonorrhea, these patients are still infected with chlamydia and eventually experience an apparent recurrence of gonorrhea that is instead a case of chlamydial NGU. Thus, patients treated for gonorrhea with drugs such as cefixime or ceftriaxone are also given azithromycin or doxycycline to treat a potential coinfection with *C. trachomatis*. A variety of clinical techniques including nucleic acid and immunological analyses are available for making a positive diagnosis of *C. trachomatis* infection, but drug therapy in the absence of a positive diagnosis is often prescribed.

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by distinct strains of *C. trachomatis* (LGV 1, 2, and 3). The disease occurs most frequently in males and is characterized by infection and swelling of the lymph nodes in and about the groin. From the infected lymph nodes, chlamydial cells may travel to the rectum and cause a painful inflammation of rectal tissues called *proctitis*. LGV has the potential to cause

regional lymph node damage and the complications of proctitis. It is the only chlamydial infection that invades beyond the epithelial cell layer.

Herpes

Herpesviruses are a large group of double-stranded DNA viruses (➡ Section 9.7), many of which are human pathogens. The herpes simplex viruses are responsible for both cold sores and genital infections.

Herpes simplex 1 virus (HSV-1) infects the epithelial cells around the mouth and lips, causing cold sores, also known as fever blisters (Figure 29.40). HSV-1 is spread via direct contact with infectious lesions or through saliva. The incubation period of HSV-1 infections is short (3–5 days), and the lesions heal without treatment in 2–3 weeks. However, latent herpes infections are common, because the virus typically persists in low numbers in nerve tissue. Recurrent acute herpes infections can then occur when the virus is triggered by coinfections with other pathogens or by bodily stress. Oral herpes caused by HSV-1 is quite common and

apparently has no long-term harmful effects on the host, beyond the discomfort of the oral blisters.

Herpes simplex 2 virus (HSV-2) infections are associated primarily with the anogenital region, where the virus causes painful blisters on the penis of males or on the cervix, vulva, or vagina of females (Figure 29.41). HSV-2 infections are generally transmitted by direct sexual contact, and the disease is most easily transmitted when active blisters are present, but may also be transmitted during asymptomatic periods, even when the infection is presumably latent. HSV-2 occasionally infects other sites such as the mucous membranes of the mouth and can also be transmitted to a newborn by contact with herpetic lesions in the birth canal at

birth. The disease in the newborn varies from latent infections with no apparent damage to systemic disease resulting in brain damage or even death. To avoid herpes infections in newborns, delivery by cesarean section is advised for pregnant women with genital herpes infections.

The long-term effects of genital herpes infections are not fully understood. However, studies have indicated a significant correlation between genital herpes infections and cervical cancer in females. Genital herpes infections are presently incurable, although a limited number of drugs have been successful in controlling the infectious blister stages. The guanine analog acyclovir (Figure 29.42), given orally and also applied topically, is particularly effective in limiting the shed of active virus from blisters and promoting the healing of blistering lesions (Figure 29.41). Acyclovir, valacyclovir, and vidarabine are nucleoside analogs that interfere with herpesvirus DNA polymerase, inhibiting viral DNA replication. (► Section 27.15).

Human Papillomavirus

As for herpesviruses, **human papillomaviruses (HPV)** comprise a family of double-stranded DNA viruses. Of more than 100 different strains, about 30 are transmitted sexually, and several of these cause genital warts and cervical cancer (► Chapter 24 Explore the Microbial World “Vaccines and Public Health”). About 20 million people in the United States are infected, and up to 80% of women over age 50 have had at least one HPV infection. Over 6 million people acquire new HPV infections annually, leading to almost 10,000 cases of cervical cancer and about 3700 deaths.

Most HPV infections are asymptomatic, with some progressing to cause genital warts. Others cause cervical neoplasia (abnormalities in cells of the cervix), and a few progress to cervical cancers. Most HPV infections resolve spontaneously but, as with many viral infections, there is no adequate treatment or cure for active infections. Because human papillomaviruses are potentially oncogenic (cancer-causing), an HPV vaccine has been developed and is currently recommended for use in females 11–26 years of age. The vaccine has also been recommended for males because immunized males no longer carry HPV and thus cannot infect females, and because HPV infection in males can lead to anal and penile cancers.

29.14 HIV/AIDS

Acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV). Worldwide, more than 80 million people have been infected with HIV, and there are nearly 3 million new infections and over 2 million deaths each year. We covered the epidemiology of AIDS in Section 28.9.

HIV and a Definition of AIDS

HIV is of two types, *HIV-1* and *HIV-2*, but since more than 99% of global AIDS cases are due to HIV-1, we focus on HIV-1 here. HIV-1 is a retrovirus (► Sections 8.10 and 9.11) that replicates in macrophages and T cells of the human immune system (Chapters 24 and 25). HIV infection eventually leads to the destruction of key immune system cells, greatly crippling the host immune response. Death from AIDS is the result of a secondary infection, typically caused by one or more **opportunistic pathogens**, potential pathogens that in a healthy individual would be controlled by the immune system.

The current definition of a case of HIV/AIDS is a patient who tests positive for HIV in immunological and/or nucleic acid-based tests and meets at least one of the following two criteria:

1. A CD4 T cell number of less than 200/ μ l of whole blood (the normal count is 600–1000/ μ l) or a CD4 T cell/total lymphocytes percentage of less than 14%.
2. A CD4 T cell number of more than 200/ μ l and any of the following diseases: candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, isosporiasis, *Pneumocystis jiroveci* pneumonia, cryptosporidiosis, or toxoplasmosis of the brain (all fungal diseases) (► Section 32.2); pulmonary tuberculosis or other mycobacterial infections, or recurrent *Salmonella* septicemia (bacterial diseases); cytomegalovirus infection, HIV-related encephalopathy, HIV wasting syndrome, chronic ulcers, or bronchitis due to herpes simplex (viral infections); or certain malignant diseases such as invasive cervical cancer, Kaposi’s sarcoma, Burkitt’s lymphoma, primary lymphoma of the brain, or immunoblastic lymphoma, or recurrent pneumonia due to any agent.

Pathogenesis of HIV/AIDS

HIV infects cells that have the CD4 cell surface protein. The two cell types most commonly infected are macrophages and a class of lymphocytes called T-helper (Th) cells, both of which are important components of the immune system (Chapter 24). Infection normally occurs first in macrophages. At the macrophage cell surface, the CD4 molecule binds to the gp120/gp41 capsid protein of HIV as the virus interacts with the macrophage receptor CCR5 (Figure 29.43). CCR5 is a coreceptor for HIV and, together with CD4, forms the docking site where the HIV envelope fuses with the host cytoplasmic membrane; this is required for the viral nucleocapsid to be inserted into the cell. Within the macrophage, HIV replicates (► Figure 9.21) and makes an altered form of gp120 that recognizes a different coreceptor, CXCR4, on Th cells. HIV virions are released from macrophages and proceed to infect and replicate in Th lymphocytes; Th cells that produce HIV no longer divide and are eventually diminished by attrition.

In some HIV/AIDS patients, HIV infection does not progress immediately to killing host immune cells. HIV can exist

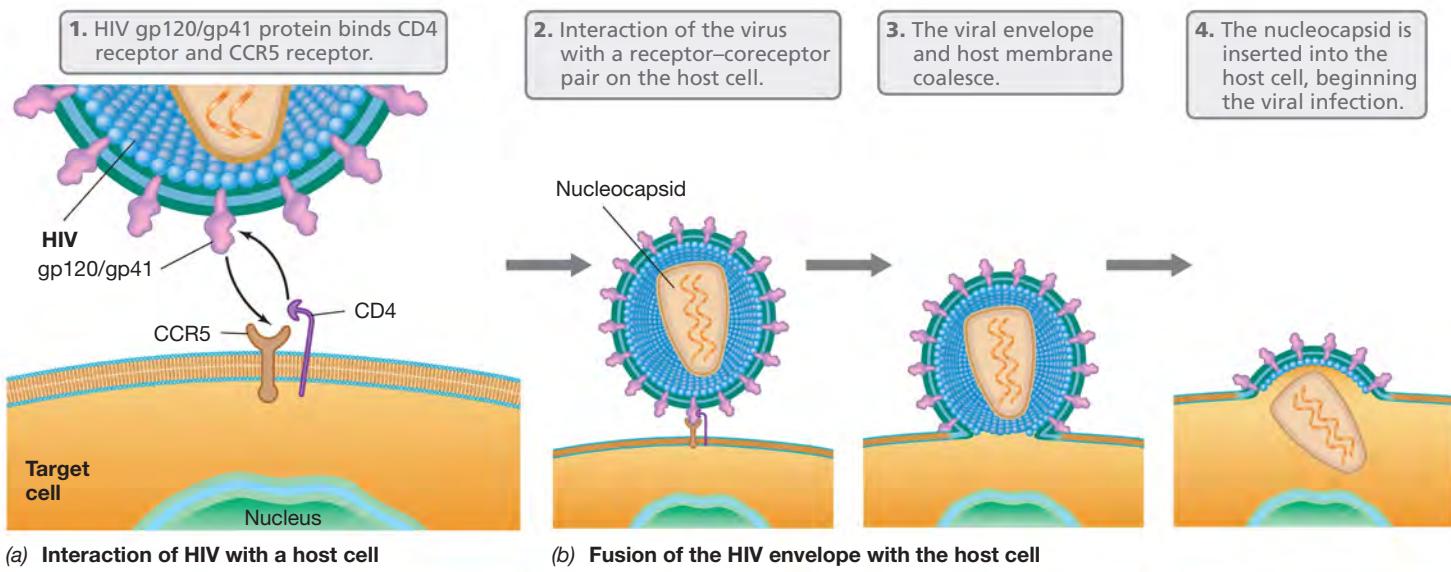

Figure 29.43 Infection of a CD4 target cell with HIV. (a) Recognition and binding of the virus by CCR5 and CD4 receptors. (b) The viral nucleocapsid eventually enters the cell. Details of the replication of the HIV genome are shown in Figures 8.24 and 9.21.

in a dormant state as a provirus; under these conditions, the reverse-transcribed HIV genome, now in the form of DNA, is integrated into host chromosomal DNA (Figure 8.24). At this point the cell may show no outward sign of infection. Indeed, HIV DNA can remain latent for long periods, replicating only as the host cell DNA replicates. However, sooner or later, HIV begins to replicate, and progeny virus are produced and released from the cell.

Symptoms of HIV/AIDS

Ongoing HIV infection results in a progressive decline in CD4 cell numbers. In a healthy human, CD4 cells constitute about 70% of the total T cell pool. In those with HIV/AIDS, CD4 numbers

steadily decrease, and by the time opportunistic infections begin to appear, CD4 cells are all but absent (Figure 29.44). The progression of untreated HIV infection to AIDS follows a typical pattern. First, there is an intense immune response to HIV and HIV numbers drop. But eventually, the immune response is overwhelmed and HIV levels slowly increase while CD4 T cells slowly decrease. When T cell numbers have dropped below about $200/\text{mm}^3$ of blood, the door is open for infections by opportunistic pathogens (Figure 29.44).

Opportunistic infections caused by normally benign protists, fungi, bacteria, and viruses occur with high prevalence in those with HIV/AIDS and are typically the actual cause of death (Figure 29.45). The most common opportunistic disease in

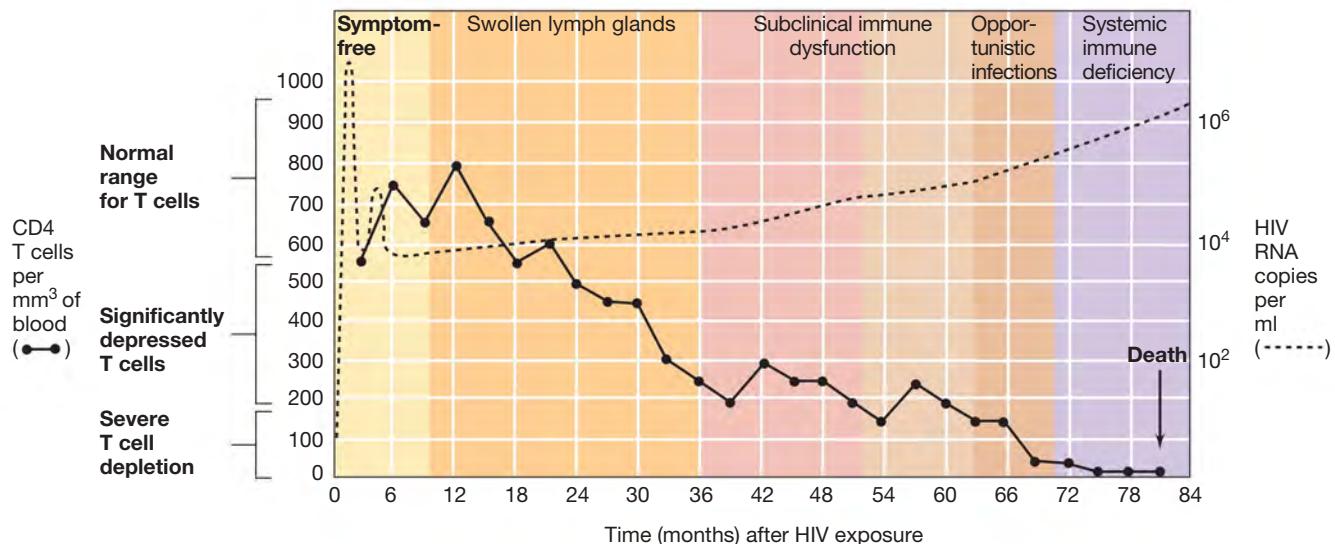

Figure 29.44 Decline of CD4 T lymphocytes and progress of HIV infection. During the typical progression of untreated AIDS, there is a gradual loss in the number and functional ability of the CD4 T cells, while the viral load, measured as HIV-specific RNA copies per milliliter of blood, gradually increases after an initial decline.

(b) *Cryptococcus neoformans*, from lung tissue of an AIDS patient. (c) *Histoplasma capsulatum*, showing reproductive structures called macroconidia. (d) *Pneumocystis jiroveci*, from lungs of immune-compromised patient. (e) *Cryptosporidium* sp. from small intestine of a patient with cryptosporidiosis. (f) *Toxoplasma gondii*, from heart tissue of patient with toxoplasmosis. (g) *Mycobacterium* spp. infection of the small bowel (acid-fast stain). Coverage of many of these fungal and parasitic diseases can be found in Chapter 32.

HIV/AIDS patients is pneumonia caused by the fungus *Pneumocystis jiroveci* (Figure 29.45d), but infections by various molds, yeasts, protists, and bacteria are also seen (Figure 29.45). Almost all of these opportunistic pathogens are difficult to treat. For example, many of the drugs used to treat infections from fungi and protists (both *Eukarya*) have significant negative side effects on the host, and mycobacterial infections are often from drug-resistant strains (Section 29.4). A cancer frequently seen in HIV/AIDS patients is *Kaposi's sarcoma*, a cancer of the cells lining the blood vessels characterized by purple splotches on the skin, especially in the extremities (Figure 29.46). Kaposi's sarcoma is caused by coinfection of HIV and human herpesvirus 8 (HHV-8) and is rarely seen outside of HIV/AIDS patients.

Diagnosing HIV/AIDS

HIV infection is typically diagnosed by identifying antibodies to the pathogen in a patient blood sample. The HIV enzyme immunoassay (EIA, ↗ Figure 27.15b, c) is used for screening purposes, typically on a large scale, for example, of donated blood. A positive HIV EIA must be confirmed by an HIV immunoblot (Western blot, ↗ Figure 27.17) or by immunofluorescence (↗ Figure 27.14) to rule out the possibility of a false-positive screening test. Rapid and inexpensive HIV tests are available for preliminary screening of blood in clinics. One test requires only a single drop of patient blood and detects the gp41 HIV surface antigen (Figure

29.43) by producing a visible agglutination reaction. A second uses saliva as a source of anti-HIV antibodies and yields a colored product. In general, however, these rapid tests are not as sensitive or specific as the standard HIV EIA and thus positive tests should

Figure 29.46 Kaposi's sarcoma. Lesions are shown as they appear on (a) the heel and lateral foot, and (b) the distal leg and ankle.

be confirmed by more sensitive and specific tests. Unfortunately, no matter how sensitive or specific, none of these tests will detect those who have recently acquired the virus and are infectious but have not yet made a detectable antibody response to HIV; this antibody response can require a period of 6 weeks or more following infection.

Diagnostic procedures are available that directly measure the number of HIV virions in a blood sample. These tests use a virus-specific reverse transcription–polymerase chain reaction assay (RT-PCR, [Section 11.3](#)). RT-PCR estimates the number of HIV virions present in the blood, the so-called **viral load**. The RT-PCR test for HIV load is not routinely used to screen for HIV because it is costly and technically demanding. However, after an initial diagnosis, the test is often used to monitor progression of an HIV infection and the effectiveness of chemotherapy ([Figure 29.47](#)).

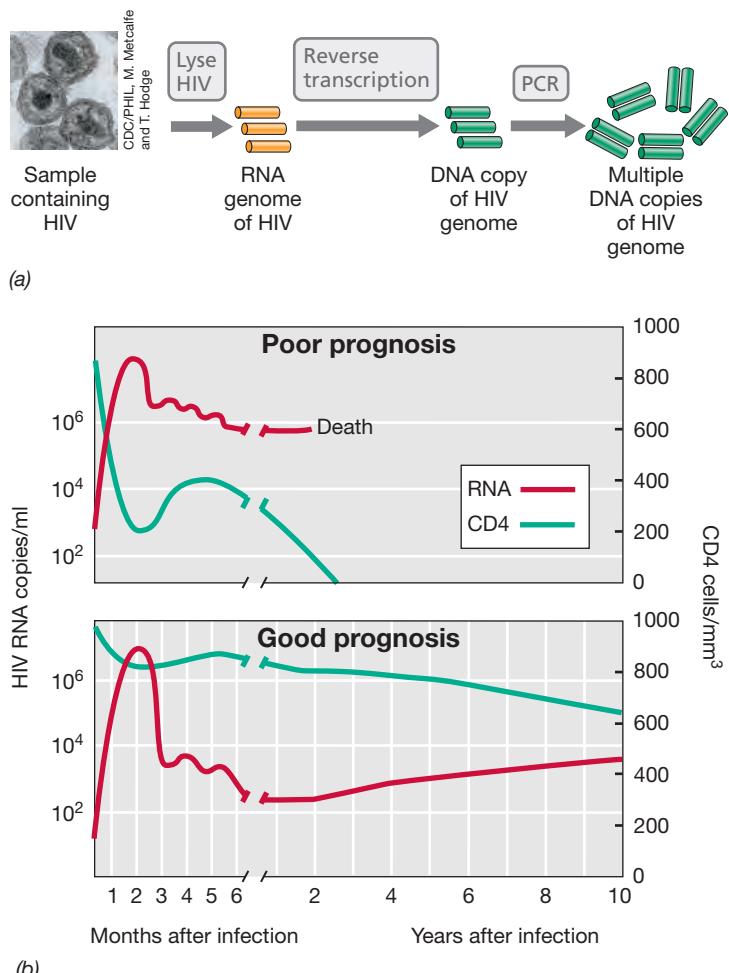

Figure 29.47 Monitoring of HIV load. (a) Procedure for detecting HIV by reverse transcription–polymerase chain reaction (RT-PCR) techniques. (b) Time course for HIV infection as monitored by HIV load and CD4 T cell counts. In the upper panel, a viral load greater than 10^4 copies/ml correlates with below normal CD4 cell numbers (normal = $600–1500/\text{mm}^3$), indicating a poor prognosis and early death of the patient. In the lower panel, a viral load less than 10^4 copies/ml correlates with normal CD4 cell numbers, indicating a good prognosis and extended survival of the patient. Data are adapted from the CDC, Atlanta, Georgia, USA.

Treatment of HIV/AIDS

The prognosis for an *untreated* HIV-infected individual is poor, as opportunistic pathogens or malignancies ([Figures 29.45](#) and [29.46](#)) eventually kill those infected. Long-term studies indicate that the average person infected with HIV progresses through several stages of decreasing immune function, with CD4 cells dropping from a normal range of $600–1000/\text{mm}^3$ of blood to near zero over a period of 5–7 years ([Figure 29.44](#)). Although the rate of decline varies from one HIV-infected individual to another, it is rare for an HIV-positive individual to live for more than 10 years without anti-HIV drug therapy.

Several drugs have been developed that delay the progression of HIV/AIDS and significantly prolong the life of those infected with HIV. Therapy is aimed at reducing the viral load of HIV-infected individuals to below detectable levels ([Figure 29.44](#)). The strategy to accomplish this is called *highly active anti-retroviral therapy* (HAART) and is carried out by administering at least three anti-retroviral drugs at once to inhibit the replication of HIV and prevent the development of drug-resistant strains. Multiple drug therapy, however, is not a cure for HIV infection. In individuals who have no detectable viral load after drug treatment, a significant viral load returns if therapy is interrupted or discontinued, or if multiple drug resistance develops.

Effective anti-HIV drugs fall into four categories, including two classes of *reverse transcriptase inhibitors*, various *protease inhibitors*, *fusion inhibitors*, and *integrase inhibitors*. Reverse transcriptase is the enzyme that converts the single-stranded RNA genome of HIV into cDNA and then double-stranded DNA and is essential for viral replication ([Sections 8.10](#) and [9.11](#)). Cells lack reverse transcriptase and thus reverse transcriptase inhibitors are viral-specific. *Azidothymidine* (AZT) closely resembles the nucleoside thymidine but lacks the correct attachment site for the next base in a replicating nucleotide chain, resulting in termination of the growing DNA chain. AZT is thus a **nucleoside reverse transcriptase inhibitor** ([Figure 29.48a](#)). **Nonnucleoside reverse transcriptase inhibitors**, such as *nevirapine* ([Figure 29.48b](#)), inhibit the activity of reverse transcriptase in a different way by interacting with the protein and altering the conformation of the catalytic site.

Another category of anti-HIV drugs is the **protease inhibitors**, such as *saquinavir* ([Figure 29.48c](#)). These are peptide analogs that inhibit processing of retroviral polypeptides ([Figure 9.22](#)) by binding to the active site of the processing enzyme, *HIV protease*; this effectively inhibits viral maturation. **Fusion inhibitors** include *enfuvirtide*, a synthetic peptide that functions by binding to the gp41 protein on HIV capsids ([Figure 29.43](#)); this stops fusion of the viral envelope and the CD4 cell cytoplasmic membrane. Finally, there are the **integrase inhibitors**, such as *elvitegravir* and *raltegravir*. These drugs target HIV integrase, the protein that integrates the HIV genome into host cell DNA. The interference with integration of viral DNA into the host cell genome interrupts the HIV replication cycle.

All anti-HIV drugs rapidly decrease the viral load when given to HIV-infected individuals, but drug-resistant strains of HIV arise quickly if only a single drug is administered. A typical HAART protocol for treatment of an established HIV infection includes at

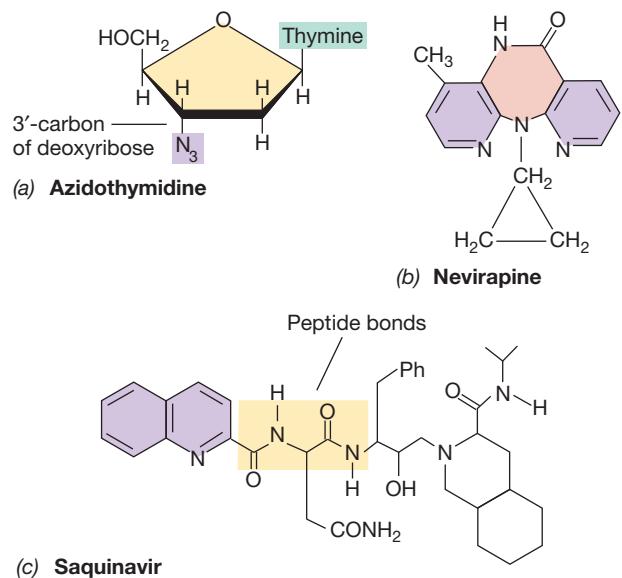

Figure 29.48 HIV/AIDS chemotherapeutic drugs. (a) Azidothymidine (AZT), a nucleoside reverse transcriptase inhibitor. This nucleoside analog is missing the $-OH$ group on the 3' carbon, causing nucleotide chain elongation to terminate when the analog is incorporated, inhibiting virus replication. (b) Nevirapine, a nonnucleoside reverse transcriptase inhibitor, binds directly to the catalytic site of HIV reverse transcriptase, also inhibiting elongation of the nucleotide chain. (c) Saquinavir, a protease inhibitor, was designed by computer modeling to fit the active site of the HIV protease. Saquinavir is a peptide analog: The tan-highlighted area shows the region analogous to peptide bonds. Blocking the activity of HIV protease prevents the processing of HIV proteins and maturation of the virus.

least one protease or nonnucleoside reverse transcriptase inhibitor plus a combination of two nucleoside reverse transcriptase inhibitors. A resistant virus would, therefore, have to develop resistance to three drugs simultaneously, and the probability of this occurring is very small. A patient receiving this combination therapy is then monitored to track changes in viral load (Figures 29.44 and 29.47). An effective HAART protocol reduces viral load to nondetectable levels within several days. Drug therapy is then continued and the patient monitored for viral load indefinitely. If the viral load again reaches detectable limits, the drug cocktail is changed because an increase in viral load indicates the emergence of drug-resistant HIV.

In addition to drug resistance, some anti-retroviral drugs are toxic to the host. In many cases, nucleoside analogs are not well tolerated by patients, presumably because they interfere with host functions such as cell division. In general, the nonnucleoside

reverse transcriptase inhibitors and the protease inhibitors are better tolerated because they target virus-specific functions. However, drug resistance and host toxicity are major problems in all forms of HIV therapy. Thus, new chemotherapeutic agents and drug protocols are constantly being developed and tailored to the needs of individual patients.

HIV/AIDS Prevention

Public education about how HIV/AIDS is transmitted, sexual abstinence, and avoidance of high-risk behavior remain the major tools used to prevent HIV/AIDS. HIV spread is linked to promiscuous sexual activities and other activities that involve exchange of body fluids, which include not only men who have sex with men, but also prostitution and intravenous drug use where needles are shared. In some countries, the fastest growing mode of HIV transmission is actually between heterosexual partners. Effective prevention of HIV transmission therefore requires avoiding high-risk behaviors, regardless of sexual partners.

The United States Surgeon General has issued specific recommendations for avoiding HIV infection. These include, in addition to the avoidance of intravenous drug use where needles are shared:

1. Avoiding mouth contact with penis, vagina, or rectum.
2. Avoiding all sexual activities that could cause cuts or tears in the linings of the rectum, vagina, or penis.
3. Avoiding sexual activities with individuals from high-risk groups. These include prostitutes (both male and female); those who have multiple sex partners, particularly homosexual men and bisexuals; and intravenous drug users.
4. If a person has had sex with someone in a high-risk group, a blood test should be done to determine if infection with HIV has occurred. The blood test should be repeated at intervals for a year or longer because of the lag time in the immune response. If the test is positive, the sexual partners of the HIV-positive individual must be protected by use of a condom during sexual activities.

BIG IDEAS

29.1 • Bacterial and viral respiratory pathogens are transmitted in air. Most respiratory pathogens are transferred from person to person via respiratory aerosols generated by coughing, sneezing, talking, or breathing, or by direct or fomite contact. Respiratory pathogens infect either the upper or lower respiratory tracts and sometimes both.

29.2 • Streptococcal diseases include strep throat and pneumococcal pneumonia. *Streptococcus pyogenes* infections may progress into serious conditions such as scarlet and rheumatic fevers, and pneumococcal pneumonia can have high mortality. Both pathogens can be cultured and both are treatable with antimicrobial drugs including penicillin.

29.3 • Diphtheria is an acute respiratory disease caused by *Corynebacterium diphtheriae*. Early childhood immunization is effective for preventing this very serious respiratory disease. Whooping cough is an endemic disease caused by *Bordetella pertussis*. Immunization of children, adolescents, and adults can control its propagation and spread.

29.4 • Tuberculosis is one of the most prevalent and dangerous infectious diseases in the world. Its incidence is increasing in developed countries in part because of the emergence of drug-resistant strains of *Mycobacterium tuberculosis*. The pathology of tuberculosis and other mycobacterial diseases such as Hansen's disease (leprosy) is influenced by the cellular immune response.

29.5 • *Neisseria meningitidis* is a common cause of meningococcemia and meningitis in young adults and occasionally occurs in epidemics in enclosed populations. Bacterial meningitis and meningococcemia can have high mortality rates, and treatment and prevention strategies including vaccines are available.

29.6 • Viral respiratory diseases are highly infectious and may cause serious health problems, although most are controllable and not life-threatening. The measles/mumps/rubella (MMR) vaccine is highly effective in controlling these diseases.

29.7 • Colds are the most common infectious viral diseases. Usually caused by a rhinovirus, colds are generally mild and self-limiting diseases; "cold drugs" may help to moderate symptoms but are not a cure. Each infection induces specific, protective immunity, but the large number of cold viruses precludes complete protective immunity or vaccines.

29.8 • Influenza is caused by an RNA virus that contains a segmented genome and is easily transmitted by the airborne

route. Influenza outbreaks occur annually due to the plasticity of the influenza genome. Antigenic drift varies the nature of the viral envelope of influenza viruses in minor ways, causing influenza seasonal epidemics, while antigenic shift varies the virus in major ways and can trigger periodic influenza pandemics. Surveillance and immunization are used to control influenza.

29.9 • Staphylococci are usually benign inhabitants of the upper respiratory tract and skin, but several serious diseases can result from pyogenic infection or from the activity of staphylococcal superantigen exotoxins. Antibiotic resistance is common, even in community-acquired infections. MRSA strains of *Staphylococcus aureus* can be very difficult to treat and cause significant tissue damage.

29.10 • *Helicobacter pylori* infection is the common cause of gastric ulcers. Gastric ulcers are now treated with antibiotics as an infectious disease, promoting a permanent cure.

29.11 • Viral hepatitis can result in acute liver disease, which may be followed by chronic liver disease (cirrhosis). Hepatitis B and C viruses in particular are transmitted by direct contact and can cause chronic infections leading to liver cancer. Vaccines are available for hepatitis viruses A and B. Viral hepatitis is still a major public health problem because of the high infectivity of the viruses and the lack of effective treatments.

29.12 • Gonorrhea and syphilis, caused by *Neisseria gonorrhoeae* and *Treponema pallidum*, respectively, are STIs with potential serious consequences if infections are not treated. In the United States, the incidence of gonorrhea has decreased in the last several years, but the incidence of syphilis has increased.

29.13 • Chlamydia is the most prevalent of STIs, and if left untreated, can cause serious complications in both males and females. Herpes simplex viruses cause incurable infections transmitted by oral or genital contact with herpes 1 or herpes 2, respectively. Human papillomaviruses cause widespread STIs that may lead to cervical and other cancers, but effective HPV vaccines are available.

29.14 • HIV is a retrovirus that destroys the immune system, leading to AIDS, and opportunistic pathogens eventually kill the host. There is no effective cure or vaccine for HIV infection, although antiviral drugs may slow or stop the progress of AIDS. Preventing HIV infection requires education and avoidance of high-risk behaviors involving exchange of body fluids.

Vampire Bats and Rabies

Rabies is a disease of warm-blooded animals—primarily mammals—caused by an RNA virus. The rabies virus triggers an acute encephalitis and eventual death of the animal. Over 55,000 people, mainly children, die each year from rabies worldwide. Most rabies deaths are linked to bites from rabid dogs. Cases of human rabies from wild animal bites, such as from a fox, raccoon, or skunk, are rare. In the United States, most cases of human rabies, which average about three per year, are linked to bites from bats.

At least 47 species of bats inhabit the United States and Canada. Most of these have a diet of either insects or fruits. One bat not native to this part of North America is the vampire bat—a species that thrives on blood (photo). Vampire bats are New World animals and inhabit warm climates. They range from Mexico to as far south as Argentina, and until 2010, no cases of human rabies in the United States had been linked to a vampire bat bite. However, in August of that year, a migrant worker died of rabies in Louisiana. The worker had received a bat bite 2 weeks earlier in Mexico and was beginning to show some of the neurological symptoms of rabies. Less than a month later the worker was dead and samples collected at autopsy showed infection with a strain of rabies virus previously linked to vampire bats.¹

This rabies death signals the possibility of a serious new means of rabies transmission in the United States. With global climate change pushing subtropical climates ideal for the vampire bat farther north, it is likely that these bats will begin to inhabit southern regions of the United States soon. And because vampire bats consume blood, they could become important new rabies vectors, transmitting the disease to livestock and other animals not normally associated with rabies.

- I Animal-Transmitted Viral Diseases 886
- II Arthropod-Transmitted Bacterial and Viral Diseases 888
- III Soilborne Bacterial Diseases 897

In this chapter we focus on pathogenic bacteria and viruses transmitted to humans by animals, arthropods, or soil. Animal-transmitted pathogens have their origins in nonhuman vertebrates, and these infected animal populations can transmit infections to humans. Some arthropods are disease vectors, spreading pathogens to new hosts from a bite. Soilborne pathogens are transmitted to humans

through either direct contact with soil or contact with infected animal fur or hides. A few of the diseases we will explore in this chapter produce only mild symptoms and are typically self-limiting. But most are highly dangerous with life-threatening symptoms and high mortality rates. These include such dreaded diseases as rabies, hantavirus syndromes, yellow fever, and plague.

I • Animal-Transmitted Viral Diseases

Zoonosis is an animal disease transmissible to humans, generally by direct contact, aerosols, or bites. Immunization and veterinary care control many infectious diseases in domesticated animals, reducing the transfer of zoonotic pathogens to humans. However, wild animals neither receive veterinary care nor are they immunized, making them a source of potential zoonoses. Diseases in animals may be **enzootic**, present endemically in certain populations, or **epizootic**, with incidence reaching epidemic proportions. In this unit we focus on two typically enzootic viral diseases, rabies and hantavirus syndromes, both of which can be transmitted to humans.

30.1 Rabies Virus and Rabies

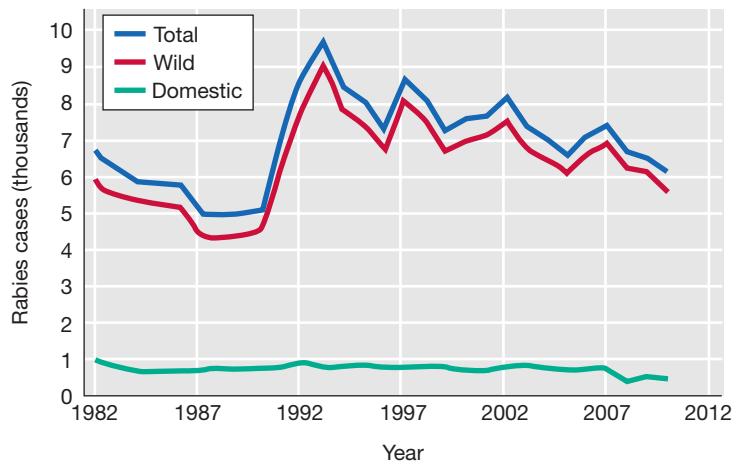

Rabies occurs in wild animals, and the major enzootic reservoirs of rabies virus in the United States are raccoons, skunks, coyotes, foxes, and bats (see page 885). A small number of rabies cases also occur annually in domestic animals (Figure 30.1).

Symptoms and Pathology of Rabies

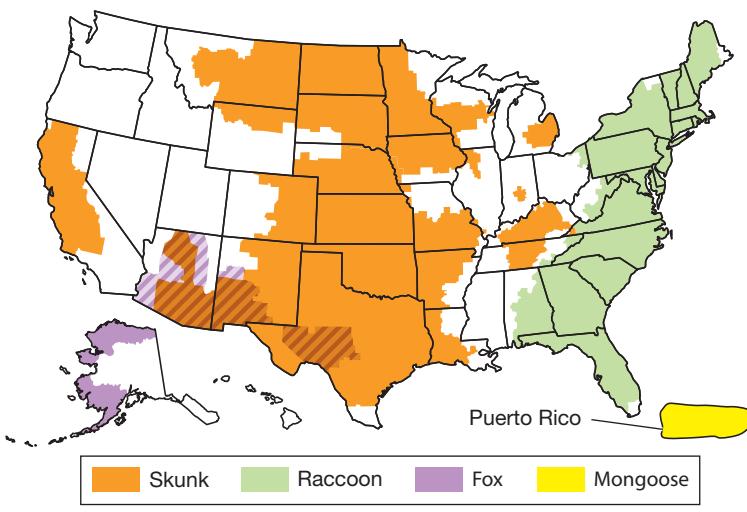

Rabies is caused by a rhabdovirus, a single-stranded minus-sense RNA virus (➡ Section 9.9) that infects cells of the central nervous system in most warm-blooded animals, almost invariably

leading to death once symptoms have developed. The virus (Figure 30.2a) enters the body from virus-contaminated saliva through a wound from a bite or through contamination of mucous membranes. Rabies virus multiplies at the site of inoculation and travels to the central nervous system. The incubation period before the onset of symptoms is highly variable and depends on the host, the size, location, and depth of the inoculating wound, and the titer of rabies virions transmitted in the bite. In dogs, the incubation period for rabies is less than two weeks. By contrast, in humans, 9 months or more may pass before rabies symptoms become apparent.

Rabies virus proliferates in the brain, especially in the thalamus and hypothalamus. Infection leads to fever, excitation, dilation of the pupils, excessive salivation, and anxiety. A fear of swallowing (hydrophobia, an early name for rabies) develops from uncontrollable spasms of the throat muscles, and death eventually results from respiratory paralysis. In humans, an *untreated* rabies infection in which symptoms have begun is almost always fatal. Fortunately for both domestic animals and humans, a very effective rabies vaccine exists and this keeps the incidence of rabies low in domestic animals (Figure 30.1a) and a rarity in humans.

(b) Major vectors of rabies in the United States

Figure 30.1 Rabies cases in wild and domestic animals in the United States. (a) Incidence of rabies by year. Human cases are fewer than 5 per year. (b) Major reservoirs of rabies virus. In some areas, for example, southwest Texas, both skunks and foxes are the major rabies reservoirs. Over 90% of all reported rabies cases occur in wild animals. However, actual numbers are probably significantly higher than shown in part a due to undiagnosed cases and undiscovered rabid animal carcasses. Data are from the Centers for Disease Control and Prevention, Atlanta, Georgia, USA.

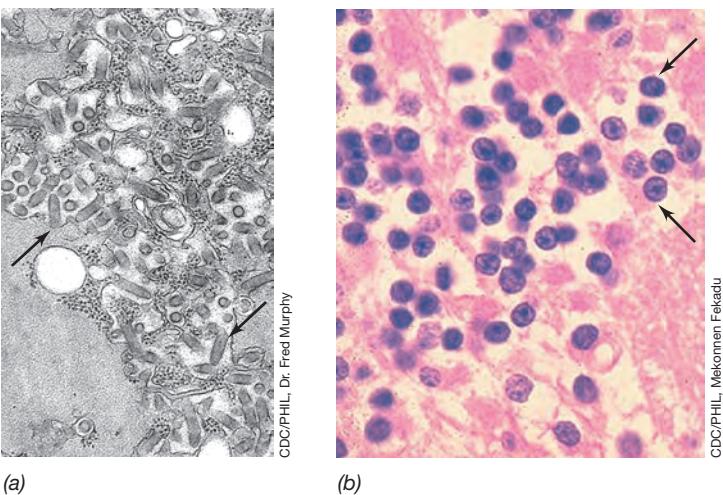

Figure 30.2 Rabies virus. (a) The bullet-shaped rabies virions (arrows) shown in this transmission electron micrograph of a tissue section from a rabid animal are about 75×180 nm. (b) Pathology of rabies in humans. In brain tissue, rabies virus causes characteristic cytoplasmic inclusions called Negri bodies (arrows), which contain rabies virus antigens. Negri bodies are about 2–10 μm in diameter.

Diagnosis, Treatment, and Prevention of Rabies

Rabies is diagnosed in the laboratory by examining tissue samples for the virus. Fluorescent antibodies that bind to rabies virus in brain tissues are used to confirm a case of rabies in a postmortem examination. Viral inclusions called *Negri bodies* are seen in the cytoplasm of nerve cells stained for light microscopy and these characteristic structures confirm rabies virus infection as well (Figure 30.2b).

Because rabies is such a serious disease, firm guidelines for treating possible human exposure to rabies have been established, and the details can be found in the rabies section of the World Health Organization website (<http://www.WHO.int>). In summary, the guidelines state that if a wild or stray animal is suspected of being rabid, it should be immediately examined for evidence of the rabies virus. If a domestic animal, generally a dog, cat, or ferret, bites a human, especially if the bite is unprovoked, the animal should be held in quarantine for 10 days to check for signs of rabies. If the animal exhibits rabies symptoms, or a definitive diagnosis of its illness cannot be made after 10 days, the human should be passively immunized with rabies immune globulin (purified human antibodies to rabies virus) injected at both the site of the bite and intramuscularly. The patient should also be actively immunized with a rabies virus vaccine. Because of the very slow progression of rabies in humans, this combination of passive and active immune therapy (Section 24.6) is nearly 100% effective, stopping the onset of the disease.

Rabies is prevented largely through immunization. An inactivated rabies vaccine is used in the United States for both humans and domestic animals. Prophylactic rabies immunization is practiced for individuals at high risk, such as veterinarians, animal control personnel, animal researchers, and individuals who work in rabies research or rabies vaccine production laboratories. The rabies problem is primarily with wild animals (Figure 30.1), where traditional means of vaccination are impossible. However, experimental

trials with an oral rabies vaccine administered in food “baits” have reduced the incidence and spread of rabies in limited geographic areas. If herd immunity (Section 28.2) could be established in some of the key carriers of rabies (Figure 30.1b), it might be possible to reduce incidence of the disease dramatically. Some states and countries, such as Hawaii and Great Britain, are rabies-free, and any animal imported into these areas is subject to quarantine.

Although rabies is vaccine-preventable, about 55,000 people per year die from rabies, primarily in developing countries in Asia and Africa where rabies is enzootic in domestic animals due to inadequate vaccination practices. Worldwide, nearly 14 million people receive prophylactic treatment for rabies after exposure annually, and in the United States, over 20,000 individuals receive such treatment. Fewer than three cases of human rabies are reported in the United States each year, nearly always the result of bites from wild animals. Because domestic animals often have exposure to wild animals, dogs and cats are routinely vaccinated against rabies beginning at 3 months of age. Large farm animals, especially horses, are often immunized against rabies, as well.

30.2 Hantavirus and Hantavirus Syndromes

Hantaviruses cause two severe, emerging diseases, **hantavirus pulmonary syndrome (HPS)**, an acute respiratory and cardiac disease, and **hemorrhagic fever with renal syndrome (HFRS)**, an acute disease characterized by shock and kidney failure. Both diseases are caused by hantaviruses transmitted from infected rodents. Hantavirus is named for Hantaan, Korea, the site of a hemorrhagic fever outbreak where the virus was first recognized as a human pathogen.

Symptoms and Pathology of Hantavirus Syndromes

Hantaviruses are enveloped viruses with single-stranded minus-sense RNA genomes arranged in segments (Figure 30.3; Section 9.9); hantaviruses are related to other hemorrhagic fever viruses such as Lassa fever virus and Ebola virus (Section 28.7). Hantaviruses infect rodents including mice, rats, lemmings, and voles, without causing disease. The virus is transmitted from these reservoirs to humans by inhalation of virus-contaminated rodent excreta. Humans are accidental hosts and are infected only when they come into contact with rodents, their waste, or their saliva.

HPS is characterized by a sudden onset of fever, muscle pain, a reduction in the number of blood platelets along with an increase in the number of circulating leukocytes, and hemorrhaging. Death if it occurs takes several days, and is usually a result of systemic shock and cardiac complications precipitated by leakage of fluid into the lungs, causing suffocation and heart failure. These symptoms are typical of hantaviruses, but other symptoms such as kidney failure are common, depending on the strain of virus causing the disease. HFRS is characterized by intense headache, back and abdominal pain, renal dysfunction, and various hemorrhagic complications. HPS strains

are more prevalent in the Americas, whereas HFRS strains are more prevalent in hantavirus outbreaks in Eurasia. HPS strains typically show a significantly higher mortality rate than HFRS strains.

Hantaviruses can be cultured in the laboratory but must be handled with biosafety level 4 (BSL-4; [Section 27.1](#)) precautions. In the world of infectious diseases, hantavirus and other BSL-4 viral pathogens are considered “the worst of the worst” and are thus handled in the United States by the Special Pathogens Branch of the Centers for Disease Control and Prevention in Atlanta (Georgia, USA) (*Explore the Microbial World*, “Handling Viral Hemorrhagic Fever Viruses”).

Epidemiology, Diagnosis, and Prevention of Hantavirus Syndromes

A significant HPS outbreak in the United States occurred near the Four Corners region of Arizona, Colorado, New Mexico, and

Utah in 1993. The outbreak resulted from an enlarged population of deer mice in the spring of 1993. The previous winter was mild and was followed by abundant spring rains, triggering unusually high food levels for the mice. The HPS outbreak caused 32 deaths among 53 infected people (60% mortality), illustrating the potential danger of outbreaks due to pathogens that can be directly transmitted from animal reservoirs. In total from 1993 through 2011, there have been 587 cases of HPS in the United States, with 211 deaths (36%), mostly in western states. In 2012, an HPS outbreak affecting 10 people occurred in Yosemite National Park (California, USA) with three fatalities. Incidence of infection with HFRS strains is much higher than with HPS strains. It is estimated that 200,000 infections occur annually, chiefly in China, Korea, and Russia, but mortality rates are typically very low.

Hantavirus syndromes can be diagnosed using immunological techniques that identify anti-hantavirus antibodies in a blood sample. These include immunoassays (Figure 30.3b and [Section 27.9](#)) that detect both exposure to the virus and the strength of the immune response. The presence of the viral RNA genome from circulating virions can also be detected using RT-PCR ([Sections 11.3 and 27.10](#)) on patient tissue or blood samples.

There is no virus-specific treatment or vaccine for hantavirus diseases. Treatment amounts to isolation, rest, rehydration, and alleviation of other symptoms. Hantavirus infection can be prevented by avoiding rodent contact and rodent habitat. Destruction of mouse habitat, restricting food supplies (for example, keeping human food in sealed containers), and aggressive rodent extermination measures are the only effective controls, since animal surveys have shown that in areas that have experienced a hantavirus outbreak, a high proportion of mice carry the virus.

II • Arthropod-Transmitted Bacterial and Viral Diseases

Pathogens can be spread to new hosts from the bite of an infected arthropod. In the bacterial and viral diseases we consider here—the rickettsial illnesses, yellow and dengue fevers, Lyme disease, and plague—humans are only *accidental hosts* for the pathogen. The *reservoir* of the pathogen is the arthropod vector. Nevertheless, the diseases can be devastating and often fatal.

30.3 Rickettsial Diseases

The **rickettsias** are small *Bacteria* that live an obligate intracellular existence and are associated with bloodsucking arthropods such as fleas, lice, or ticks. We discussed the biology of rickettsias in Section 15.1. Of the diseases that rickettsias can cause in humans and other vertebrates, the most important are *typhus fever*, *spotted fever rickettsiosis* (*Rocky Mountain spotted fever*),

and *ehrlichiosis*. Rickettsias have not been cultured in artificial culture media but can be grown in laboratory animals, ticks and lice, mammalian tissue culture cells, and the yolk sac of chick embryos (see Figure 30.6b). In animals, growth takes place primarily in phagocytes, such as macrophages.

Rickettsias are divided into three groups, based loosely on the clinical diseases they cause. The groups are (1) the *typhus group*, such as *Rickettsia prowazekii*; (2) the *spotted fever group*, such as *Rickettsia rickettsii*; and (3) the *ehrlichiosis group*, characterized by *Ehrlichia chaffeensis*.

Handling Viral Hemorrhagic Fever Viruses

The Special Pathogens Branch of the Centers for Disease Control and Prevention (CDC) specializes in the handling of a subgroup of dangerous viral pathogens, the *hemorrhagic fever viruses*. These viruses are the most lethal infectious agents known and cause a series of viral hemorrhagic fevers (VHFs), including hantavirus syndromes and Ebola.

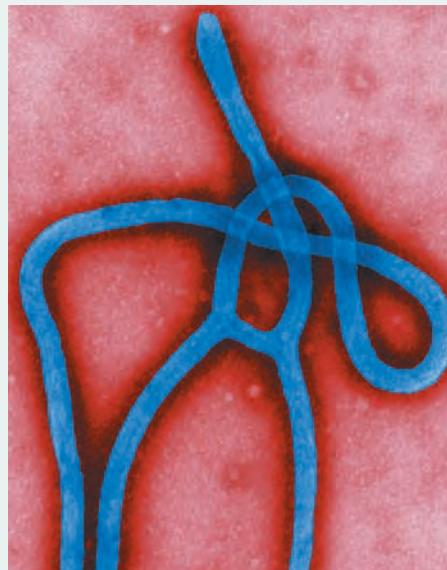

CDC/PHL, James Gathany

Figure 1 Biosafety level 4. Microbiologists suit up before entering the CDC BSL-4 lab. The suits supply filtered air and are positively pressurized to prevent back-flushing of laboratory air or particles.

Hemorrhagic fever viruses are handled under biosafety level 4 (BSL-4) standards (**Figure 1**). BSL-4 is the highest level of biological containment and is used only when working with samples that pose a high risk of life-threatening disease and for which no treatment or effective vaccines exist. VHF viruses are definitely in this category as they cause severe symptoms that affect multiple organ systems and show a high rate of mortality.

In the United States, the only endemic hemorrhagic fever viruses are the hantaviruses. With hantaviruses we understand the vectors and hosts and how to prevent human infections. However, with many hemorrhagic fever viruses, the vectors and mechanisms of transmission are unknown. For example, Ebola virus (**Figure 2**) is endemic in rural parts of central Africa and can spread quickly among humans. There have been seven major Ebola outbreaks in Africa since 1976, the latest in 2009, and the results have been devastating. For example, of 1748 confirmed cases of Ebola, 1162 have been fatal (67% mortality). Obviously, if Ebola were to infect a densely populated area, a major medical emergency would ensue. The primary goal of the Special Pathogens Branch is to see that something like this does not happen.

The overwhelmingly high mortality rates for VHFs makes them some of the most feared of diseases, and so research to produce vaccines and treatments is ongoing. In the meantime, the Special Pathogens Branch of the CDC remains focused on the current disease scene. The branch is charged with managing hantavirus patients in the United

States, developing diagnostic tools to identify known and emerging VHF viruses, and understanding the biology, pathology, and transmission of these dangerous pathogens. A major goal is to be able to predict outbreaks of VHFs, quickly identify them when they occur, and implement adequate measures to stop the outbreak quickly. mammalian host. During World War I, a typhus epidemic spread throughout Eastern Europe and caused almost 3 million deaths. Typhus has historically been a problem among troops in wartime. Because of the unsanitary, cramped conditions characteristic of wartime military operations, infected lice can spread easily among soldiers with devastating results. Up until World War II, typhus caused more military deaths than did combat.

Cells of *R. prowazekii* are introduced through the skin when a puncture caused by a louse bite becomes contaminated with louse feces that contain the rickettsial cells. During an incubation period of 1–3 weeks, the organism multiplies inside cells lining the small blood vessels. Symptoms of typhus (fever, headache,

and general body weakness) then begin to appear. Several days later, a characteristic rash is observed in the armpits and generally spreads over the body, except for the face, palms of the hands, and soles of the feet. Complications from untreated typhus include damage to the central nervous system, lungs, kidneys, and heart. Epidemic typhus has a mortality rate of as much as 30%. Tetracycline and chloramphenicol are most commonly used to control infections caused by *R. prowazekii*. *Rickettsia typhi*, the organism that causes murine typhus, is another important pathogen in the typhus group and can also infect humans. A typhus vaccine is available but is typically only administered to those traveling to typhus endemic areas.

(b)

Figure 30.4 Arthropod vectors of rickettsial diseases. (a) The female body louse, about 3 mm long, can carry *Rickettsia prowazekii*, the agent that causes typhus. In addition, the body louse can carry *Borrelia recurrentis*, the agent of relapsing fever, and *Bartonella quintana*, the agent of trench fever. (b) The American dog tick that carries *Rickettsia rickettsii*, the causative agent of Rocky Mountain spotted fever, is about 5 mm long, but can expand to three times this size when engorged with blood.

The Spotted Fever Group: *Rickettsia rickettsii*

Spotted fever rickettsiosis, commonly called *Rocky Mountain spotted fever* (RMSF), was first recognized in the western United States about 1900 but is more prevalent today in the central and mid-South region (Figure 30.5). RMSF is caused by *R. rickettsii* and is transmitted to humans by various ticks, most commonly the dog tick (Figure 30.4b) and wood ticks. Over 2000 people acquire RMSF yearly in the United States, a significant increase since 2002 which is probably due to increased human activities in tick-infested areas. Humans acquire the pathogen from the bite of an infected tick; rickettsial cells are present in the salivary glands of the tick and in the ovaries of female ticks.

Cells of *R. rickettsii*, unlike other rickettsias, grow within the nucleus of the host cell as well as in host cell cytoplasm (Figure 30.6a, c). Following an incubation period of 3–12 days, characteristic symptoms, including fever and a severe headache, occur. A few days later, a systemic rash breaks out (Figure 30.6d), generally accompanied by gastrointestinal problems

such as diarrhea and vomiting. The clinical symptoms of RMSF persist for over 2 weeks if the disease is untreated. Tetracycline or chloramphenicol generally promotes a prompt recovery from RMSF if administered early in the course of the infection, and treated patients have less than 1% mortality. Mortality in untreated cases resembles that of typhus, up to 30%. No effective vaccine against RMSF is currently available.

Ehrlichiosis and Tickborne Anaplasmosis

Ehrlichia and related genera (► Section 15.1) are responsible for two emerging tickborne diseases in the United States, *human monocytic ehrlichiosis* (HME) and *human granulocytic anaplasmosis*

The whole-body rash is indicative of spotted fever rickettsiosis and helps distinguish it from typhus, in which the rash does not cover the whole body.

The electron micrograph shows inclusions in a human monocyte that contain large numbers of *E. chaffeensis* cells. The blue arrows indicate two of the many bacteria in each inclusion. The *E. chaffeensis* cells are about 0.3–0.9 µm in diameter. Mitochondria are shown with red arrows.

(HGA). The pathogens that cause HME are *Ehrlichia chaffeensis* and *Rickettsia sennetsu*, and those that cause HGA are *Ehrlichia ewingii* and *Anaplasma phagocytophilum*.

The onset of these clinically indistinguishable rickettsial diseases is characterized by flulike symptoms that can include fever, headache, malaise, changes in liver function, and a reduction in white blood cell numbers. Peripheral blood leukocytes have visible inclusions of rickettsial cells, a diagnostic indicator for the diseases (Figure 30.7). The symptoms, except for the inclusions, are similar to other rickettsial infections, and can range from subclinical to fatal. Long-term complications for progressive untreated cases may include respiratory and renal insufficiency and serious neurological involvement.

HGA and HME are spread by ticks of various species, and mammalian reservoirs of the pathogens include deer, some rodents, and humans. In the United States, HGA occurs primarily in the upper Midwest and coastal New England, while HME is concentrated in the lower Midwest and the East Coast; together, almost 2000 cases are reported each year, with cases of HGA predominating. Diagnosis of rickettsial syndromes is not straightforward because the rash observed can be mistaken for other diseases, such as scarlet fever, or even measles or syphilis. Confirmation of a rickettsial disease requires immunological tests, including fluorescent antibodies or immunoassays, or PCR-based analyses that detect pathogen DNA.

Prevention of HGA and HME is best achieved either by avoiding tick habitat or by wearing tick-proof clothing and applying insect repellents containing diethyl-*m*-toluamide (DEET). It is also good practice to examine yourself carefully for ticks after hiking in tick habitat and to remove any ticks immediately, taking care to remove all tick mouthparts if the tick has already attached. Doxycycline, a tetracycline antibiotic, is the drug of choice for the treatment of HGA and HME. Vaccines are currently unavailable for the prevention of HGA and HME.

Q Fever

Q fever is a pneumonia-like infection caused by the obligate intracellular parasite *Coxiella burnetii*, a bacterium related to the rickettsias (Section 15.1). Although not transmitted to humans by an insect bite, *C. burnetii* cells are transmitted to animals such as sheep, cattle, and goats by insect bites, and from these reservoirs to humans. Domestic animals generally have inapparent infections, but may shed large quantities of *C. burnetii* cells in their urine, feces, milk, and other body fluids. Infected animals or contaminated animal products such as wool, meat, and milk are potential sources for human infection. The resulting influenza-like illness can progress to include prolonged fever, headache, chills, chest pains, pneumonia, and endocarditis (inflammation of the inner lining of the heart). In the United States, Q fever is most prevalent in rural states with large farm or ranch animal populations, and only about 150 cases are reported annually.

As for rickettsial infections, laboratory diagnosis of *C. burnetii* infection is typically made by immunological tests designed to measure host antibodies to the pathogen. Q fever responds well to tetracycline, and therapy should be started quickly in any suspected case to prevent endocarditis and heart valve damage. Q fever is also a potential biological warfare agent (Section 28.8).

30.4 Lyme Disease and *Borrelia*

Lyme disease is a tickborne disease that affects humans and other animals. Lyme disease was named for Old Lyme, Connecticut, where cases were first recognized, and is currently the most prevalent arthropod-borne disease in the United States. Lyme disease is caused by infection with a spirochete, *Borrelia burgdorferi* (Figure 30.8; Section 14.20), transmitted by a tick bite. The ticks that carry *B. burgdorferi* feed on the blood of

Figure 30.8 Scanning electron micrograph of the Lyme spirochete, *Borrelia burgdorferi*. A single cell is approximately 0.4 µm in diameter.

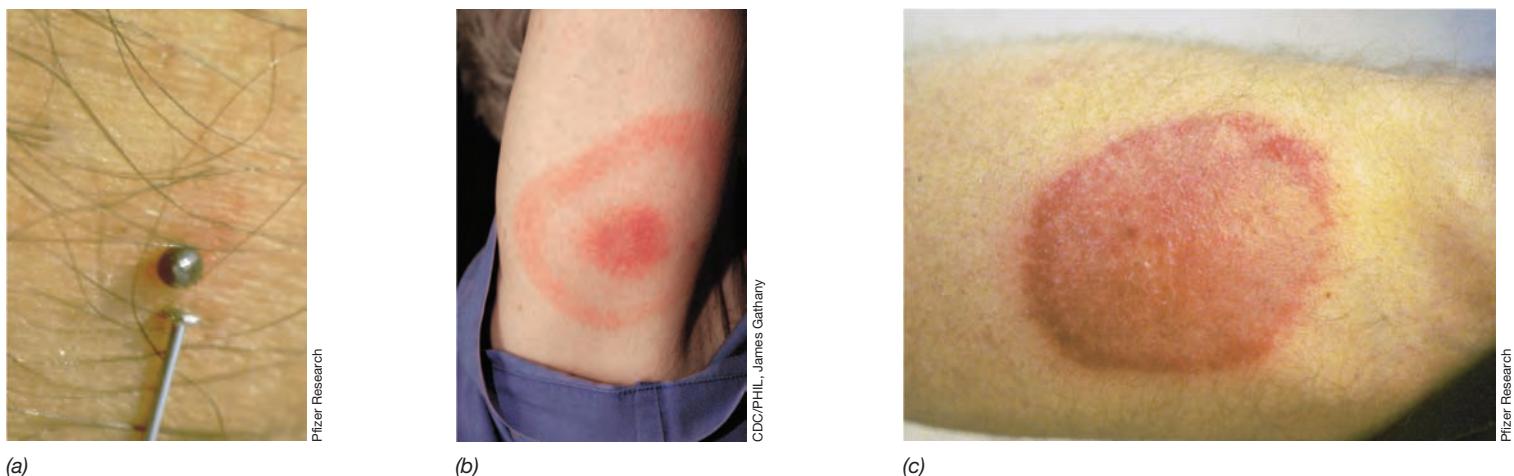

Figure 30.9 **Lyme disease infection.** (a) Transmission from a deer tick obtaining a blood meal from a human. (b), (c) Characteristic Lyme disease rash. The rash starts at the site of a tick bite and grows in a concentric circular fashion (b) or bull's-eye fashion (c) over a period of several days. A typical rash is about 5 cm in diameter.

birds, domesticated animals, various wild animals, and humans. *B. burgdorferi* is of interest in a nonmedical way as well, because it is one of only a handful of *Bacteria* that contain a linear (as opposed to a circular) chromosome (no linear chromosomes are known in *Archaea*) (see Section 4.3).

Pathology, Diagnosis, and Treatment of Lyme Disease

Cells of *B. burgdorferi* are transmitted to humans while the tick is obtaining a blood meal (Figure 30.9a). A systemic infection develops, leading to the acute symptoms of Lyme disease: headache, backache, chills, and fatigue. In about 75% of Lyme cases, a concentric circular or “bull’s-eye” rash forms within a week at the site of the tick bite (Figure 30.9b, c). During this acute stage, Lyme disease is readily treatable with tetracycline or penicillin.

Untreated cases of Lyme disease may progress to a chronic stage weeks to months after the initial tick bite, causing arthritis in about half of those infected. Neurological problems such as palsy, weakness in the limbs, and heart damage can also occur. In untreated cases, cells of *B. burgdorferi* infecting the central nervous system may lie dormant for long periods before causing additional chronic symptoms, including problems with vision and facial muscle movements, or seizures. Interestingly, the symptoms of chronic Lyme disease, especially neurological symptoms, mimic those of chronic syphilis, caused by a different spirochete, *Treponema pallidum* (see Sections 14.20 and 29.12). Unlike syphilis, however, Lyme disease is not spread person to person.

No toxins or other major virulence factors have been identified in Lyme disease pathogenesis, but the pathogen triggers a strong immune response. Antibodies to *B. burgdorferi* appear 4–6 weeks after infection and can be detected by various immunological assays. However, because antibodies to *B. burgdorferi* antigens persist for years after infection, the presence of these antibodies does not necessarily indicate a recent infection. A PCR assay (see Section 11.3) is also in use to detect *B. burgdorferi* DNA in body fluids and tissues. In practice, however, Lyme disease is typically diagnosed from clinical symptoms and only confirmed later by

laboratory assays. If a patient has Lyme disease symptoms and other findings such as facial tics or arthritis, or has had recent tick exposure or exhibits the characteristic Lyme rash (Figure 30.9), a presumptive diagnosis of Lyme disease is made and antibiotic treatment is initiated.

Treatment of early stage Lyme disease is usually with doxycycline or amoxicillin for 20 to 30 days. For patients having neurological or cardiac symptoms, the antibiotic ceftriaxone is administered intravenously because this drug crosses the blood–brain barrier and can thus kill spirochetes in the central nervous system.

Epidemiology and Prevention of Lyme Disease

Deer and white-footed field mice are prime mammalian reservoirs of *B. burgdorferi* in the northeastern United States, a hotbed of infection (see Figure 30.11). These animals become infected from bites by the deer tick, *Ixodes scapularis* (Figure 30.10), although some other ticks can transmit the Lyme spirochete as well. Lyme disease has also been identified in Europe and Asia. In these countries, both the tick vector and the species of *Borrelia* differ from those in the United States, which shows that Lyme

Confirmed and probable cases totaled over 36,000, with 96% of these localized to 13 states in the upper regions of the Midwest and East Coast. disease has a broad geographic distribution. But in all cases, Lyme disease is caused by related species of pathogenic *Borrelia* transmitted to humans by tick vectors.

Deer ticks are typically smaller than many other ticks, making them easy to overlook. Moreover, unlike the case with ticks that carry other tickborne diseases (Figure 30.4), a very high percentage of deer ticks carry *B. burgdorferi*. Both of these factors—small vector size and high occurrence of the pathogen—undoubtedly contribute to the fact that Lyme is the most commonly reported vectorborne disease in the United States. Most cases of Lyme disease in the United States have been reported from the Northeast and upper Midwest—areas of the country where deer are abundant—but cases have been observed in nearly every state (Figure 30.11). The incidence of Lyme disease in the United States is significant, with over 30,000 cases reported in 2011.

As for any tickborne infection, prevention of Lyme disease begins by avoiding contact with the vector. Insect repellents containing DEET or the wearing of snug-fitting clothing is helpful, as is a thorough body exam following walks in tick-infested environments. Lyme disease vaccines are available for domestic animals, but no human Lyme disease vaccine is currently in use.

30.5 Yellow Fever and Dengue Fever

Several arthropod-transmitted diseases are caused by flaviviruses. These are single-stranded plus-sense RNA viruses (see Section 9.8) transmitted by the bite of an infected arthropod. Because of this characteristic mode of transmission, these viruses are also called *arboviruses* (*arthropod-borne* viruses).

Many serious human diseases are caused by arboviruses including various types of encephalitis and hemorrhagic fevers. Here we consider two potentially fatal flavivirus diseases still common in developing countries, yellow fever and dengue. Both viruses are transmitted by the same vector, infected mosquitoes of the genus *Aedes* (Figure 30.12), and some of the disease symptoms are similar.

Yellow Fever

Yellow fever is an endemic disease of tropical and subtropical climates, especially in Latin America and Africa. Brazil, Colombia, Venezuela, and parts of Bolivia and Peru, along with most countries in sub-Saharan central Africa, experience the greatest incidence. Yellow fever is absent from the United States except in unvaccinated individuals who contract the disease through travel to an endemic area. Yellow fever virus is related to dengue virus (see later), West Nile virus (Section 30.6), and certain encephalitis viruses. Yellow fever is one of only a handful of infectious diseases for which isolation and quarantine are practiced (see Section 28.5). In the case of yellow fever, although the disease is not transmitted person to person, isolation of active cases prevents local mosquitoes from taking a blood meal from the infected individual and transmitting the disease to others.

Following a bite from an infected mosquito, the yellow fever virus replicates in lymph nodes and certain immune system cells

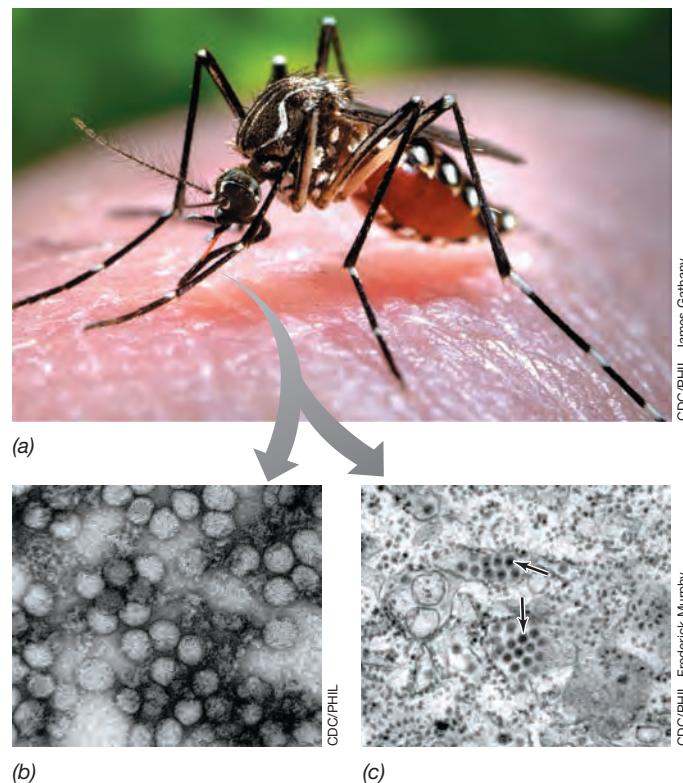

Figure 30.12 Yellow fever and dengue fever. (a) Yellow and dengue fever viruses are both transmitted by the bite of an infected *Aedes aegypti* mosquito. Transmission electron micrographs of (b) yellow fever virus and (c) dengue fever virus (arrows, in a tissue specimen). and eventually travels to the liver. Once a person is infected, symptoms range anywhere from none to major organ failure and death. Most infected individuals display a mild fever with accompanying chills, a headache and back pains, nausea, and other symptoms that are not diagnostically useful. Presumably these are cases in which the immune system has the infection under control. However, in about one in five yellow fever cases, the disease enters its toxic phase, characterized by jaundice (thus the name, *yellow fever*) and by hemorrhaging from the mouth, eyes, and gastrointestinal tract. This triggers the onset of bouts of bloody vomit, and if bleeding continues, it leads to toxic shock and multiple organ failure. About 20% of cases that reach this stage are fatal. Humans and nonhuman primates are the main reservoir for the yellow fever virus.

Yellow fever is fully preventable by an effective vaccine. A yellow fever vaccine was developed in the 1930s and widely used by military and support personnel in tropical battlefields. Historically, the disease has been controlled by a combination of vaccination and elimination of both the vector (mosquito) population by chemical agents and vector breeding grounds by draining swamps and low-lying wetlands in endemic areas.

The yellow fever vaccine is highly recommended for those traveling to endemic areas, and many countries require proof of vaccination for anyone entering their country from a foreign country where yellow fever is endemic. In addition, the World Health Organization (WHO) has initiated a mass vaccination program in Africa. Despite the availability of a vaccine, the WHO estimates that each year nearly 200,000 cases of yellow fever occur, mostly unreported, and that about 15% of all cases are fatal. No treatment for yellow fever is known. However, once the disease is diagnosed, typically by detecting anti-yellow fever virus antibodies in a blood sample, the patient is isolated and prescribed rest and drugs to control symptoms. Recovery without entering the toxemia stage is due to the immune response.

Dengue Fever

Like yellow fever, dengue (pronounced deng-gay) fever is transmitted by mosquitoes of the genus *Aedes* (Figure 30.12) and is a disease of tropical and subtropical regions. Up to 100 million cases of dengue are estimated worldwide per year with concentrations in Mexico, Latin America, India, Indonesia, and Africa (Figure 28.11).

Dengue begins with a high fever and headache or joint pains and in some patients, severe eye pain and a systemic rash. Most infected individuals show self-improvement within a week and no further symptoms, presumably because of an immune response to the dengue virus. But, as for yellow fever, a dengue infection can take a more severe course of events and proceed to *dengue hemorrhagic fever*. This condition is characterized by severe symptoms that can include bleeding from the nose and gums, bloody vomit and/or feces, intense abdominal pain, respiratory distress, and a general feeling of malaise. The blood pressure of a dengue patient can drop dramatically during the hemorrhagic fever stage and a small percentage of these cases are fatal. Treatment for dengue is primarily to relieve symptoms, particularly dehydration from loss of blood and other fluids. Unlike yellow fever, no effective vaccine exists for dengue, and thus rest and

symptom relief, even in cases of dengue hemorrhagic fever, is the only effective treatment.

Dengue can be controlled by eliminating either the vector or contact with the vector. Extensive chemical spraying for mosquito eradication was widely practiced in urban centers of the southern United States and kept dengue in check in the twentieth century. Now, however, spraying programs are less common and global climate change is moving tropical temperature patterns northward. In response, the *Aedes* mosquito has become entrenched in southern and central regions of the United States. Besides *Aedes aegypti* (Figure 30.12), the Asian tiger mosquito (*Aedes albopictus*), which is spreading quickly in the United States, also carries the dengue virus. Drainage of small puddles of water, such as those in discarded tires or other water traps, removes mosquito breeding grounds and greatly reduces the opportunities for a dengue outbreak. Personal protection from mosquito bites by using effective insect repellents and clothing is also a proven means of preventing infection.

The WHO estimates that nearly a half million cases of dengue hemorrhagic fever occur yearly with about 22,000 being fatal. Cases of dengue in the United States are rare, with virtually all of them being imported from endemic areas. Dengue is a prime example of an *emerging disease* (Section 28.7), since cases were geographically restricted until the mid-twentieth century when global commerce is thought to have transmitted species of the *Aedes* mosquito beyond their original range.

30.6 West Nile Fever

West Nile virus (WNV) causes **West Nile fever**, a human viral disease that is transmitted through the bite of a mosquito and thus is a seasonal disease. WNV is a flavivirus, as are the yellow fever and dengue viruses (Section 30.5), and has an enveloped capsid (Figure 30.13b) containing a plus-sense, single-stranded RNA genome (Section 9.8). The virus can invade the nervous system of its warm-blooded hosts, which include some species of both birds and mammals.

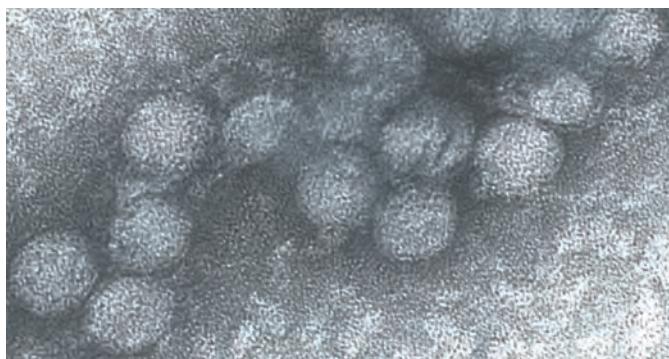

WNV Transmission and Pathology

WNV causes active disease in over 100 species of birds and is transferred to hosts by the bite of an infected mosquito. Over 40 species of mosquito can carry the virus including *Culex* species (Figure 30.13a), common in central and eastern states of the United States and in urban centers throughout the country. Infected birds develop a systemic viral infection (viremia) that is often fatal. Mosquitoes feeding on viremic birds are infected and can then infect other susceptible birds, renewing the cycle. In contrast to birds, humans and other animals are dead-end hosts for the virus because they do not develop the viremia necessary to infect mosquitoes.

Mortality rates for WNV infection are species-specific. For example, the human mortality rate from WNV is 4% while that for horses is significantly higher, near 40%. Most human infections are asymptomatic or mild and are not reported. After an incubation period of 3–14 days, about 20% of infected individuals develop West Nile fever, a mild illness lasting 3–6 days. The fever may be accompanied by headache, nausea, myalgia, rash, lymphadenopathy (swelling of lymph nodes), and malaise. Less than 1% of infected individuals develop serious neurological diseases such as *West Nile encephalitis* or *West Nile meningitis* from viral replication in neural tissues (Figure 30.14). These are more common in adults over age 50, and the neural effects may be permanent. About 5% of West Nile cases that progress to these forms are fatal. Diagnosis of WNV disease includes assessment of clinical symptoms followed by confirmation by immunological tests that detect WNV antibodies in blood.

Control and Epidemiology of WNV

Human WNV disease was first identified in the West Nile region of Africa in 1937 and spread from there to Egypt and

Israel. In the 1990s there were WNV outbreaks in horses, birds, and humans in African and European countries. In 1999, the first cases were reported in the United States in the Northeast, around New York. Within three years this emerging disease had shifted from the East Coast to the Midwest, with a peak reported number of cases in Illinois and a nationwide case total of 4156. Shortly thereafter the disease moved even farther west and by 2012, the majority of the total of 5674 cases reported were firmly entrenched in the central and south central United States and California (Figure 30.15). West Nile disease is now enzootic in the bird population in the United States and in only low incidence in the human population, its accidental host.

Control of WNV illness is much the same as for other vector-borne diseases: Limit exposure to mosquitoes using insect repellents or wear tight-fitting clothing. Spraying for mosquitoes has limited effectiveness, but removal of mosquito breeding grounds, particularly sources of standing water, is very helpful in controlling mosquito populations. A veterinary WNV vaccine is widely used in horses where mortality rates demand it, but no human WNV vaccine is currently available.

30.7 Plague

Plague has caused more human deaths than any other infectious disease except for malaria and tuberculosis (Chapter 1 Explore the Microbial World, “The Black Death Decoded”). Plague is primarily a zoonosis of wild rodents, but humans can become accidental hosts when rodent populations experience a die-off. Plague is caused by *Yersinia pestis*, a gram-negative, facultatively aerobic, rod-shaped, and encapsulated enteric bacterium (Section 15.3) that is easily grown in laboratory culture (Figure 30.16).

Pathology and Treatment of Plague

The pathogenesis of plague is not clearly understood, but cells of *Y. pestis* produce several virulence factors that contribute to the disease process. The V and W antigens in *Y. pestis* cell walls are protein-lipoprotein complexes that inhibit immune cell phagocytosis. *Murine toxin*, an exotoxin that is lethal for mice, is produced by virulent strains of *Y. pestis*. Murine toxin is a respiratory inhibitor that causes systemic shock, liver damage, and respiratory distress in mice. The toxin likely plays a role in human plague as well, because these symptoms are common in plague patients. *Y. pestis* also produces a highly immunogenic endotoxin that may play a role in the disease process.

Plague can occur in several forms (see Figure 30.19). *Sylvatic plague* is enzootic among wild rodents. Plague is transmitted by several species of fleas, a main one being *Xenopsylla cheopis*, the rat flea (Figure 30.17a). Fleas ingest *Y. pestis* cells in a blood meal and the bacterium multiplies in the flea's intestine. From there, the infected flea transmits the disease to rodents or humans in the next bite. The most common form of plague in humans is *bubonic plague*. In this case, cells of *Y. pestis* travel to the lymph nodes, where they replicate and cause swelling. The regional and pronounced swollen lymph nodes are called

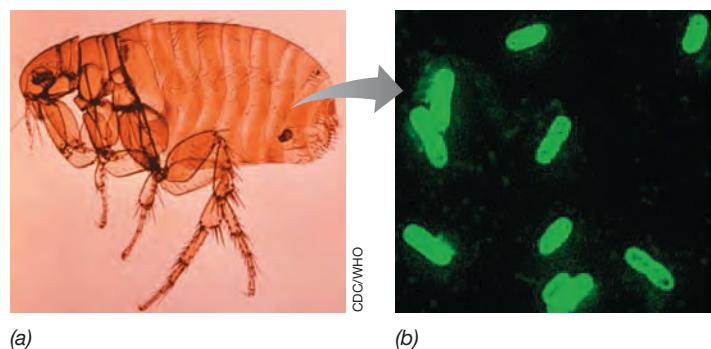

Figure 30.17 The rat flea, a major vector of plague. (a) The rat flea *Xenopsylla cheopis* carries cells of *Yersinia pestis*. The bacterium replicates in the flea gut and (b) cells of *Y. pestis* are transmitted to a host in a flea bite. The rat flea was the major vector for the pandemics of plague that ravaged medieval Europe in the fourteenth century. Cells in part b were stained with a fluorescent antibody prepared against *Y. pestis* cell surface antigens.

*bubo*s, and the disease gets its name from these structures (Figure 30.18a). The buboes become filled with *Y. pestis* cells, and the bacterium's capsule prevents phagocytosis and destruction by cells of the immune system. Secondary buboes form in peripheral lymph nodes, and cells eventually enter the bloodstream, causing septicemia. Multiple local hemorrhages produce dark splotches on the skin, giving plague its historical name, the “Black Death” (Figure 30.18b). If the infection is not treated quickly, the symptoms of plague (lymph node swelling and pain, prostration, shock, and delirium) usually progress and cause death within 3–5 days.

Pneumonic plague occurs when cells of *Y. pestis* are either inhaled directly or reach the lungs via the blood or lymphatic circulation. Significant symptoms are usually absent until the last day or two of the disease when large amounts of bloody sputum are produced. About 90% of untreated cases of pneumonic plague die within 48 h. Moreover, pneumonic plague is highly contagious and can spread rapidly from person to person if those infected are not immediately isolated. *Septicemic plague* is the rapid spread

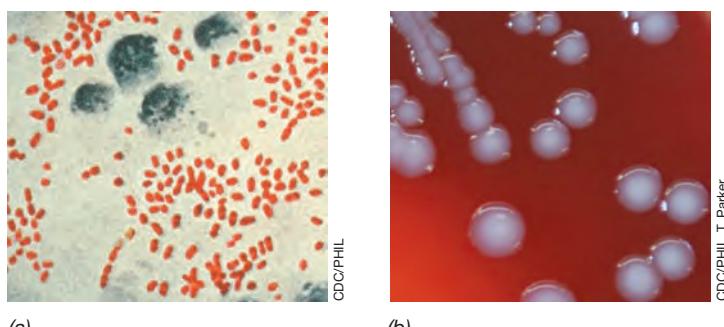

Figure 30.16 *Yersinia pestis*. (a) Blood smear containing cells of *Y. pestis* (red) and a few white blood cells. The bacterial cells are about 0.8 µm in diameter. (b) Colonies of *Y. pestis* grown on blood agar.

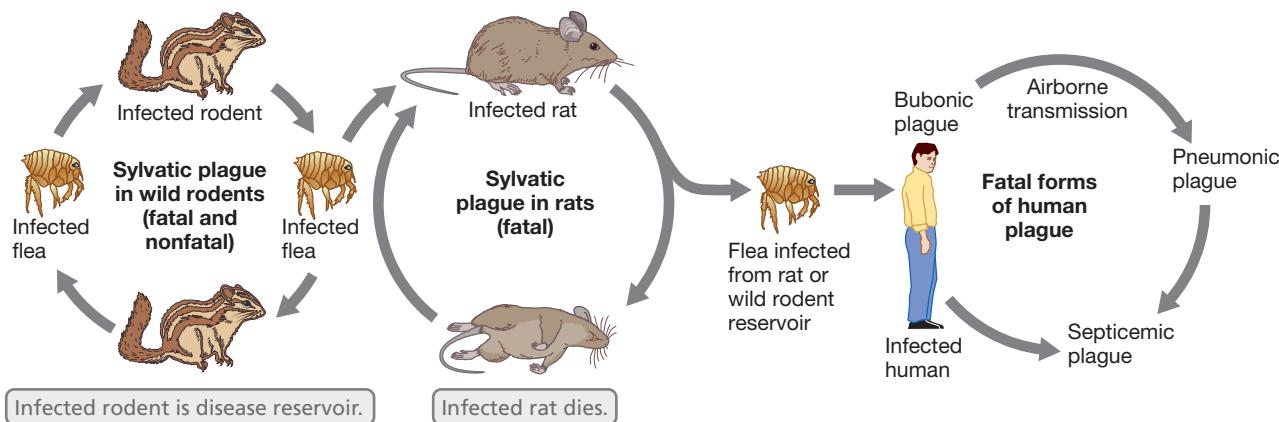

Figure 30.19 Plague epidemiology. In some wild rodents, sylvatic plague causes only a mild infection but diseased animals remain a reservoir of *Yersinia pestis*. In rodents that act as disseminating hosts, for example, rats, and in humans, plague is often fatal. When the domestic rodent reservoir dies off in an epidemic, infected fleas seek alternate hosts in humans.

of *Y. pestis* throughout the body via the bloodstream without the formation of buboes and is so severe that it usually causes death before a diagnosis can be made.

Bubonic plague can be successfully treated with streptomycin or gentamicin, administered by injection. Alternatively, doxycycline, ciprofloxacin, or chloramphenicol may be given intravenously. If treatment is started promptly, mortality from bubonic plague can be reduced to less than 5%. Pneumonic and septicemic plague can also be treated, but these forms progress so rapidly that antibiotic therapy, even if begun when symptoms first appear, is usually too late. *Y. pestis* is an organism that could be used for a bioterrorism attack (Section 28.8), and oral doxycycline and ciprofloxacin would be used as treatments in such a scenario.

Plague Epidemiology and Control

Sylvatic plague is enzootic in a variety of rodents including ground squirrels, prairie dogs, chipmunks, and mice; rats are the primary hosts in urban communities and were typically the hosts in episodes of sylvatic plague that triggered human pandemics during the Middle Ages. Fleas are intermediate hosts and vectors for plague, spreading the disease between rodent hosts and humans (Figure 30.19). Most infected rats or other rodents die soon after symptoms appear, but a small proportion of survivors develop a chronic infection, providing a persistent reservoir of *Y. pestis* cells to fuel new outbreaks.

Plague is endemic in developing countries in Africa, Asia, the Americas, and in south-central Eurasia; most cases occur in sub-Saharan Africa. Pandemic plague was historically associated with unsanitary surroundings, a major factor supporting large rat populations. In sparsely populated rural areas, this is not so great a problem as the disease runs its course when the rodent population dies off, leaving a shortage of hosts. But in urban centers where alternative hosts (humans) are plentiful, an outbreak of sylvatic plague can set the stage for a human plague epidemic. In the United States only a handful of cases of plague are diagnosed annually, mostly in the southwestern states where sylvatic plague is enzootic among wild rodents (Figure 30.19).

Plague control is accomplished through good sanitation practices, surveillance and control of rodent reservoirs and vectors (fleas), isolation of active cases, and imposing quarantine on those who have had contact with diseased individuals. Improved public health practices and the control of rodent populations are the major reasons that outbreaks of plague are extremely rare in developed countries.

III • Soilborne Bacterial Diseases

30.8 Anthrax

Some human diseases are caused by microorganisms whose major habitat is soil, and anthrax is an excellent example. We covered some aspects of the disease anthrax in Section 28.8 in the context of its use as a potential bioterrorism or biological warfare agent. Here we focus more on the biology of the organism and the disease process.

Discovery and Properties of Anthrax

The famous pioneering medical microbiologist Robert Koch (Section 1.8) first isolated the causative agent of the disease anthrax, the endospore-forming bacterium *Bacillus anthracis* (Figure 30.20a). Using mice caught in the wild as experimental animals, Koch used the disease anthrax to develop his principles for linking cause and effect in infectious disease—Koch's postulates

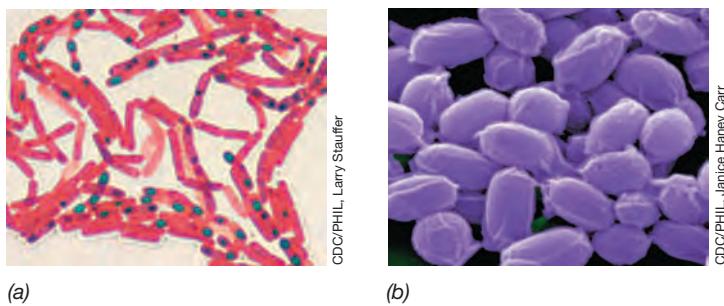

Figure 30.20 *Bacillus anthracis*. The anthrax pathogen produces endospores. (a) Light micrograph of a malachite green-stained smear of *B. anthracis* cells showing greenish-blue endospores. (b) Colorized scanning electron micrograph of *B. anthracis* endospores. Cells of *B. anthracis* are about 1.2 µm in diameter.

(Figure 1.20). Anthrax is quickly fatal in mice, but in humans, anthrax can take on several different forms, from mild to severe skin infections to respiratory failure and death.

Anthrax is an enzootic disease of worldwide occurrence. *B. anthracis* lives a saprophytic existence in soils, growing as an aerobic chemoorganotroph and forming endospores (Figure 30.20b) when conditions warrant. From soil, cells or spores of *B. anthracis* can become embedded in animal hair, hides, or other animal materials, or can be ingested, and from here the disease can develop, allowing *B. anthracis* spores to be transmitted to humans. Anthrax is primarily seen in domesticated farm animals, particularly in cattle, sheep, and goats, and is transmitted from them to humans.

Forms of Human Anthrax

The disease anthrax can manifest itself in one of three forms: cutaneous (on the skin), intestinal, and respiratory (inhalation anthrax). In all forms, disease symptoms are due to a series of toxins whose mode of action was discussed when we considered anthrax as a bioterrorism agent in Section 28.8. The different forms of anthrax show increasing severity, which is primarily a function of where in the body these toxins are excreted. The unusual protein capsule that surrounds cells of *B. anthracis* (Figure 30.21a) is also an important virulence factor as it prevents destruction of the bacterium following ingestion by macrophages. Instead, cells of *B. anthracis* grow within the macrophage, eventually killing it and giving it access to the bloodstream.

Virtually all cases of human anthrax are *cutaneous anthrax*, where spores of *B. anthracis* have entered through a skin lesion, germinate, and form a painless, black and swollen pustule (Figure 30.21b); this is highly characteristic of the disease and allows for a firm diagnosis even though human anthrax is rarely seen in clinical medicine. In cutaneous anthrax the bacterium usually remains localized and the disease is easily treatable. Although cutaneous anthrax is fatal for about 20% of those untreated, most cases are treated because of the obvious symptoms, and thus fatalities are rare. *Intestinal anthrax* is very uncommon and is triggered by the ingestion of spores of *B. anthracis* (Figure 30.20b) in undercooked meat from diseased animals. Symptoms of intestinal anthrax include abdominal pain, bloody diarrhea, and ulcer-like lesions throughout the intestinal tract. The disease

is still treatable at this stage but because of its rarity, diagnoses are easily missed. As a result, about half of all cases of intestinal anthrax are fatal.

Inhalation anthrax is the most severe form of the disease and is fatal in almost every case (Figure 30.21c, d). Inhalation anthrax occurs from the inhalation of endospores of *B. anthracis* and, along with cutaneous anthrax, is an occupational hazard for farm workers that process wool and hides (inhalation anthrax is also known as “woolsorter’s disease”). In inhalation anthrax, the organism enters the bloodstream from inhaled dust or animal dander and multiplies to become systemic. The mounting toxemia from this runaway growth of *B. anthracis* triggers septic shock and fluid accumulation in the lungs (Figure 30.21c) that can kill a patient in less than a day.

Prevention and Vaccines

Complete prevention of anthrax is impossible because the reservoir of the organism is the soil. However, anthrax is avoidable by limiting close exposure to farm animals and is easily treatable with antibiotics. For the cutaneous form this is a routine treatment, but antibiotic therapy is less effective in intestinal anthrax and especially in inhalation anthrax. By the time the latter is diagnosed, the disease has progressed to the point where it is usually too late to save the patient. An anthrax vaccine is available but because the disease is so rare, it is only recommended for high-risk individuals such as scientists working with the organism, slaughterhouse or livestock workers, and military personnel (for biowarfare reasons). An effective and inexpensive anthrax vaccine is available for vaccinating livestock and is commonly used in cattle, sheep, goats, and horses.

30.9 Tetanus and Gas Gangrene

Tetanus is a serious, life-threatening disease. Although tetanus is completely preventable through immunization, it still causes over 150,000 deaths per year, mostly in countries in Africa and Southeast Asia. **Gas gangrene** is caused by the growth in dead tissues of bacteria related to the tetanus pathogen, leading to a gassy putrefaction and loss of an infected limb or death from systemic shock. Both diseases are caused by clostridia.

Biology and Epidemiology of Tetanus

Tetanus is caused by an exotoxin produced by *Clostridium tetani*, an obligately anaerobic, endospore-forming rod (Figure 30.22a; ↗ Section 15.7). The natural reservoir of *C. tetani* is soil, where it is a ubiquitous resident, although it is occasionally found in the gut of healthy humans, as are other *Clostridium* species.

Cells of *C. tetani* normally gain access to the body through a soil-contaminated wound, typically a deep puncture. In the wound, anoxic conditions develop around the dead tissue and allow germination of endospores, growth of the organism, and production of a potent exotoxin, the *tetanus toxin*. *C. tetani* is essentially non-invasive; its sole ability to cause disease is through toxemia, and thus tetanus is observed only as the result of untreated deep tissue injuries. The onset of tetanus symptoms may take from four days to several weeks, depending on the number of endospores inoculated at the time of the injury.

Pathogenesis of Tetanus

We have already examined the activity of tetanus toxin at the cellular and molecular level (↗ Section 23.9). The toxin directly affects the release of inhibitory signaling molecules in the nervous system. These inhibitory signals control the “relaxation” phase of muscle contraction. The absence of inhibitory signaling molecules results in rigid paralysis of the voluntary muscles,

often called *lockjaw* because it is observed first in the muscles of the jaw and face. Preceding actual lockjaw, tetanus symptoms typically include mild spasms of facial muscles and muscles of the neck and upper back. Later on, the paralysis extends to the torso and lower body (Figure 30.22b). When tetanus is fatal, death is usually due to respiratory failure. Mortality is relatively high, occurring in about 10% of all reported cases, and up to 50% of cases in which treatment is delayed until generalized full body tetanus has set in.

Diagnosis, Control, Prevention, and Treatment of Tetanus

Diagnosis of tetanus is based on exposure, clinical symptoms (Figure 30.22b), and, rarely, identification of the toxin in the blood or tissues of the patient. The natural reservoir of *C. tetani* is the soil and thus control measures must focus on disease prevention rather than pathogen removal. The tetanus toxoid vaccine is highly effective, and thus virtually all tetanus cases occur in individuals who were inadequately immunized.

A second line of tetanus protection is to administer appropriate medical care to serious cuts, lacerations, and punctures. Even though vaccination against tetanus is widely practiced, any serious wound should be thoroughly cleaned and the damaged tissue removed. If the vaccination status of the individual is unclear or the last tetanus booster was more than 10 years ago, revaccination is recommended. If a deep wound is severe or heavily contaminated by soil, treatment might also include administration of a tetanus antitoxin preparation, especially if the patient's immunization status is unknown or is out of date.

Acute symptomatic tetanus (Figure 30.22b) is treated with antibiotics, usually penicillin, to stop growth and toxin production by *C. tetani*, and antitoxin is injected intramuscularly (or into the sheath surrounding the spinal cord if necessary) to prevent binding of newly released toxin to cells. Supportive therapy such as sedation, administration of muscle relaxants, and mechanical respiration may be necessary to control the effects of paralysis. Treatment cannot provide a quick reversal of symptoms, because toxin that is already bound to tissues cannot be neutralized. Even with antitoxin and antibiotic administration and supportive therapy, tetanus patients show significant morbidity and mortality. A complete recovery from tetanus often takes many months.

Gas Gangrene

Tissue destruction due to the growth of proteolytic and gas-producing clostridia is called **gas gangrene**. In this life-threatening condition, amino acids obtained from the breakdown of muscle proteins are fermented to the gases H₂ and CO₂ plus a variety of foul-smelling organic compounds, including short-chain fatty acids and other putrid molecules; ammonia released during amino acid fermentation (↗ Section 13.13) adds to the stench. In addition, a variety of bacterial toxins are produced that accelerate tissue destruction.

Although *C. tetani* is a proteolytic *Clostridium* species, it does not cause gangrene but can be associated with cases of gangrene triggered by a deep tissue wound. The most common causes of gangrene are *Clostridium perfringens* (Figure 30.23a), which is also a common cause of foodborne illness unrelated to gangrene,

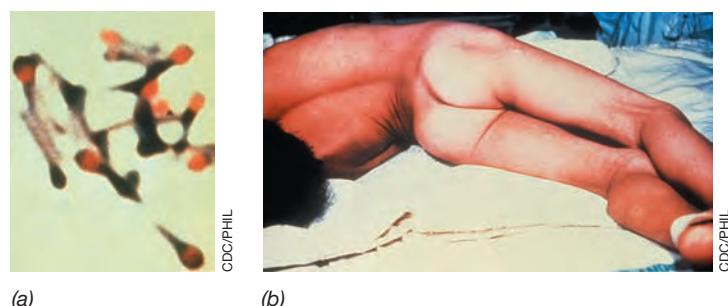

Figure 30.22 **Tetanus.** (a) *Clostridium tetani* showing the “drumstick” appearance of sporulating cells with their terminal endospores. Cells of *C. tetani* are about 0.8 µm in diameter. (b) A tetanus patient showing the rigid paralysis characteristic of tetanus. Tetanus paralysis typically begins with the facial muscles (“lockjaw”) and descends to lower body regions.

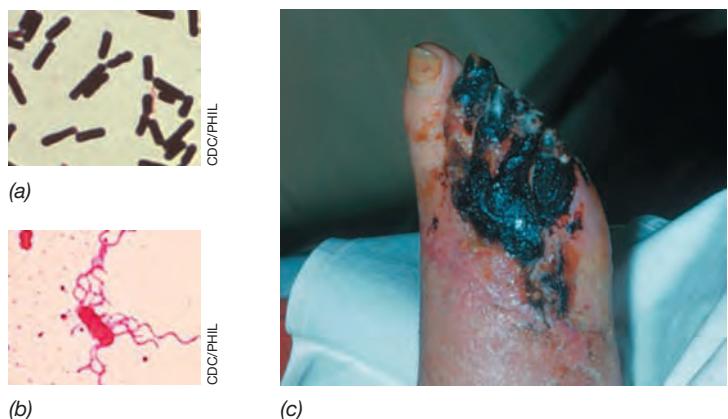

Figure 30.23 Gas gangrene. (a) Gram stain of cells of *Clostridium perfringens*, the most common cause of gangrene. (b) Flagellum stain showing a cell of *Clostridium novyi*, also an agent of gangrene. (c) A case of gas gangrene. Cells of both *C. perfringens* and *C. novyi* are about 1.2 μm in diameter.

C. novyi, and *C. septicum*. These organisms reside in soil and are also part of the normal human intestinal flora. When these species reach deep into tissues, typically from traumatic tissue invasion such as a war wound or other puncture wound, or occasionally from gastrointestinal tract surgery, spores and vegetative cells of proteolytic clostridia are inserted into what are now dead tissues. As the bacteria grow, they release enzymes that destroy collagen and tissue proteins and also excrete a series of toxins. *C. perfringens* (Figure 30.23a) *alpha toxin*, which is distinct from the toxins it produces in perfringens food poisoning (Section 31.9), is a major virulence factor in gangrene, as is the general

ability of the pathogens to grow rapidly in the warm, moist environment created by an invasive injury. Alpha toxin is a phospholipase that hydrolyzes the membrane phospholipids of host cells, leading to cell lysis and the typical accumulation of gas and fluids that accompanies gas gangrene (Figure 30.23c).

In severe cases of gas gangrene, the toxemia can become systemic and cause death. Antibiotic treatment is taken as a preventive measure in cases of gangrene in addition to the typical though dramatic treatment: amputation of the infected limb. Gangrenous tissues are dead and will not regenerate, and amputation prevents the infection from reaching healthy tissues.

Hyperbaric oxygen treatment of the infected limb is attempted in some cases to try to save it, with the high levels of O₂ inhibiting growth of the obligately anaerobic clostridia. In hyperbaric treatment, the patient sits in an enclosed chamber containing 100% O₂ at about twice atmospheric pressure. This enriches the blood in O₂ and helps still living blood vessels seed the formation of new tissue. Several hyperbaric treatments are administered and may be accompanied by surgical removal of some of the dead tissue. If an adequate blood supply can be established in damaged tissues, a skin graft may also be done to help connect regenerating with damaged tissues.

BIG IDEAS

30.1 • Rabies occurs primarily in wild animals but can be transmitted to humans and domestic animals. In the United States rabies is transmitted primarily from the wild animal reservoir to domestic animals or, very rarely, to humans. Vaccination of domestic animals is key to the control of rabies. Most human deaths from rabies occur in developing countries.

30.2 • Hantaviruses are present worldwide in rodent populations and cause zoonotic diseases such as hantavirus pulmonary syndrome and hemorrhagic fever with renal syndrome in humans. Hantavirus is a highly dangerous hemorrhagic fever virus related to Ebola. In the Americas, hantavirus infections have case fatality rates of over 30%.

30.3 • Rickettsias are obligate intracellular parasitic bacteria transmitted to hosts by arthropod vectors. The incidence of spotted fever rickettsiosis and other rickettsial syndromes is increasing due to several factors. Most rickettsial infections can be controlled by antibiotic therapy, but prompt recognition and diagnosis of these diseases remains difficult.

30.4 • Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is the most prevalent arthropod-borne disease in the United States today. Lyme is transmitted from several mammalian host vectors to humans by ticks. Prevention and treatment of Lyme disease are straightforward, but accurate and timely diagnosis of infection is essential.

30.5 • Yellow and dengue fevers are caused by related flaviviruses transmitted to humans by mosquito bites. Both

diseases are widespread in tropical and subtropical countries and both can show mild to very severe symptoms, including hemorrhagic fevers. An effective vaccine for yellow fever is in use, but no vaccine is available to prevent dengue infection.

30.6 • West Nile fever is a mosquito-borne viral disease. In the natural cycle of the pathogen, birds are infected with West Nile virus by the bite of infected mosquitoes. Humans and other vertebrates are occasional terminal hosts. Most human infections are asymptomatic and undiagnosed, but complications of some infections cause about 5% mortality.

30.7 • Plague can be transmitted to individuals who have had contact with rodent populations and their parasitic fleas, the enzootic reservoirs for the plague bacterium, *Yersinia pestis*. A systemic infection or a pneumonic infection leads to rapid death, but the bubonic form is treatable with antibiotics.

30.8 • Anthrax is caused by the endospore-forming bacterium *Bacillus anthracis* and can take on three different forms: cutaneous, intestinal, or inhalation. Cutaneous anthrax is most common and along with inhalation anthrax is an occupational hazard for livestock workers, where *B. anthracis* endospores can be transmitted from animal hides to humans.

30.9 • *Clostridium tetani* is a soil bacterium that causes tetanus, a potentially fatal disease characterized by a toxemia and rigid paralysis. Treatment for acute tetanus includes antibiotics and active and passive immunization, and the disease is preventable by toxoid immunization. Gas gangrene occurs from the growth of various proteolytic clostridia in traumatic wounds, leading to gas and toxin formation.

APPLICATION QUESTIONS

- Describe the sequence of steps you would take if your child received a bite (provoked or unprovoked) from a stray dog with no collar and record of rabies immunization. Present one scenario in which you were able to capture and detain the dog and another for a dog that escaped. How would these procedures differ from a situation in which the child was bitten by a dog that had a collar and rabies tag with documented, up-to-date rabies immunizations?
- Discuss at least three common properties of the disease agents and review the disease process for spotted fever rickettsiosis, typhus,

and ehrlichiosis. Why is ehrlichiosis emerging as an important rickettsial disease? Compare its emergence to that of Lyme disease.

- Devise a plan to prevent the spread of West Nile virus to humans in your community. Identify the relative costs involved in such a plan, both at the individual level and at the community level. Find out if a mosquito abatement program is active in your community. What methods, if any, are used in your area for the reduction of mosquito populations? What is a simple way to limit mosquito numbers around your residence?

Prison Pruno Packs a Life-Threatening Punch

Conditions inside prisons often drive prisoners to extremes. These include making homemade prison wine—a powerful drink called “pruno.” However, even if prisoners are relegated to a life behind bars, they are not immune to foodborne illnesses. And in the case of pruno, this can be a potentially fatal foodborne illness.

Pruno is made from a mixture of oranges, grapes, apples, and sugar, with potatoes, corn, or even bread sometimes thrown in. Each batch is unique and is a reflection of the ingredients available at the time. The ingredients (photo) are crushed in warm water, stored in a plastic bag, and allowed to ferment for up to 2 weeks. The fermented product is then strained through a sock or pillowcase to yield a yellowish-orange to red (depending on the ingredients) juice containing anywhere from 2 to 14% alcohol. The latter is similar to the alcohol content of a full-bodied red wine.

Since 2011, prison pruno has been linked to at least 20 cases of botulism, a severe form of food poisoning. In 2012, eight prisoners in the Arizona Correctional System nearly died from drinking pruno containing botulinum toxin.¹ All affected inmates were given botulinum antitoxin (antibodies that neutralize the botulinum toxin), and several required gastrointestinal intubation, a medical procedure used to remove intestinal contents. All inmates were lucky to survive what would have been certain death without medical intervention.

Botulism is caused by the gram-positive endospore-forming anaerobic bacterium *Clostridium botulinum*, commonly found in soil. In the Arizona and other outbreaks, the common ingredient in the tainted batches of pruno was raw potatoes. It is likely that spores of *C. botulinum* entered the fermenting pruno from soil on the potatoes, and the anoxic state of the brew was the perfect environment for growth and toxin production.

In this chapter we consider microbial pathogens whose mode of transmission is either water or food. The diseases these pathogens cause are called “common-source” diseases because they occur

only in those who have consumed the same contaminated water or eaten the same contaminated food. Waterborne and foodborne illnesses are common infectious diseases worldwide.

I • Water as a Disease Vehicle

Water is used in enormous quantities, and its microbiological safety rests in the hands of wastewater and drinking water engineers and microbiologists. Indeed, water quality is the single most important factor for ensuring public health. In Chapter 21 we examined the microbiology of wastewater and examined how highly polluted water can be cleaned by microbial activities and reused for many purposes, including for drinking. Here we see what can happen when water intended for human use becomes a vehicle for disease.

Waterborne diseases begin as infections (or occasionally as toxemias), and contaminated water may cause an infection even if only small numbers of the particular pathogen are present. Whether or not exposure causes disease is a function of the virulence of the pathogen and the ability of the host to resist infection.

31.1 Agents and Sources of Waterborne Diseases

Many different microorganisms can cause waterborne infectious diseases, and some of the major ones are summarized in **Table 31.1**. Waterborne pathogens include bacteria, viruses, and parasitic protists. Here we will consider bacterial pathogens with a major focus on cholera, a waterborne disease of pandemic proportions. We consider parasitic diseases in Chapter 32 and a few waterborne viral pathogens that are also transmitted in food later in this chapter.

^bSee Chapter 32.

We begin by considering the disease vehicle itself—water. Waterborne illnesses can be transmitted through untreated or improperly treated water used for drinking or food preparation or from water used for swimming and bathing (recreational water sources). The major waterborne illnesses traced to drinking water and recreational waters are typically quite different, and these different disease patterns are shown in **Table 31.2**.

Potable Water

Water supplies in developed countries typically meet rigid quality standards, greatly reducing the spread of waterborne diseases. Drinking water in particular undergoes extensive treatment that includes both filtration and chlorination. Although filtration removes turbidity and many microorganisms, it is *chlorination* that makes drinking water safe. Chlorine gas (Cl_2) is a strong oxidant and oxidizes both organic matter dissolved in the water and microbial cells themselves. Drinking water chlorination facilities add sufficient chlorine to allow a residual level to remain in the water all the way to the consumer. Water suitable for human consumption is called **potable** water (► Sections 21.6–21.9).

Despite filtration and chlorination, waterborne disease outbreaks from potable water occasionally occur. In the United States an average of 25 outbreaks of disease associated with drinking water are recorded in a year (a waterborne outbreak is defined as two or more human illnesses specifically linked to the consumption of the same water at the same time). Nearly 60% of drinking water disease outbreaks are due to *bacterial* pathogens, most notably *Legionella*, the causative agent of legionellosis (Table 31.2 and Section 31.4).

Recreational Waters

Recreational waters include freshwater aquatic systems such as ponds, streams, and lakes, as well as public swimming and wading

pools. Recreational waters can be sources of waterborne disease, and on average they cause disease outbreaks at levels slightly lower than those due to drinking water, about 20 outbreaks per year. In contrast to drinking water, where *bacterial* pathogens are most common, disease outbreaks from recreational waters are more frequently linked to *parasitic* pathogens. In addition, recreational waters often transmit gastrointestinal illnesses that are of either unknown microbial origin or due to chemicals or other toxic materials (Table 31.2).

In the United States, the operation of public swimming pools is regulated by state and local health departments. The United States Environmental Protection Agency (EPA) establishes limits for bacterial numbers in both potable and public recreational water sources, but local and state governments can set standards above or below these guidelines for nonpotable sources. By contrast, the water quality of *private* recreational waters, such as swimming pools, spas, and hot tubs is totally unregulated, and these are therefore prime vehicles for waterborne disease outbreaks.

MINIQUIZ

- What is potable water?
- Contrast the major pathogens responsible for disease outbreaks in drinking water versus recreational waters.

31.2 Public Health and Water Quality

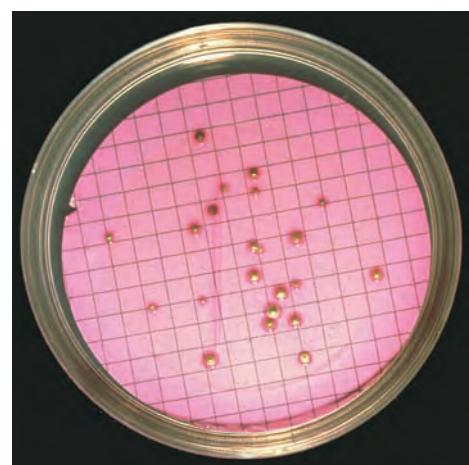

Water that looks perfectly transparent may still be contaminated with high numbers of microorganisms and thus pose a risk of disease. It is impractical to screen water for every pathogenic organism that may be present (Tables 31.1 and 31.2), and so both potable and recreational waters are routinely tested for specific *indicator organisms*, the presence of which signals the potential for waterborne disease.

Coliforms and Water Quality

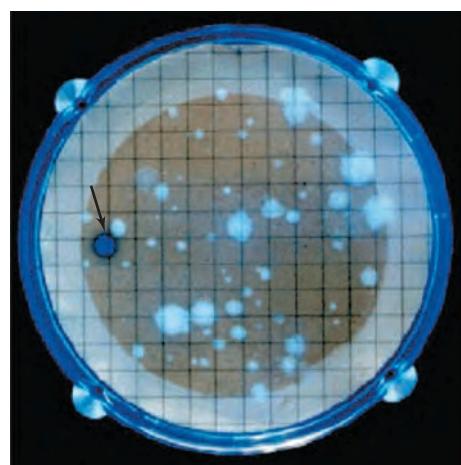

A widely used indicator for microbial water contamination is the **coliform** group of bacteria. Coliforms are useful because many of them inhabit the intestinal tract of humans and other animals. Thus, the presence of coliforms in water indicates likely fecal contamination. Coliforms are defined as facultatively aerobic, gram-negative, rod-shaped, nonsporulating bacteria that ferment lactose with the production of gas within 48 h at 35°C. However, this definition includes several bacteria that are not necessarily restricted to the intestine; for this reason, it is *fecal coliforms* that are important in water safety assessments. *Escherichia coli*, a coliform whose only habitat is the intestine and that survives only a relatively short time outside the intestine, is the key fecal coliform of interest. The presence of cells of *E. coli* in a water sample is taken as evidence of fecal contamination and means that the water is unsafe for human consumption. Conversely, however, the absence of *E. coli* does not ensure that a water source is potable, since other pathogenic bacteria or pathogenic viruses or protists may still be present.

Testing for Fecal Coliforms and the Importance of *Escherichia coli*

Well-developed and standardized methods are in routine use for detecting coliforms and fecal coliforms in water samples. A common method is the *membrane filter* (MF) procedure where at least 100 ml of freshly collected water is passed through a sterile membrane filter, trapping any bacteria on the filter surface. The filter is placed on a plate of eosin–methylene blue (EMB) medium, which is selective for gram-negative, lactose-utilizing bacteria. EMB medium is also differential, allowing strongly fermentative species such as *E. coli* to be distinguished from weakly fermentative species such as *Proteus* (Figure 31.1a).

(b)

(c)

A drinking water sample was passed through the filter and the filter placed on an eosin–methylene blue (EMB) agar plate (EMB is both selective and differential for coliforms; more strongly fermentative species form colonies with darker centers). (b) Total

coliforms and *Escherichia coli*. A filter exposed to a drinking water sample was incubated at 35°C for 24 hours on a medium containing special compounds that fluoresce when metabolized. The filter was then examined under UV light. The single *E. coli* colony in the sample fluoresces dark blue (arrow). Coliforms that do not metabolize the compound form colonies that

fluoresce white to light blue. (c) The IDEXX Colilert water quality test system. When specific reagents are added to water samples and incubated for 24 h, they develop a yellow color if they contain coliforms (right). Samples containing *Escherichia coli* develop a yellow color but also fluoresce blue (left). Samples negative for coliforms remain clear (center).

Selective media are also available that not only detect total coliforms but also specifically identify *E. coli* simultaneously. These *defined substrate tests* are typically faster and more accurate than EMB-based assays. One popular plate-based test is based on the ability of *E. coli* but not other enteric bacteria to metabolize a combination of two specific chemicals to form a fluorescent blue compound (Figure 31.1b). A commonly used liquid method reveals whether coliforms are present and also specifically detects *E. coli* in the water sample (Figure 31.1c).

In properly regulated drinking water supply systems, total coliform and *E. coli* fecal coliform tests should be negative. A positive test indicates that a breakdown has occurred in either the purification or distribution system (or both). In the United States, microbiological standards for drinking water are specified in the *Safe Drinking Water Act* and are administered by the Environmental Protection Agency (EPA). Water utilities must report coliform test results to the EPA monthly, and if they do not meet the

prescribed standards, the utilities must notify the public and take steps to correct the problem.

Major improvements in public health in the United States beginning in the early twentieth century were largely due to the adoption of water filtration and chlorination procedures in large-scale wastewater and drinking water treatment plants (➡ Figure 28.7). Where drinking water standards have not reached this level, especially in undeveloped countries, a variety of waterborne diseases are common. We turn our attention to these diseases now, beginning with cholera, the most widespread and devastating of all waterborne diseases.

II • Waterborne Diseases

31.3 *Vibrio cholerae* and Cholera

Cholera is a severe gastrointestinal diarrheal disease that is now largely restricted to countries in the developing world. Cholera is caused by ingestion of contaminated water containing cells of *Vibrio cholerae*, a gram-negative and motile curved species of *Proteobacteria* (Figure 31.2). Cholera can also be contracted from contaminated food, especially improperly cooked shellfish.

The ingestion of a large number ($>10^8$) of *V. cholerae* cells is required to cause disease. The ingested cells attach to epithelial cells in the small intestine where they grow and release *cholera toxin*, a potent enterotoxin (➡ Figure 23.23). Studies with human volunteers have shown that normal stomach acidity (about pH 2) is why the large inoculum of *V. cholerae* cells is needed to initiate disease. In studies with human volunteers, those given bicarbonate to neutralize gastric acidity develop cholera when given as few

as 10^4 cells. Even lower cell numbers can initiate infection if *V. cholerae* is ingested with food, presumably because the food protects the vibrios from destruction by stomach acidity.

Cholera enterotoxin causes severe diarrhea that can result in dehydration and death unless the patient is given fluid and electrolyte therapy. The enterotoxin causes fluid losses of up to 20 liters (20 kg or 44 lb) per person per day, causing severe dehydration. The mortality rate from *untreated* cholera is 25–50% and can be even higher under conditions of severe crowding and malnutrition as often occurs in refugee camps or in areas that have experienced natural disasters such as floods, earthquakes, and the like. In these situations there is often a near-complete breakdown in sanitation leading to the contamination of drinking water with feces and the rapid transmission of cholera.

Diagnosis, Treatment, and Prevention of Cholera

At treatment facilities in large outbreaks of cholera, each cholera patient is placed on a “cholera cot,” which is a conventional folding cot containing an opening into which feces can be voided (Figure 31.3a). The feces of a cholera patient are more liquid than solid, and confirmation of the disease is straightforward since the pathogen is easily cultured on selective agar media (Figure 31.3b–d). Cholera treatment is simple and effective. An oral (or in severe cases, intravenous) liquid and electrolyte replacement therapy is the most effective means of treatment. Oral treatment is preferred because no special equipment or sterile precautions are necessary. The rehydration solution is a mixture of glucose, salt (NaCl), sodium bicarbonate (NaHCO₃), and potassium chloride (KCl). If the solution is administered quickly during an outbreak, cholera mortality can be greatly reduced, as rehydration allows patients the time necessary to mount an immune response.

Antibiotics may shorten the course of cholera infection and the shedding of viable cells, but antibiotics are of little health benefit without simultaneous fluid and electrolyte replacement. Public health measures such as adequate sewage treatment and

Cholera cots are used during cholera outbreaks for treating active disease cases with rehydration therapy. (b) Feces from a cholera patient. The “rice-water” stool is mostly liquid (the solid material in the bottom is mucus). (c) *Vibrio cholerae* is easily cultured on medium TCBS, which is both selective and differential. TCBS contains high levels of bile salts and citrate, which inhibit enteric bacteria and gram-positive bacteria, and thiosulfate and sucrose, which cells of *V. cholerae* (d) use as a sulfur and carbon-energy source, respectively.

a reliable source of safe drinking water are the keys to preventing cholera. *V. cholerae* is eliminated from wastewater during proper sewage treatment and drinking water purification procedures (Chapter 21). For individuals traveling in cholera-endemic areas, attention to personal hygiene and avoidance of untreated water or ice, raw food, and raw or undercooked fish or shellfish that can feed on phytoplankton contaminated with *V. cholerae* (Figure 31.4) can prevent cholera.

Since 1817, cholera has swept the world in seven major pandemics with an eighth pandemic likely already started (Section 28.10 and Figure 28.17). The World Health Organization estimates that only 5–10% of cholera cases are reported, so the total worldwide incidence of cholera probably exceeds 1 million cases per year. Only a handful of cases of cholera are reported each year in the United States, typically from imported shellfish that are eaten raw or after only minimal cooking.

The *V. cholerae* cells are stained green by a fluorescently labeled antibody against a *V. cholerae* cell surface protein. The red color is from chlorophyll *a* fluorescence of the algae.

31.4 Legionellosis

Legionella pneumophila, the bacterium that causes *legionellosis*, is an important waterborne pathogen whose transmission was originally linked to aerosols from evaporative cooling devices. However, *L. pneumophila* (Figure 31.5) is now known to be a major pathogen in residential water systems as well, where the organism persists in biofilms that form on water distribution pipe surfaces and also within the cells of certain microbial parasites. In these sites, *L. pneumophila* is protected from the chlorine present in potable waters, and thus biofilms and infected parasites are reservoirs for transmitting legionellosis by a waterborne route (Section 21.9 and Figure 21.21).

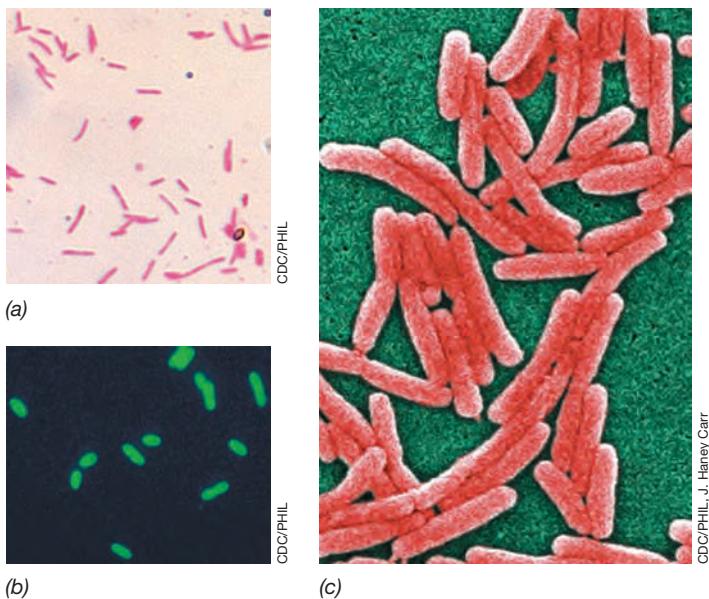

Figure 31.5 *Legionella pneumophila*. (a) Gram-stained cells of *L. pneumophila* from lung tissue of a legionellosis victim. (b) Cells of *L. pneumophila* can be positively identified using fluorescent anti-*L. pneumophila* antibodies. (c) Colorized scanning electron micrograph of *L. pneumophila* cells. Cells are about $0.5 \times 2 \mu\text{m}$.

Pathogenesis, Diagnosis, and Treatment

Cells of *L. pneumophila* invade the lungs and grow within macrophages and monocytes. Infections are often asymptomatic or produce only a mild cough, sore throat, mild headache, and fever; these self-limiting cases typically resolve themselves in 2–5 days. However, the elderly, whose resistance may be naturally reduced, and those with compromised immune systems often acquire more serious *Legionella* infections resulting in pneumonia. Prior to the onset of pneumonia, intestinal disorders, followed by high fever, chills, and muscle aches, are common. These symptoms precede the dry cough and chest and abdominal pains typical of legionellosis. Up to 10% of cases that reach this stage are fatal, usually due to respiratory failure.

Clinical detection of *L. pneumophila* infection is usually done by culture of the organism from bronchial washings, pleural fluid, or other body fluids or tissues (Figure 31.5a). Various serological tests can detect anti-*Legionella* antibodies or *Legionella* cells in these samples and also in patient urine, and this is used to confirm a diagnosis (Figure 31.5b). Legionellosis can be treated with the antibiotics rifampin and erythromycin, and intravenous administration of erythromycin is the treatment of choice for life-threatening cases.

Epidemiology

L. pneumophila is a gram-negative, obligately aerobic rod-shaped gammaproteobacterium (Figure 31.5), and shows complex nutritional requirements including an unusually high requirement for iron. The organism can be isolated from terrestrial and aquatic habitats as well as from legionellosis patients. *Legionella pneumophila* was first recognized as the pathogen that caused an outbreak of fatal pneumonia in Philadelphia (USA) in 1976. Besides legionellosis, the same bacterium can also cause a milder syndrome called *Pontiac fever*.

L. pneumophila is present in freshwaters and in soil. It is relatively resistant to heating and chlorination, so it can spread through drinking water distribution systems (Section 21.9). The pathogen is often found in large numbers in improperly sanitized cooling towers and evaporative condensers of large air conditioning systems. The pathogen grows in the water and is disseminated in humidified aerosols. Human infection is by way of airborne droplets, but the infection does not spread from person to person.

Besides evaporative coolers and domestic water systems, *L. pneumophila* has also been detected in hot water tanks and spas; in the latter, it can reach high cell numbers in warm ($35\text{--}45^\circ\text{C}$), stagnant water, especially if chlorine (or other sanitizer) levels are not maintained. Many outbreaks of legionellosis have been linked to swimming pools. *L. pneumophila* can be eliminated from water supplies by hyperchlorination or by heating water to greater than 63°C . Although incidence peaks in the summer months, epidemiological studies indicate that *L. pneumophila* infections can occur at any time of year, primarily as a result of aerosols generated from heating and cooling systems and contaminated premise water (Section 21.9) used for showering or bathing. In the United States, there are typically a few thousand cases of legionellosis reported each year.

31.5 Typhoid Fever and Norovirus Illness

Although cholera remains the most widespread and potentially dangerous of waterborne diseases, other waterborne pathogens also cause serious disease. We focus on two major ones here, the causative agents of typhoid (a bacterium) and norovirus gastrointestinal illness (an RNA virus).

Typhoid Fever

On a global scale, probably the most important waterborne bacterial pathogens are *Vibrio cholerae* (Section 31.3) and *Salmonella enterica* serovar Typhi, the organism that causes typhoid fever. *S. enterica* serovar Typhi is a gram-negative peritrichously flagellated bacterium related to *Escherichia coli* and other enteric bacteria (Figure 31.6a). The organism is transmitted in feces-contaminated water, and thus typhoid fever, like cholera, is primarily restricted to areas where sewage treatment and general sanitation are either absent or ineffective. Typhoid today is a well-entrenched endemic disease in sub-Saharan Africa, the Indian subcontinent, and Indonesia, but appears only sporadically in North America, Europe, northern Asia, and Australia.

Typhoid fever progresses in several stages. Cells of the pathogen (Figure 31.6a) ingested in contaminated water (or occasionally food) reach the small intestine where they grow and enter the lymphatic system and the bloodstream; from here, the pathogen can travel to many different organs. One to two weeks later, the first symptoms of typhoid appear; these include a mild fever, headache, and general malaise. During this period, the liver and spleen of the typhoid patient become heavily infected. About a week later, the fever becomes more intense (up to 40°C) and the

patient typically becomes delirious; diarrhea can occur in this stage and abdominal pain can be severe. Complications can follow, including intestinal bleeding and perforation of the small intestine. The latter releases large numbers of bacterial cells into the abdomen, leading to a condition called *sepsis* (systemic infection and inflammation) and possibly to septic shock; both are potentially fatal conditions (up to 40% of sepsis cases are fatal). After about a week in this crisis stage, the symptoms of typhoid begin to wane and recovery occurs.

In the United States, fewer than 400 cases of typhoid occur per year, but typhoid fever used to be a major public health threat before drinking water was routinely filtered and chlorinated (Figure 28.7). However, breakdown of water treatment methods, contamination of water during floods, earthquakes, and other disasters, or contamination of water supply pipes with leaking sewer lines can propagate epidemics of typhoid fever, even in developed countries.

In some typhoid patients, the gallbladder becomes infected with the pathogen. If these individuals also have gallstones, these can become colonized with *S. enterica* serovar Typhi cells and serve as a long-term reservoir of the pathogen from which it is continuously shed into feces and urine. Such individuals are otherwise

healthy “carriers” of typhoid and can transmit the disease over long periods. The notorious cook, “Typhoid Mary,” was the classic example of a typhoid carrier (Section 28.4).

Norovirus Illness

Viruses can be transmitted in water and cause human disease. Norovirus (Figure 31.6b) is one of these and is a common cause of gastrointestinal illness due to contaminated water (or food, Section 31.14). Norovirus is a single-stranded plus-sense RNA virus (Section 9.8) and is the leading cause of gastrointestinal illnesses worldwide (see Table 31.5).

Norovirus infection causes symptoms of vomiting, diarrhea, and malaise of relatively short duration. The disease is rarely fatal, although in compromised individuals (very young, elderly, or immune deficient), the significant dehydration that accompanies repeated bouts of norovirus-triggered vomiting and diarrhea can be life-threatening. A clinical diagnosis of norovirus gastrointestinal illness is made by a combination of observing symptoms and the direct detection of either viral RNA by RT-PCR (Sections 11.3 and 27.10) or viral antigens by enzyme immunoassay in samples of feces or vomit.

Norovirus disease is easily transmitted person to person or to food by the fecal–oral route. The infectious dose is very small, as exposure to as few as 10–20 norovirus virions (Figure 31.6b) is sufficient to initiate disease. The sources of waterborne norovirus outbreaks are most often well water or recreational waters that have been contaminated with sewage. Norovirus is also often the culprit when mass common-source gastrointestinal illnesses strike people on cruise ships or in long-term care facilities or other group settings. In these situations, the virus can be transmitted person to person, by contaminated food or water (usually food), or by any combination of these.

III • Food as a Disease Vehicle

The foods we eat, whether they are fresh, prepared, or preserved, are rarely sterile. Instead, they are almost always contaminated with spoilage microorganisms of various kinds and occasionally with pathogens. Microbial activities are key to the production of some foods, such as fermented foods, but most of the microorganisms in or on food are unwelcome and diminish either food quality or safety (or both). In this unit, we explore the contrasting processes of food spoilage and food preservation, how food safety is assessed, and the transmission of pathogens in food. In the next two units we focus on major foodborne diseases.

31.6 Food Spoilage and Food Preservation

Many foods provide an excellent medium for the growth of bacteria and fungi. Properly stored food can still undergo food spoilage

but is usually not a vehicle for disease assuming that it was free of pathogens to begin with. This is because with rare exception, organisms responsible for food spoilage are not the same as those that cause foodborne illnesses.

Food Spoilage

Food spoilage is any change in the appearance, smell, or taste of a food product that makes it unacceptable to the consumer, whether or not it is due to microbial growth. Foods are rich in organic matter and the physical and chemical characteristics of a food determine its susceptibility to microbial activity. With respect to spoilage, a food or food product falls into one of three categories: (1) **Perishable foods** include many fresh food items such as meats and many vegetables; (2) **semiperishable foods**

include foods such as potatoes, some apples, and nuts; and (3) **nonperishable foods**, such as sugar and flour. The foods in these categories differ primarily with regard to their *moisture content*, as measured by their water activity (a_w , [Section 5.15](#)). Nonperishable foods have low moisture levels and can generally be stored for long periods without spoilage. Perishable and semi-perishable foods, by contrast, typically have higher moisture levels and hence these foods must be stored under conditions that inhibit microbial growth.

Fresh foods can be spoiled by many different bacteria and fungi ([Table 31.3](#)). The chemical properties of foods vary widely, and each food is characterized by its moisture level and the nutrients it contains as well as other factors, such as its acidity or alkalinity. As a result, each susceptible food is typically spoiled by a specific group of microorganisms. The time required for a microbial population to reach a significant level in a given food product depends on both the size of the initial inoculum and the rate of growth during the exponential phase. Microbial numbers in a food product may initially be so low that no measurable effect can be observed, with only the last few cell doublings leading to observable spoilage. Hence, an unconsumed portion of a food product that is palatable and eaten one day can be badly spoiled the next.

The type of food spoilage and the microbial composition of the spoilage community ([Table 31.3](#)) are functions of both the food product and the storage temperature. Food spoilage microorganisms are often *psychrotolerant*, meaning that although they grow best at temperatures above 20°C, they can also grow at

refrigeration temperatures (3–5°C) ([Section 5.12](#)). However, at any given storage temperature, some species grow faster than others, and thus the composition of the microbial spoilage community of the same food product stored at different temperatures can vary significantly.

Food Preservation and Fermentation

Food storage and preservation methods are designed to slow or stop the growth of microorganisms that spoil food or that can cause foodborne disease. The major methods of food preservation include altering the temperature, acidity, or moisture level of the food, or treating it with radiation or chemicals that prevent microbial growth.

Refrigeration slows microbial growth but a remarkable number of microorganisms, particularly bacteria, can grow at refrigeration temperatures. Storage in the household freezer reduces growth considerably, but slow growth still occurs in pockets of liquid water trapped within the frozen food. In general, a lower storage temperature results in less microbial growth and slower spoilage, but storage at temperatures below –20°C is too expensive for routine use and also can negatively affect food appearance, consistency, and taste.

Heat reduces the bacterial load and can even sterilize a food product, and is especially useful for the preservation of liquids or high-moisture foods. The limited heat treatment of **pasteurization** ([Section 5.17](#)) does not sterilize liquids but reduces microbial numbers and eliminates pathogens. **Canning**, by contrast, typically sterilizes the food but requires careful processing in a sealed container at the correct temperature for the correct length of time. If viable microorganisms remain in a can or glass jar, their growth can produce gas, resulting in bulges or even explosions ([Figure 31.7](#)). The environment inside a can or sealed jar is anoxic, and an important genus of anaerobic bacteria that can grow in canned foods is the endospore-forming *Clostridium*, one species of which causes botulism ([Section 31.9](#)).

Foods can be made drier by either physically removing the water or by adding solutes, such as salt or sugar. Extremely dry or solute-loaded foods help prevent bacterial growth, but spoilage

can still occur and when it does, it is typically from fungi. Many foods are preserved by the addition of small amounts of antimicrobial chemicals. These chemicals, which include nitrates, sulfites, propionate, and benzoate along with a few others, find wide application in the food industry for enhancing or preserving food texture, color, freshness, or flavor. Although not widely practiced in many countries, the *irradiation* of food with ionizing radiation is also an effective means for reducing microbial contamination.

Many common foods and beverages are preserved through the metabolic activities of microorganisms; these are *fermented foods* (Figure 31.8 and Table 31.4). The fermentation process (Chapters 3 and 13) yields large amounts of preservative chemicals. The major bacteria important in the fermented foods industry are organic acid-producing bacteria such as the lactic acid bacteria (in fermented milks), the acetic acid bacteria (in pickling), and the propionic acid bacteria (in certain cheeses) (Table 31.4). The yeast *Saccharomyces cerevisiae* produces alcohol as the preservative in the production of alcoholic beverages. The high level of organic acids or alcohol generated from these fermentations prevents the growth of both spoilage organisms and pathogens in the fermented food product.

31.7 Foodborne Diseases and Food Epidemiology

Foodborne illnesses resemble waterborne illnesses in being *common-source* diseases. Most foodborne disease outbreaks are due to improper food handling and preparation by domestic consumers;

these typically affect only a few people and are rarely reported. However, occasional disease outbreaks due to breakdowns in safe food handling and preparation at restaurants or food-processing and distribution plants can affect large numbers of people in geographically widespread regions.

Foodborne Diseases and Microbial Sampling

The most prevalent foodborne diseases in the United States are *food infections* and *food poisonings*; some foodborne diseases fall into both categories. Food infections are the most common foodborne illnesses in the United States and account for four of the top five leading foodborne illnesses. Table 31.5 lists the major microorganisms that cause food infections and food poisonings in the United States.

Eight microorganisms account for the great majority of foodborne illness, hospitalizations, and deaths in the United States: *Salmonella* species, *Clostridium perfringens*, *Campylobacter jejuni*, *Staphylococcus aureus*, *Listeria monocytogenes*, and *Escherichia coli* (all bacteria); norovirus; and *Toxoplasma* (a protist) (Table 31.5). Four of these—norovirus, *Salmonella*, *C. perfringens*, and *Campylobacter*—account for nearly 90% of all foodborne illness, with norovirus (Sections 31.5 and 31.14) being the most common culprit (60%).

^aData from the Centers for Disease Control and Prevention, Atlanta, Georgia, USA.^bFP, food poisoning; FI, food infection.^cThe number in parentheses is the rank of the top five foodborne pathogens in the United States.^dAll of these protists are discussed in Chapter 32.

Food poisoning, also called **food intoxication**, results from ingestion of foods containing preformed microbial toxins. The microorganisms that produced the toxins do not have to grow in the host and may not even be alive at the time the contaminated food is consumed; ingestion and activity of the toxin is what causes the illness. We previously discussed some of these toxins, notably the exotoxin of *Clostridium botulinum* and the superantigen toxins of *Staphylococcus* and *Streptococcus* (Sections 23.9 and 24.9). In contrast to food poisoning, **food infection** occurs from the ingestion of food containing sufficient numbers of viable pathogens to cause colonization and growth of the pathogen in the host, ultimately resulting in disease.

Rapid diagnostic methods that do not require culturing an organism have been developed to detect important food pathogens and many of these were described in Chapter 27. Isolation of pathogens from foods usually requires preliminary treatment of the food to suspend microorganisms embedded or entrapped within. A standard method for this purpose employs a blender called a *stomacher* (Figure 31.9), a device to process food samples

Figure 31.9 A **stomacher**. Paddles in this specialized blender homogenize the food sample in a sealed and sterile bag. The sample is first suspended in a sterile solution to form a uniform mixture.

sealed in sterile bags. Paddles in the stomacher crush, blend, and homogenize the samples in a fashion resembling the peristaltic action of the stomach but under conditions that prevent contamination. The homogenized samples are then analyzed for specific pathogens or their products.

In addition to identifying pathogens in the food itself, disease investigators must also recover the foodborne pathogen from the diseased patient in order to establish a cause-and-effect relationship between the pathogen and the illness. In fact, identification of the *same strain* of a particular pathogen in patients and the suspected contaminated food is the “gold standard” for linking cause and effect in a foodborne disease outbreak, and a variety of microbiological, immunological, and molecular techniques are available for these purposes (Chapter 27).

Foodborne Disease Epidemiology

An outbreak of foodborne disease can occur in a home, a school cafeteria, a college dining hall, a restaurant, a military mess hall, or anywhere a contaminated food is consumed by many individuals. In addition, central food-processing plants and distribution centers provide opportunities for contaminated foods to cause disease outbreaks far from where the food was originally processed. It is the job of the food epidemiologist to track disease outbreaks and determine their source, often down to the precise location in which the food was contaminated.

A good example of effective foodborne disease tracking is the outbreak caused by *Escherichia coli* O157:H7 (see Section 31.11 and Figure 31.14) in the United States in 2006. Through culturing and molecular studies, this outbreak was linked to the consumption of contaminated packaged spinach and was quickly traced to a food-processing facility in California. The contaminated

spinach was distributed nationwide from the California plant, but most disease cases were in the Midwest. In the summer of 2013, another “packaged” outbreak occurred in the Midwest but in this case was linked to lettuce instead of spinach and to the parasite *Cyclospora cayetanensis* (☞ Section 32.4) instead of to the bacterium *E. coli*.

To be effective, foodborne disease trackers must work quickly. For example, when the first case in the *E. coli* spinach outbreak appeared in late August, a link to the specific spinach product was made less than a month later. Because *E. coli* O157:H7 has been well studied, public health officials were able to quickly identify the strain contaminating the bagged spinach. Authorities then traced this strain back to the processing plant and eventually identified a specific agricultural field near the processing plant as the source of the pathogen. Although it remains unclear how the spinach was contaminated, domestic animal manure was the likely source. During the outbreak, two foodborne disease surveillance networks, *FoodNet* (Centers for Disease Control and

Prevention) and *PulseNet* (an international molecular typing network for foodborne diseases) played important roles in exposing and ending the outbreak.

The spinach *E. coli* epidemic, although serious and even deadly for some, was discovered, contained, and stopped very quickly. However, this incident shows how centralized food-processing facilities can quickly spread disease to distant populations. Because of this, food hygiene standards and surveillance must be maintained at the highest possible level at all times in restaurants and central food-processing and distribution facilities.

IV • Food Poisoning

Food poisoning can be caused by various bacteria and a few fungi. Here we consider *Staphylococcus aureus*, *Clostridium botulinum*, and *Clostridium perfringens*, the most common causes of bacterial food poisoning. Two of these bacteria—*S. aureus* and *C. perfringens*—are part of the “top five” causes of foodborne illness (Table 31.5).

31.8 Staphylococcal Food Poisoning

A powerful form of food poisoning is caused by enterotoxins produced by the gram-positive bacterium *Staphylococcus aureus* (Figure 31.10; ☞ Section 15.7). This organism is commonly associated with the skin and upper respiratory tract and is a frequent cause of pus-forming wounds (☞ Section 29.9 and Figure 29.30). *S. aureus* can grow aerobically or anaerobically in many common foods and produces heat-stable enterotoxins. When consumed, the toxins cause gastrointestinal symptoms characterized by one or more of nausea, vomiting, diarrhea, and dehydration. The onset of symptoms is rapid, within 1–6 h of ingestion depending

on the amount of enterotoxin consumed, but the symptoms usually pass within 48 h.

Staphylococcal Enterotoxins

S. aureus can produce several related enterotoxins. Many of these are fairly heat-stable and all are stable to stomach acidity. Most strains of *S. aureus* produce only one or two of these toxins, and some strains are nonproducers. However, any one of the staph enterotoxins can cause food poisoning. The toxins pass through the stomach to the small intestine and trigger disease symptoms from there. Besides their normal gastrointestinal activities, staph enterotoxins are also *superantigens* and can lead to potentially lethal toxic shock syndrome (☞ Sections 23.9 and 24.9).

S. aureus enterotoxins are given acronyms beginning with “SE” (for “staphylococcus enterotoxin”): SEA, SEB, SEC, and SED, which are encoded by the genes *sea*, *seb*, *sec*, and *sed*. Not all of these genes are on the *S. aureus* chromosome but their sequences show them to be highly related. The genes *seb* and *sec* are encoded on the bacterial chromosome, *sea* on a lysogenic bacteriophage (☞ Section 8.8), and *sed* on a plasmid. The phage- and plasmid-encoded genes can transfer the ability to make toxin to non-toxicogenic strains of *Staphylococcus* by horizontal gene transfer (Chapter 10). SEA is the most common cause of staph food poisoning worldwide.

Disease Properties and Prevention

Foods may contain cells of *S. aureus* for several reasons. The organism may have been present on the food source itself; for example, on a meat product. But more commonly, cells of *S. aureus* are introduced to the food by contamination from the food preparer or by contamination of the food product with raw meat or a contaminated sauce or dressing. A common scenario for a staph food poisoning incident is when a food preparer introduces *S. aureus* from nasal secretions or from an uncovered skin

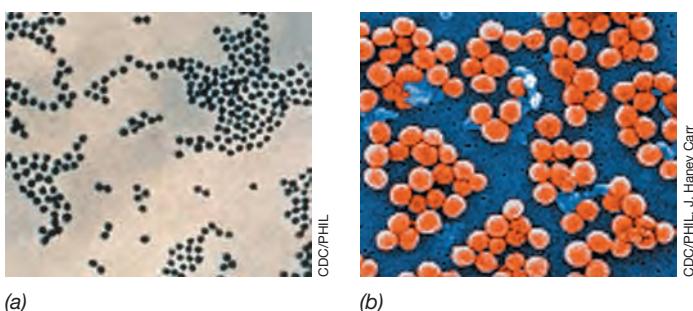

Figure 31.10 *Staphylococcus aureus*. (a) Gram-stained light micrograph showing the typical “cluster of grapes” morphology of staphylococci. (b) Colored scanning electron micrograph of cells of *S. aureus*. A single cell is about 0.8 µm in diameter.

wound or leaking bandage into the food during its preparation. If the contaminated food is then stored at room temperature or above, the stage is set for the rapid growth of *S. aureus* and the production of staph enterotoxins.

Each year there are an estimated nearly quarter million cases of staphylococcal food poisoning in the United States. The foods most commonly implicated are custard- and cream-filled baked goods, poultry, eggs, raw and processed meat, puddings, and creamy salad dressings. Salads prepared with mayonnaise-based dressings or those that contain shellfish, chicken, pasta, tuna, potato, egg, or meat, are also common vehicles. Salted foods such as ham can be vehicles because of the ability of *S. aureus* to grow quickly in salty environments (☞ Section 29.9). If any of these foods are contaminated with *S. aureus* but are refrigerated immediately after preparation, they usually remain safe because the organism grows poorly at low temperatures. But if enterotoxin has already been produced, mild heating may not make the food safe, as staph enterotoxins are stable to 60°C.

Treatment of staph food poisoning with antibiotics is not useful because any ingested cells of *S. aureus* have already been killed by the acidity in the stomach and antibiotics have no effect on the enterotoxins. As for any foodborne illness, staphylococcal food poisoning can be prevented by proper sanitation and hygiene in food production, preparation, and storage. In this regard, food preparers should practice thorough and frequent handwashing, prevent foods from coming into contact with nasal tissues and secretions, and routinely wear and frequently change disposable gloves when handling food products, especially if they have a bandaged hand wound.

31.9 Clostridial Food Poisoning

The endospore-forming anaerobic bacteria *Clostridium perfringens* and *Clostridium botulinum* (☞ Section 15.8) cause serious food poisoning. Canning and cooking procedures kill vegetative cells of these species but may not kill all endospores. If this occurs, viable endospores in the food can germinate and the resulting cells produce toxins.

There is a clear distinction in the disease process between perfringens food poisoning and botulism. In the case of botulism, the toxin is a neurotoxin and only the toxin is required for disease; growth of *C. botulinum* in the human body is not required but may occur, particularly in cases of infant botulism. By contrast, with perfringens food poisoning, a large number of cells must be ingested in order for the toxin—in this case, an enterotoxin—to be produced.

Clostridium perfringens Food Poisoning

Clostridium perfringens (Figure 31.11a) is commonly found in soil but can also be found in sewage, primarily because it lives in small

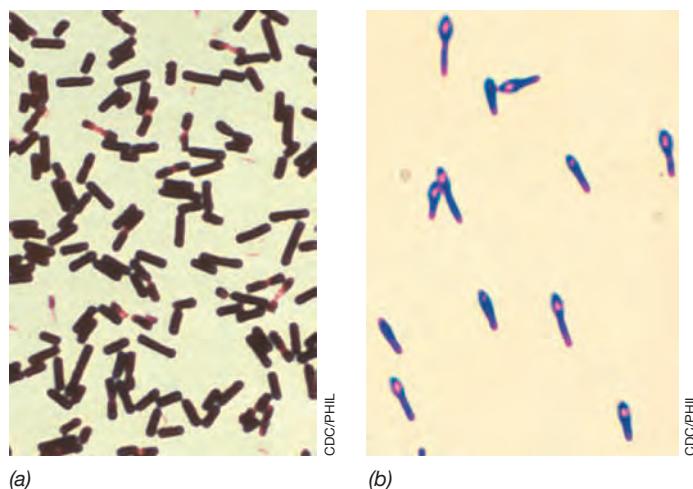

Figure 31.11 Food poisoning clostridia. (a) Gram stain of a growing culture of *Clostridium perfringens*, the bacterium that causes perfringens food poisoning. numbers in the intestinal tract of humans and other animals. *C. perfringens* is the third most often reported cause of food poisoning in the United States behind norovirus illnesses (Sections 31.5 and 31.14) and *Salmonella* infections (Section 31.10 and Table 31.5). In 2011, nearly 1 million perfringens cases were estimated to have occurred in the United States.

C. perfringens is a proteolytic bacterium; proteins are catabolized by fermentation (☞ Section 13.13). Perfringens food poisoning requires the ingestion of a large dose ($>10^8$) of *C. perfringens* cells in contaminated cooked or uncooked foods, usually high-protein foods such as meat, poultry, and fish. *C. perfringens* can grow in meat dishes cooked in bulk where heat penetration is often insufficient. *C. perfringens* grows quickly in the food, especially if left to cool at room temperature. It is when sporulation begins that the perfringens enterotoxin is produced. The toxin alters the permeability of the intestinal epithelium, leading to nausea, diarrhea, and intestinal cramps. The onset of perfringens food poisoning typically begins 7–15 h after consumption of the contaminated food and usually resolves within 24 h; fatalities from perfringens food poisoning are rare.

A diagnosis of perfringens food poisoning is made from isolation of *C. perfringens* from the feces or, more reliably, by an immunoassay that can detect *C. perfringens* enterotoxin in feces. Prevention of perfringens food poisoning requires that cooked foods not be contaminated with raw foods and that all foods be properly heated during cooking and home canning. The perfringens enterotoxin is heat-labile and thus any toxin that may have formed in a food product is destroyed by proper heating (75°C). Cooked foods should be refrigerated as soon as possible to rapidly lower temperatures and inhibit the growth of any *C. perfringens* that may have been present.

Botulism

Botulism is a severe and potentially fatal food poisoning caused by the consumption of food containing the exotoxin produced by *C. botulinum* (Figure 31.11b and see page 903). This bacterium

normally inhabits soil or water, but its cells or endospores may contaminate raw and processed foods. If viable endospores of *C. botulinum* remain in the food, they may germinate and produce botulinum toxin; ingesting even a small amount of this highly poisonous substance can cause severe illness or death.

Botulinum toxin is a neurotoxin that affects autonomic nerves that control key body functions such as respiration and heartbeat; the typical result is a flaccid paralysis (see Section 23.9). At least seven distinct botulinum toxins are known. Because the toxins are destroyed by heat (80°C for 10 minutes), thoroughly cooked food, even if contaminated with toxin, is harmless. Much foodborne botulism is from improperly processed home-canned foods, especially nonacidic foods such as corn and beans. Any viable *C. botulinum* endospores that remain in the sealed (and now anoxic) jar may germinate during storage and produce toxin. Many of these foods are used without cooking when making cold salads, and hence any botulinum toxin present is not destroyed. Prevention of foodborne botulism thus requires careful attention to canning and related food preservation practices.

Although infants can be poisoned by toxin-contaminated food, the majority of infant botulism cases occur from toxin produced following actual *infection* of the infant with *C. botulinum*. This occurs most commonly in newborns up to about 2 months of age because they lack a well-developed intestinal microflora that can outcompete *C. botulinum*. Ingested *C. botulinum* endospores germinate in the infant's intestine, triggering growth and toxin

production. Wound botulism can also occur from infection, presumably from endospores in contaminating material introduced via a parenteral route. Wound botulism is most commonly associated with illicit injectable drug use.

All forms of botulism are rare. In the United States about 150 cases are observed each year with about 70% being infant, 15% wound, and 15% foodborne. Botulism, however, is very serious because of the high mortality associated with untreated disease. Because most cases are diagnosed and treated, less than 5% of all botulism cases result in death. Botulism is diagnosed when either botulinum toxin or *C. botulinum* cells are detected in the patient (or in the contaminated food) coupled with clinical observations of localized paralysis (impaired vision and speech) beginning 18–24 h after ingestion of the contaminated food. Treatment for botulism is by administration of botulinum antitoxin if the diagnosis is early, and mechanical ventilation if signs of respiratory paralysis have already appeared. If the dose of toxin is not too high, infant botulism is usually self-limiting, and most infants recover with only supportive therapy, such as assisted ventilation.

MINIQUIZ

- Compare and contrast toxin production and toxemia in botulism and perfringens food poisoning.
- Describe differences in the transmission of botulism in adults versus infants.

V • Food Infection

Food infection results from ingestion of food containing sufficient numbers of viable pathogens to cause growth of the pathogen and disease in the host. Food infections are very common, and in the United States, the sum total of food infections greatly outnumbers cases of food poisoning by nearly 10-fold. Sections 23.1 and 23.6–23.8 review the infection process, summarizing the steps by which microorganisms—both friend and foe alike—attach and become established in host tissues.

31.10 Salmonellosis

Salmonellosis is a gastrointestinal disease typically caused by ingesting food contaminated with *Salmonella* or by handling *Salmonella*-contaminated animals or animal products (Figure 31.12). Salmonellosis is the most common bacterial food infection in the United States and second only to norovirus in total number of cases. Symptoms of salmonellosis begin after the pathogen—a gram-negative, facultatively aerobic rod related to *Escherichia coli* (see Section 15.3 and see Figure 31.13)—colonizes the intestinal epithelium. *Salmonella* species normally inhabit the intestine of warm-blooded and many cold-blooded animals (Figure 31.12) and are common in sewage. Thus, some cases of salmonellosis are waterborne rather than foodborne infections and this is especially the case for typhoid fever (Section 31.5).

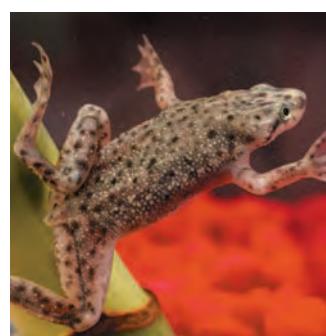

The accepted species epithet for pathogenic *Salmonella* is *enterica*, and there are seven subspecies of *S. enterica*. Most human salmonellae fall into the *S. enterica* subspecies *enterica*

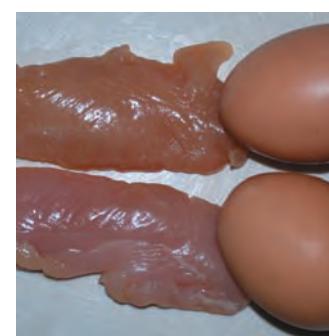

(a)

(b)

(c)

(d)

group. Each subspecies is also divided into *serovars* (serological variants). Thus, there is *Salmonella enterica* serovar Typhi, *Salmonella enterica* serovar Typhimurium, and so on. *S. enterica* serovars Typhimurium and Enteritidis are most frequently associated with foodborne salmonellosis.

Pathogenesis and Epidemiology

The most common form of salmonellosis is *enterocolitis*. Ingestion of food containing viable cells of *Salmonella* results in colonization of both the small and large intestines. From here, cells of *Salmonella* invade phagocytic cells and grow intracellularly, spreading to adjacent cells as host cells die. After invasion, pathogenic *Salmonella* deploy several virulence factors including endotoxins, enterotoxins, and cytotoxins that damage and kill host cells (Sections 23.9 and 23.10). Symptoms of enterocolitis typically appear 8–48 h after ingestion and include a headache, chills, vomiting, and diarrhea, followed by a fever that can last for several days. The disease normally resolves without intervention in 2–5 days. After recovery, however, patients may shed *Salmonella* in their feces for several weeks and some become healthy carriers. A few serovars of *S. enterica* may also cause septicemia (a blood infection) and enteric or typhoid fever, a potentially fatal disease characterized by systemic infection and high fever lasting several weeks (Section 31.5).

The incidence of salmonellosis in the United States has been steady over the last decade, with about a million estimated cases each year. There are several routes by which *Salmonella* may enter the food supply. The bacteria may reach food through fecal contamination from food handlers. Food production animals such as chickens, pigs, and cattle harbor *Salmonella* serovars that are pathogenic to humans, and these may be carried through to fresh foods such as eggs, meat, and dairy products (Figure 31.12). *Salmonella* food infections are often traced to products such as custards, cream cakes, meringues, pies, and eggnog made with uncooked eggs. Other foods commonly implicated in salmonellosis outbreaks are meats and meat products, especially poultry, cured but uncooked sausages and other meats, milk, and milk products. The simple handling of *Salmonella*-contaminated animals (Figure 31.12) can also lead to salmonellosis.

Diagnosis, Treatment, and Prevention

Foodborne salmonellosis is diagnosed from a combination of clinical symptoms, a history of recent consumption of high-risk foods, and culturing of the organism from feces. Selective, differential media are used to isolate *Salmonella* and discriminate it from other gram-negative enteric bacteria (Figure 31.13). Tests for the presence of *Salmonella* are commonly carried out on foods of animal origin such as raw meat, poultry, eggs, and powdered milk. Tests include several rapid tests (Chapter 27), but even rapid tests usually rely on enrichment procedures to increase cell numbers of *Salmonella* to testable levels.

Treatment of enterocolitis is usually unnecessary, and antibiotic treatment does not shorten the course of the disease or eliminate the carrier state. Foods containing *Salmonella* but heated to at least 70°C are generally safe if consumed immediately, held at 50°C or above, or quickly refrigerated. Any foods that become contaminated by an infected food handler can support the growth

31.11 Pathogenic *Escherichia coli*

Most strains of *Escherichia coli* are common microflora in the human colon and are not pathogenic. However, a few strains are potential foodborne (and occasionally waterborne) pathogens (Figure 31.14) and produce potent enterotoxins. These pathogenic strains are grouped on the basis of the type of toxin they produce and their specific disease syndromes. We focus here on Shiga toxin-producing *E. coli* and briefly consider some other toxigenic *E. coli* strains.

Although not in the “top five” in terms of foodborne infection pathogens (Table 31.5), pathogenic *E. coli* strains cause disease symptoms so severe that they often require hospitalization. Indeed, infections with pathogenic *E. coli* may cause life-threatening diarrheal disease and urinary tract distress.

Shiga Toxin-Producing *Escherichia coli* (STEC)

Shiga toxin-producing *Escherichia coli* (STEC) strains produce verotoxin, an enterotoxin similar to the Shiga toxin produced by

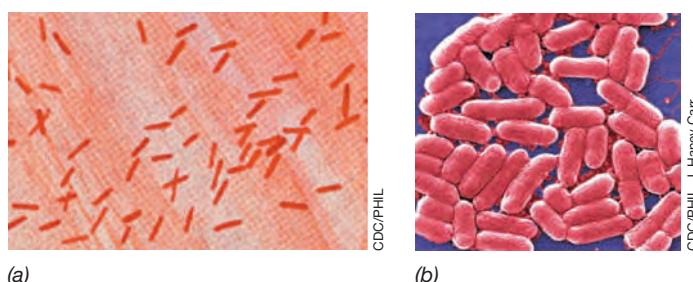

Figure 31.14 Pathogenic *Escherichia coli*. (a) Gram-stained cells showing the typical gram-negative rod-shaped morphology of *E. coli*. (b) Colorized scanning electron micrograph of cells of *E. coli* O157:H7. Cells measure about 1 × 3 µm.

Shigella dysenteriae (↳ Table 23.5), a close relative of *E. coli*. STEC strains of *E. coli* are also called *enterohemorrhagic E. coli* (EHEC). The most widely distributed STEC is *E. coli* O157:H7 (Figure 31.14b). Following ingestion of food or water containing STEC, the bacteria infect the small intestine where they grow and produce verotoxin, which both causes a bloody diarrhea and initiates signs of kidney failure.

Nearly half of STEC infections are caused by the consumption of contaminated uncooked or undercooked meat, particularly mass-processed ground beef. *E. coli* O157:H7 is normally present in the intestines of healthy cattle and enters the human food chain if meat is contaminated with the animal's intestinal contents during slaughter and processing. STEC strains have also been implicated in food infection outbreaks caused by dairy products (especially raw milk products), fresh fruit, and raw vegetables. Contamination of the fresh foods by fecal material, typically from cattle carrying STEC strains, has been implicated in several of these cases (Section 31.7).

Other Pathogenic *Escherichia coli*

Children in developing countries often contract diarrheal disease caused by *E. coli*, and *E. coli* can also be the cause of "traveler's diarrhea," a common infection causing watery diarrhea (as opposed to the bloody diarrhea of STEC strains) in travelers to developing countries. The primary causal agents here are *enterotoxigenic E. coli* (ETEC). These strains infect the small intestine and produce one of two heat-labile, diarrhea-producing enterotoxins.

In studies of United States citizens traveling in Mexico, the infection rate with ETEC is often greater than 50%. The prime vehicles are perishable foods such as fresh vegetables (for example, lettuce in salads) and public water supplies. The local population is typically resistant to the ETEC strains because of long-term contact with the organism. Other pathogenic *E. coli* strains include *enteropathogenic E. coli* (EPEC) strains that cause diarrheal diseases in infants and small children but do not cause invasive disease or produce toxins, and *enteroinvasive E. coli* (EIEC) strains, which invade the colon and cause watery and sometimes bloody diarrhea.

Diagnosis, Treatment, and Prevention

The general pattern established for the diagnosis, treatment, and prevention of STEC infection reflects current procedures used for all pathogenic *E. coli* strains. Laboratory diagnosis requires culture from the feces and identification of the O (lipopolysaccharide) and H (flagellar) antigens and toxins by immunological methods. Identification and typing can also be done using various molecular analyses.

Treatment of STEC infections includes supportive care for dehydration and monitoring of renal function, blood hemoglobin, and platelets. Antibiotics may actually be harmful because they may trigger the release of large amounts of verotoxin from dying *E. coli* cells that would otherwise be voided intact in feces. For other pathogenic *E. coli* infections, treatment includes supportive therapy and, for severe cases and invasive disease, antimicrobial drugs to shorten and eliminate infection.

The most effective way to prevent infection with pathogenic *E. coli* of any types is to wash raw foods vigorously and make sure

that meat, especially ground beef, is cooked thoroughly, which means that it should appear gray or brown with clear juices and have attained a temperature of greater than 70°C. In general, proper food handling, water purification, and appropriate hygiene also prevent the spread of pathogenic *E. coli*. While traveling, diarrhea from pathogenic *E. coli* can be prevented by drinking water only from properly sealed bottled water and avoiding any uncooked foods.

- Why are meats prime vehicles for pathogenic *E. coli*? How can contaminated meat be rendered safe to eat?

31.12 *Campylobacter*

Along with salmonellosis (Section 31.10) and perfringens food poisoning (Section 31.9), *Campylobacter* infections are the most common bacterial foodborne infections in the United States (Table 31.5). Cells of *Campylobacter* are gram-negative and motile spiral-shaped *Epsilonproteobacteria* (↳ Section 15.5) that grow best at reduced oxygen tension (microaerophilic). Several species of *Campylobacter* are recognized, but *C. jejuni* and *C. fetus* (Figure 31.15) are mostly commonly linked to human foodborne illnesses.

Epidemiology and Pathology

Campylobacter is transmitted to humans via contaminated food, most commonly in undercooked poultry or pork, raw shellfish, or

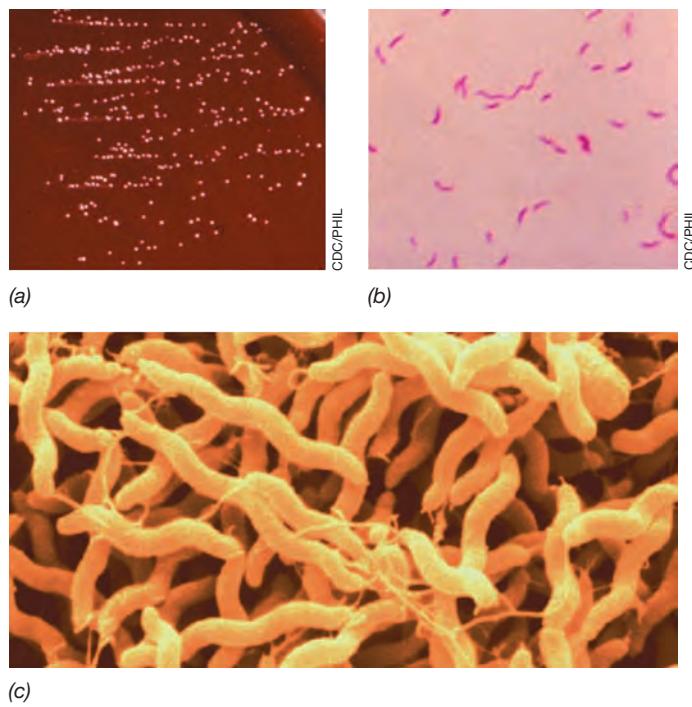

Figure 31.15 *Campylobacter*. (a) Colonies of *C. jejuni* grown on *Campylobacter* agar, a selective medium. The medium contains several antibiotics to which *Campylobacter* species are naturally resistant. (b) Gram stain and (c) scanning electron micrograph of cells of a *Campylobacter* species. Single cells average $0.4 \times 2 \mu\text{m}$ in size.

occasionally in fecally contaminated water from surface sources. *C. jejuni* is a normal resident of the intestinal tract of poultry, and according to the United States Department of Agriculture, up to 90% of turkey and chicken carcasses are contaminated with *Campylobacter*. Pork can also carry *Campylobacter*, while beef is rarely a vehicle. *Campylobacter* species also infect domestic animals such as dogs, causing a milder form of diarrhea in the animal than that observed in humans. *Campylobacter* infections in infants in particular are often traced to infected domestic animals, especially dogs.

After cells of *Campylobacter* are ingested, the organism multiplies in the small intestine, invades the epithelium, and causes inflammation. Because *C. jejuni* is sensitive to gastric acid, cell numbers as high as 10^4 may be required to initiate infection. However, this number may be reduced to fewer than 500 cells if the pathogen is ingested in food or if the person is taking medication to reduce stomach acid production. *Campylobacter* infection causes a high fever (usually greater than 40°C), headache, malaise, nausea, abdominal cramps, and diarrhea with watery, frequently bloody emissions; symptoms subside in about a week.

Diagnosis, Treatment, and Prevention

Diagnosis of *Campylobacter* food infection requires isolation of the organism from feces and identification by growth-dependent tests, immunological assays, or genomic analyses. Culture media containing multiple antibiotics to which campylobacters are naturally resistant have been developed for selective isolation of this organism (Figure 31.15a). Various immunological methods are also available for diagnosing a campylobacter infection.

Antibiotic treatment with the drug azithromycin is widely practiced if a confirmed diagnosis is made from culture or culture-independent evidence. In addition, severe cases of dehydration from a *Campylobacter* infection may require intravenous perfusion and hospitalization. Rigorous personal hygiene, especially by those in food preparation facilities, proper washing of uncooked poultry (and any kitchenware coming in contact with uncooked poultry), and thorough cooking of meat are the major means of preventing *Campylobacter* infections.

MINIQUIZ

- Describe the pathology of *Campylobacter* food infection. What are the major vehicles for this pathogen?
- How might *Campylobacter* contamination of food production animals be controlled?

31.13 Listeriosis

Listeria moncytogenes causes **listeriosis**, a gastrointestinal food infection that may lead to bacteremia (bacteria in the blood) and meningitis. *L. moncytogenes* is a gram-positive, nonsporulating coccobacillus (*Firmicutes*) that is acid-, salt-, and cold-tolerant and facultatively aerobic (Figure 31.16) (Section 15.7). Although a minor foodborne pathogen in terms of the number of cases observed per year, *Listeria* infections can be very severe and cause an estimated 20% of all deaths from foodborne illness in the United States.

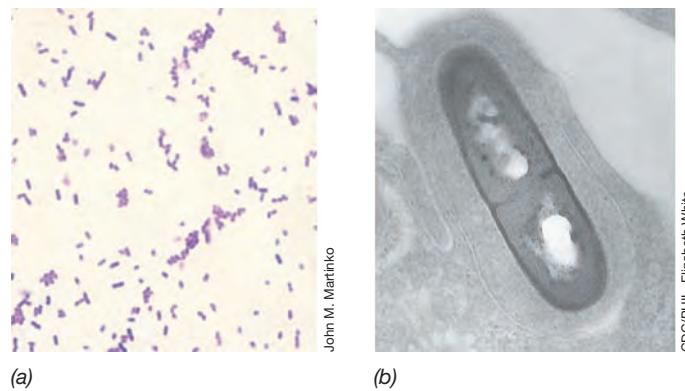

Figure 31.16 *Listeria monocytogenes*. (a) Gram stain and (b) transmission electron micrograph of cells of *L. monocytogenes*, the cause of listeriosis. The *Listeria* cell in part b is within host tissues (see Figure 31.17).

Epidemiology

L. monocytogenes is present in soil and water and although it is not common in foods, virtually no food source is safe from possible *L. monocytogenes* contamination. Food can become contaminated at any stage during production or processing. Ready-to-eat meats, fresh soft cheeses, unpasteurized dairy products, and inadequately pasteurized milk are the major food vehicles for *Listeria*, even when these foods are properly stored at refrigerator temperature (4°C). Food preservation by refrigeration, which ordinarily prevents the growth of other foodborne pathogens, is ineffective in the case of *Listeria* because the organism is psychrotolerant. Cells of *L. monocytogenes* produce a series of branched-chained fatty acids that keep the cytoplasmic membrane functional at cold temperatures (Section 5.12).

Evidence from animal studies and from observations of human cases of listeriosis, along with the high frequency of contamination of both raw and processed foods with *L. monocytogenes*, suggests that the organism is not highly invasive and that a large inoculum is likely required to initiate disease symptoms. Listeriosis is primarily seen in the elderly, pregnant women, newborns, and adults with weakened immune systems. Typically fewer than a thousand cases of listeriosis are reported in the United States each year, but mortality can be as high as 25% of those showing symptoms.

Pathology

Immunity to *L. monocytogenes* is normally conferred by cell-mediated Th1 inflammatory cells (Section 25.6). However, if cells of *Listeria* evade these immune cells, as they can in those with a compromised immune system, the organism is taken up by intestinal phagocytic cells. Although one might think that this is good from the standpoint of host defense, it is actually not because phagocytic uptake begins the *Listeria* infection cycle.

Listeria cells are taken up by host phagocytic cells into a vacuole called the *phagosome*. This triggers production of a major *Listeria* virulence factor, the toxin *listeriolysin O*, and this protein lyses the phagosome and releases *L. monocytogenes* into the cytoplasm (Figure 31.17). Here the bacterium multiplies and produces a second major virulence factor, *ActA*, a protein that induces host cell actin polymerization; the actin coats the bacterial cell and assists

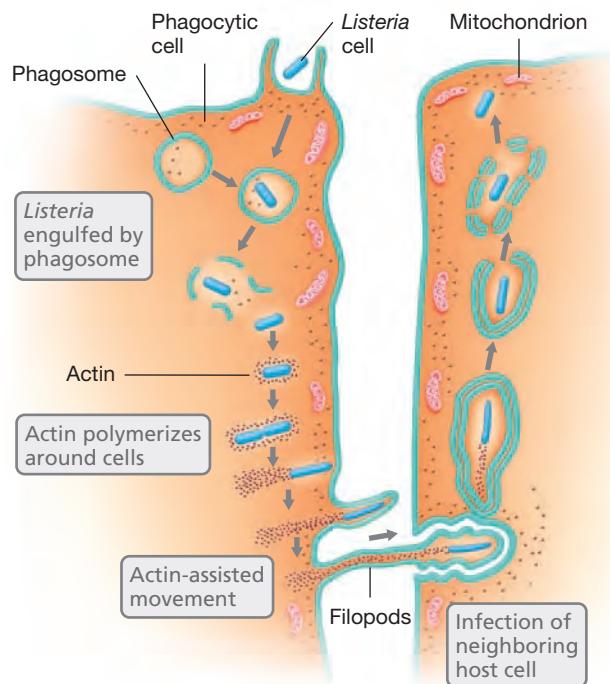

Figure 31.17 Transmission of *Listeria* during listeriosis. Cells of *Listeria* are taken up by phagocytic cells in phagosomes. These are eventually lysed by the virulence factor listeriolysin O to release *Listeria* cells. The bacterial cells then become covered with actin that assists in their movement to the cell periphery. Filopods facilitate transfer of *Listeria* cells to neighboring host cells, where the cycle repeats.

in moving the pathogen to the host cell cytoplasmic membrane. Once there, the complex pushes out, forming protrusions called *filopods* and these are then taken up by surrounding phagocytic cells (Figure 31.17). Filopod formation allows cells of *L. monocytogenes* to move about host tissues without exposure to the major weapons of the immune system: antibodies, complement, and neutrophils (Chapters 24 and 25).

Cells of *Listeria* in the intestine cross the intestinal barrier and are carried by the lymph and blood to other organs, in particular the liver, and multiply there as they do in intestinal phagocytes (Figure 31.17). From here cells of *L. monocytogenes* can infect the central nervous system, where they grow in neurons and lead to inflammation of the meninges (the tissues covering the brain and spinal cord), causing meningitis. In addition to listeriolysin O, which also allows *Listeria* to establish chronic infections in many host tissues, other major virulence factors include phospholipases that can destroy host cell membranes, antioxidants that counter phagocytic cell oxidants, and an array of “stress proteins” common in many bacteria (Section 7.10).

Diagnosis, Treatment, and Prevention

Listeriosis is diagnosed by culturing *L. monocytogenes* (Figure 31.16) from the blood or cerebrospinal fluid. *L. monocytogenes* can be identified in foods by direct culture or by several molecular methods. The latter are also used to subtype clinical isolates in order to track the source(s) of infection. Intravenous antibiotic treatment with penicillin, ampicillin, or trimethoprim plus sulfamethoxazole is used in invasive cases of listeriosis.

Prevention measures include recalling contaminated food and taking steps to limit *L. monocytogenes* contamination at the food-processing site. Because *L. monocytogenes* is susceptible to heat and radiation, raw food and food-handling equipment can be readily decontaminated. However, without pasteurizing or cooking the finished food product, the risk of contamination cannot be eliminated because of the widespread distribution of the pathogen.

MINIQUIZ

- What is the likely outcome of *Listeria monocytogenes* exposure in normal healthy individuals?
- Which populations are most susceptible to serious disease from *L. monocytogenes* infection?

31.14 Other Foodborne Infectious Diseases

Over 200 microorganisms, viruses, and other infectious agents can cause foodborne diseases, and we have thus far summarized the major ones. Here we consider a few other bacterial pathogens that are rather uncommon compared with the “top five” (Table 31.5), and we take a second look at norovirus (previously considered as a waterborne pathogen, Section 31.5) in its more frequent context as a foodborne pathogen and overall number one cause of gastrointestinal illness in the United States.

Bacteria

Besides the major *bacterial* foodborne pathogens we have already considered, several other bacteria cause human gastrointestinal illnesses. *Yersinia enterocolitica* is an enteric bacterium commonly found in the intestines of domestic animals and causes foodborne infections from contaminated meat and dairy products. The most serious consequence of *Y. enterocolitica* infection is *enteric fever*, a severe, life-threatening infection. *Y. enterocolitica* can be isolated on the same selective/differential medium used to isolate *Salmonella* (Figure 31.18a, b) but is easily distinguished from this organism on plates (compare Figures 31.13a and 31.18b).

Bacillus cereus is responsible for a relatively small number of food poisoning cases. This endospore-producing bacterium (Sections 2.16 and 15.8) produces two enterotoxins that cause different symptoms. In the *emetic form*, symptoms are primarily nausea and vomiting. In the *diarrheal form*, diarrhea and gastrointestinal pain are observed. *B. cereus* grows in foods such as rice, pasta, meats, or sauces that are cooked and left at room temperature to cool slowly. When endospores of this bacterium germinate, toxin is produced. Reheating may kill the *B. cereus* cells, but the toxin is heat-stable and may remain active. *B. cereus* is readily culturable and can be tentatively identified by a combination of microscopy and its typically large, grainy, and spreading colonies (Figure 31.18c, d).

The enteric bacterium *Shigella* causes the food infection *shigellosis*, and species of *Vibrio* can also cause food poisoning, primarily from consumption of contaminated shellfish. Most *Shigella* infections are the result of fecal to oral contamination, but food and water

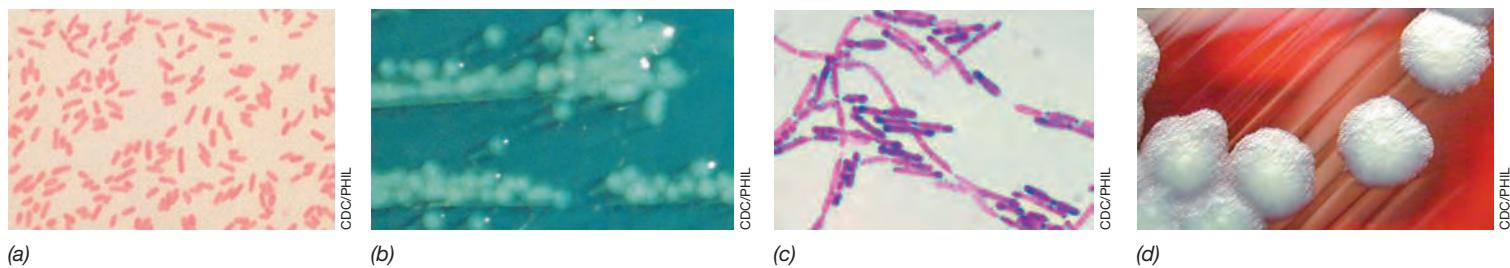

Figure 31.18 Less common foodborne bacterial pathogens: *Yersinia enterocolitica* and *Bacillus cereus*. (a) Gram-stained cells of *Y. enterocolitica*. (b) Colonies of *Y. enterocolitica* on Hektoen agar, a selective and differential medium (compare these with colonies of *Salmonella* on Hektoen agar in Figure 31.13a). (c) Gram-stained cells of a sporulating culture of *B. cereus*. (d) Large crystalline-like colonies of *B. cereus* formed on blood agar. are occasional vehicles. We discussed the Shiga-like toxin produced by some pathogenic strains of *Escherichia coli* in Section 31.11.

Viruses

About 70% of annual foodborne infections in the United States are caused by norovirus (Figure 31.19a) (Section 31.5). The virus is also known as *Norwalk virus* and is a single-stranded, plus-sense RNA virus related to poliovirus (Section 9.8). In general, noroviral foodborne illnesses are characterized by diarrhea, often accompanied by nausea and vomiting. Recovery from norovirus infections is typically spontaneous and rapid, usually within 24–48 h (thus the disease is often nicknamed “the 24-hour bug”).

Rotavirus, astrovirus, and hepatitis A make up the bulk of the remaining foodborne *viral* infections. These viruses inhabit the gut and are often transmitted in food or water contaminated with feces. Hepatitis A virus (HAV, Figure 31.19b) is an RNA virus that, like norovirus, is related to poliovirus, but it replicates in liver cells. We considered hepatitis viruses transmitted primarily by blood in Section 29.11, but HAV is mainly a foodborne virus. HAV usually triggers mild, and in many cases subclinical, symptoms, but rare cases of severe liver disease from HAV can occur. The most significant food vehicles for HAV are shellfish, usually oysters or clams harvested from water polluted by human feces and then eaten raw. In recent years, HAV has also been seen in fresh produce served without cooking.

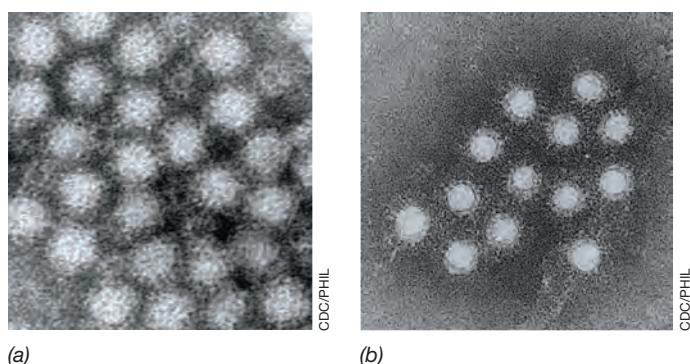

Figure 31.19 Viruses transmitted in contaminated foods. (a) Transmission electron micrograph of norovirus; an individual virion is about 30 nm in diameter. (b) Transmission electron micrograph of hepatitis A virus; a virion is 27 nm in diameter.

The general trend for incidence of both foodborne and blood-borne hepatitis has moved steadily downward and is now at all-time record low levels, partly due to the availability of effective vaccines against both HAV and HAB (Figure 29.33). HAV causes more cases of viral hepatitis than any other hepatitis virus, and over 30% of individuals in the United States have circulating antibodies to HAV, indicating past subclinical infections.

Protists and Other Agents

Important foodborne protist diseases are listed in Table 31.5. The major pathogens here include *Giardia intestinalis*, *Cryptosporidium parvum*, and *Toxoplasma gondii*. *G. intestinalis* and *C. parvum* are spread in foods when contaminated water is used to wash, irrigate, or spray crops. Fresh foods such as fruits are often implicated as vehicles for these protists. *Toxoplasma gondii* is a protist spread primarily through cat feces, but it can also be found in raw or undercooked meat, especially pork. We discuss the diseases giardiasis, cryptosporidiosis, and toxoplasmosis in Chapter 32.

At least one foodborne disease agent is neither cellular nor viral; these are the prions. Prions are proteins that adopt novel conformations, inhibiting normal protein function and causing degeneration of host neural tissues (Section 9.13). Human prion diseases are characterized by neurological symptoms including depression, loss of motor coordination, and eventual dementia. A foodborne human prion disease called *variant Creutzfeldt-Jakob disease* (vCJD) has been linked to consumption of meat products from cattle suffering from *bovine spongiform encephalopathy* (BSE), a disease caused by a prion. Although several thousand cases of vCJD were diagnosed in Great Britain in the mid-1990s, bans on cattle feeds containing rendered cattle parts and bone meal have greatly diminished the incidence of BSE in Europe and have kept the incidence of this disease very low in the United States.

MINIQUIZ

- In what two forms can *Bacillus cereus* food poisoning manifest itself?
- Compared with all other foodborne or waterborne pathogens, what is unique about prions?

BIG IDEAS

31.1 • Contaminated drinking and recreational waters are sources of waterborne pathogens. In the United States, the number of disease outbreaks due to these sources is relatively small in relation to the large exposure the population has to water. Worldwide, lack of adequate water treatment facilities and access to clean water contribute significantly to the spread of infectious diseases.

31.2 • Drinking water quality is determined by counting coliform and fecal coliform bacteria using standardized techniques. Filtration and chlorination of water significantly decreases microbial numbers. Water purification methods in developed countries have been a major factor in improving public health, although in developing countries, waterborne illness is still a significant source of infectious disease.

31.3 • The bacterium *Vibrio cholerae* causes cholera, an acute diarrheal disease associated with severe dehydration. Cholera occurs in pandemics, primarily in developing countries where sewage treatment and sanitation is lacking. Oral rehydration and electrolyte replacement can effectively treat cholera and greatly reduce disease mortality.

31.4 • *Legionella pneumophila* is a respiratory pathogen that causes Pontiac fever and legionellosis, a more serious infection that may result in pneumonia. *L. pneumophila* grows to high numbers in warm waters and is spread via cooling tower aerosols and in domestic water distribution systems where the bacterium develops in biofilms.

31.5 • Typhoid fever, caused by a *Salmonella* species, and norovirus illness are important waterborne diseases. Typhoid is common in developing countries while norovirus illness is seen worldwide. Both of these diseases can be controlled by good sanitation practices and effective water treatment.

31.6 • The potential for microbial food spoilage depends on the nutrients and moisture levels of the food. Growth of microorganisms in perishable foods can be controlled by refrigeration, freezing, canning, pickling, dehydration, chemicals, and irradiation. Microbial fermentations can be used to naturally preserve many foods, including dairy products, meats, fruits and vegetables, and alcoholic beverages.

31.7 • Food poisoning results from the activities of microbial toxins while food infections are due to the growth of the pathogen within the body. Identification of common characteristics of foodborne pathogens from seemingly isolated foodborne outbreaks can pinpoint the origin of foodborne contamination and track the spread of the disease.

The top five foodborne pathogens in the United States in decreasing order of their appearance are: norovirus, *Salmonella* spp., *Clostridium perfringens*, *Campylobacter jejuni*, and *Staphylococcus aureus*.

31.8 • Staphylococcal food poisoning results from the ingestion of a preformed staphylococcal enterotoxin, a superantigen produced by cells of *Staphylococcus aureus* as they grow in food. Proper food preparation, handling, and storage can prevent staphylococcal food poisoning.

31.9 • *Clostridium* food poisoning results from ingestion of toxins produced by microbial growth in foods or from microbial growth followed by toxin production in the body. *Perfringens* food poisoning is quite common and is usually a self-limiting gastrointestinal disease. Botulism is a rare but serious disease, with significant mortality.

31.10 • More than a million cases of salmonellosis occur every year in the United States. Infection results from ingestion of cells of *Salmonella* introduced into food primarily from animal-derived food products or food handlers.

31.11 • Toxigenic *Escherichia coli* cause many food infections, and of these, STEC strains are the most severe. Contamination of foods from animal feces spreads these pathogenic strains of *E. coli*, but good hygiene practices and specific antibacterial measures such as irradiation or thorough cooking of ground beef, a major vehicle, can control disease outbreaks.

31.12 • *Campylobacter* infection is the third most prevalent foodborne bacterial infection in the United States. Poultry is a major vehicle for *Campylobacter* illness, whereas beef and pork are not. Proper poultry preparation and cooking can prevent *Campylobacter* illness.

31.13 • *Listeria monocytogenes* is a ubiquitous bacterium, and in healthy individuals, it seldom causes infection. However, in immunocompromised individuals, *Listeria* can cause serious disease as it grows as an intracellular pathogen and invades the central nervous system. Listeriosis is uncommon but shows high mortality.

31.14 • Viruses, especially norovirus, cause the most foodborne illness while the bacteria *Bacillus cereus* and *Yersinia enterocolitica* are only occasionally linked to foodborne disease outbreaks. Hepatitis A virus is also a serious foodborne pathogen. Some protists and prions also cause foodborne illness but are far less common foodborne pathogens than are bacteria and viruses.

Deadly Fungi

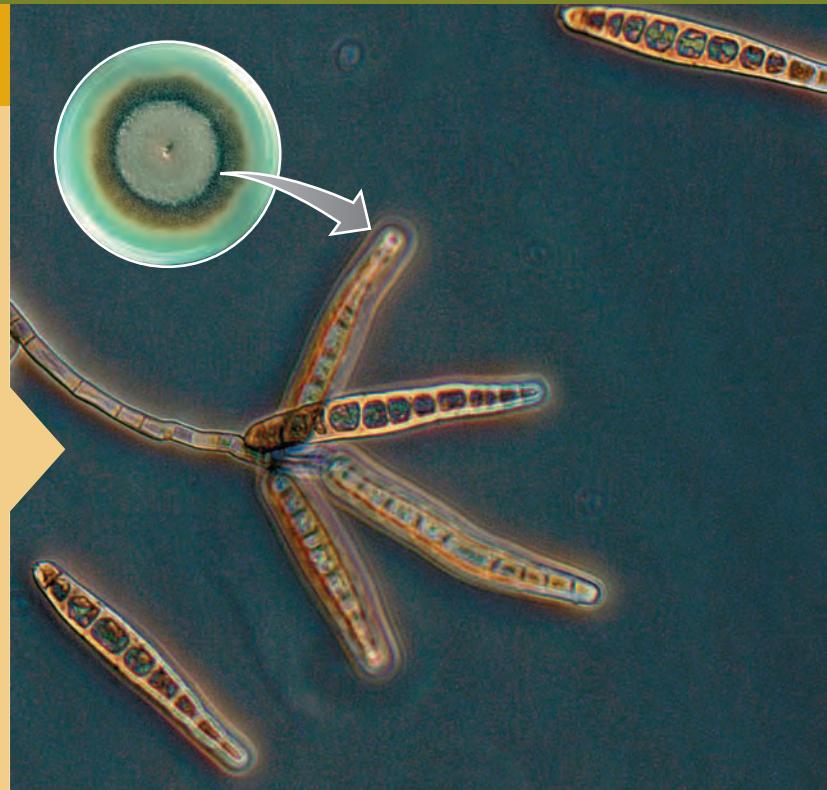

People usually associate fungi with decaying organic matter, or in a medical context, with superficial fungal infections such as athlete's foot. But fungi can cause serious, even deadly infections, as we were reminded when pathogenic fungi triggered a widespread outbreak of fungal meningitis in the United States in 2012.¹

Glucocorticoids such as methylprednisolone are often prescribed for pain relief, especially in adults suffering chronic lower back pain. The drug is typically injected directly into the outermost part of the spinal canal (epidural injection). Several lots of methylprednisolone formulated by a small pharmaceutical company in Massachusetts were found to be contaminated with fungi, including the mold *Exserohilum rostratum* (photo). *E. rostratum* is common in soil and can naturally infect several human tissues, in particular the cornea, lungs, and lining of the heart (pericardium). By early December of 2012 there were 590 fungal infections—mostly cases of meningitis—linked to injections of the contaminated drug, with 37 of these being fatal.

Using standard epidemiological techniques, the Centers for Disease Control and Prevention (Atlanta, Georgia, USA) and a specially formed multistate response team quickly linked the contaminated medication to the Massachusetts company and more specifically, to particular batches of the drug produced by this company. *E. rostratum* was found in sealed vials of methylprednisolone, and the nonpathogenic yeast *Rhodotorula* and mold *Rhizopus* were found in some others.

This outbreak of fungal disease underscores the critical importance of ensuring that drugs are both sterile and uncontaminated with foreign substances, especially drugs used for injections. In addition, the quick action by public health authorities to identify the disease source and prevent further infections is a testimony to the effectiveness of this branch of the healthcare system in the United States.

- I Fungal Infections 924
- II Visceral Parasitic Infections 928
- III Blood and Tissue Parasitic Infections 931

In this chapter we focus on pathogenic microorganisms that are eukaryotic. These include several fungi—both molds and yeasts—and various parasitic protists. Some small worms also cause infectious diseases and we consider the most significant of these in the final section.

A common problem in treating diseases caused by eukaryotic pathogens is the fact that their hosts are also eukaryotic. This thwarts many therapeutic strategies and often makes these diseases highly refractory and long-term chronic infections. This is especially true of systemic fungal pathogens.

I • Fungal Infections

Fungi cause a variety of human diseases. Some are mild and self-limiting, whereas others can be firmly entrenched systemic diseases. We begin by considering some of the major fungal pathogens followed by a description of some major fungal diseases, the mycoses.

32.1 Medically Important Fungi and Disease Mechanisms

The fungi include the *yeasts*, which normally grow as single cells, and *molds*, which form branching filaments called *hyphae* with or without septa (cross walls); hyphae eventually intertwine to form visible masses called *mycelia*. The diversity of the molds and yeasts was discussed in Chapter 17.

Common Fungal Pathogens

Fortunately, most fungi are harmless to humans. Most fungi grow in nature as saprophytes on dead organic material; in so

doing, fungi are important catalysts in the carbon cycle, especially in oxic environments in soil. Fungi are also important in medicine as both agents of disease and in chemotherapy (antibiotic production). Only about 50 species of fungi cause human diseases, and in healthy individuals, the incidence of serious fungal infections is low although certain superficial fungal infections (for example, athlete's foot) are fairly common. In those with compromised immune systems, however, fungal infections can be systemic, reaching even the deepest of internal tissues. Such infections can cause serious health problems and be life-threatening.

Common fungal pathogens include both yeasts and molds (Figure 32.1). However, many pathogenic fungi are *dimorphic*, meaning that they can exist as either yeasts or in filamentous form. In *Histoplasma*, for example, cells in laboratory culture form hyphae and mycelia and thus exist in the mold form (Figure 32.1a). By contrast, when *Histoplasma* causes histoplasmosis, cells grow in the host in the yeast form (see Figure 32.5a).

^aSymptoms of many of these diseases are shown in Figures 32.3–32.5.^b*Aspergillus* can also cause allergies, toxemia, and limited infections.^cAn opportunistic pathogen frequently implicated in the pathogenesis of HIV/AIDS.

In the mold form spores are produced, either asexual spores—*conidia*—or sexual spores (► Sections 17.9 and 17.10). When filamentous fungi are cultured from an infection, the morphology of these spore-bearing structures is observed and is often a major clue in reaching a diagnosis. In addition to microscopy, a variety of clinically useful molecular and immunological tools (Figure 32.1c) are also available to diagnose fungal infections. **Table 32.1** lists some major fungal pathogens and the types of infections they cause.

Fungal Disease Classes and Treatment

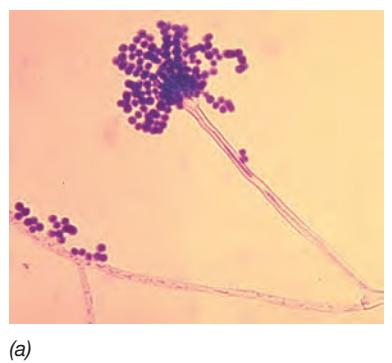

Fungi cause disease through three major mechanisms: inappropriate immune responses; toxin production; and mycoses. Some fungi trigger immune responses that result in allergic (hypersensitivity) reactions following exposure to specific fungal antigens. Reexposure to the same fungi, whether growing on the host or in the environment, may cause allergic symptoms. For example, *Aspergillus* spp. (Figure 32.2a), a common saprophyte often found in nature as a leaf mold, produces potent allergens, triggering asthma attacks or other hypersensitivity reactions in susceptible individuals.

Fungal disease may occur from the production of *mycotoxins*, a large and diverse group of fungal exotoxins. The best-known examples of mycotoxins are the *aflatoxins* (Figure 32.2b) pro-

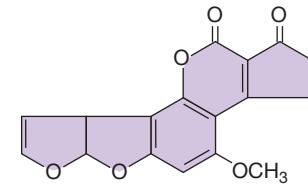

duced by *Aspergillus flavus*, a species that commonly grows on improperly stored dry foods, such as grain. Aflatoxins are highly toxic and are also carcinogenic, inducing tumors in some animals, especially in birds that feed on contaminated grain. Although aflatoxins are known to cause human liver damage including cirrhosis and even liver cancer, adults are not seriously affected by low-level aflatoxin exposure. However, chronic exposure in children can cause serious liver disease and other health effects.

The final fungal disease-producing mechanism is through actual host infection. The growth of a fungus on or in the body is called a **mycosis** (plural, **mycoses**). Mycoses are fungal infections that range in severity from superficial to life-threatening. Mycoses fall into three classes (Table 32.1). **Superficial mycoses** are those in which the fungus infects only the surface layers of skin, hair, or nails (see Figure 32.3). **Subcutaneous mycoses** are infections of deeper layers of skin (see Figure 32.4) and are typically caused by different fungi than superficial infections (Table 32.1). The **systemic mycoses** are the most serious category of fungal infections. These are characterized by fungal growth in internal organs of the body (see Figure 32.5) and can be either primary or secondary infections. A *primary* infection occurs when an otherwise normal, healthy individual is infected with the fungal pathogen; these are rather uncommon. By contrast, a *secondary* infection occurs in a host that harbors a predisposing condition, such as antibiotic therapy or immunosuppression, which makes the individual more susceptible to infection.

Superficial and subcutaneous mycoses are for the most part easily treatable with topical drugs, including tolnaftate (applied topically), various azole drugs (applied either topically or orally), and griseofulvin, a relatively nontoxic drug that can be taken orally but passes through the bloodstream to the skin where it inhibits fungal growth. Chemotherapy against systemic fungal infections is more difficult because of issues with host toxicity (► Section 27.16). For example, one of the most effective antifungal agents, amphotericin B, is widely used to treat systemic fungal infections but can also affect kidney function and have other unwanted side effects. Hence, effective treatment of the most serious of the mycoses is sometimes very difficult.

32.2 Mycoses

The two extremes of fungal infection are the superficial mycoses and the systemic mycoses. *Superficial mycoses* are quite common, and most individuals experience at least one in their lifetime. By contrast, *systemic mycoses* are far less common, and primarily affect the elderly or otherwise immune compromised. As people age, cell-mediated immunity slowly declines due to surgeries, transplants, immunosuppressive drug treatments for rheumatism and autoimmune diseases, and the onset of other conditions, such as pulmonary decline, diabetes, and cancer. Any of these can predispose the elderly to disease. Systemic mycoses also target those of any age whose immune systems have been impaired or destroyed, for example, by HIV/AIDS (Figure 29.45). Systemic mycoses are thus diseases of **opportunistic pathogens**, microorganisms that cause disease only in those whose immune defenses can no longer fight them off.

Superficial Mycoses

Table 32.1 listed some of the fungi that cause superficial mycoses; collectively, these pathogens are called *dermatophytes*. In general, superficial mycoses can be bothersome and often recurrent infections, but are not serious health concerns. Fungi such as *Trichophyton* (Figure 32.1b) cause infections of the feet (athlete's foot) and other moist skin surfaces, and are quite common (Figure 32.3a). These infections cause flaking and itchy skin and are easily transmitted by cells or spores of the pathogen present in contaminated shower stalls, gymnasium and locker room floors, contaminated shared articles such as towels or bed linens, or from close person-to-person contact. Superficial mycoses

can be treated with topical antifungal creams or liquid aerosols, although prophylactic application on a long-term basis may be necessary if constant exposure to the pathogen (for example, to *Trichophyton* on a locker room floor) is unavoidable.

Related surface mycoses include “jock itch,” an itchy infection of the groin, skin folds, or anus, and *ringworm* (Table 32.1). Despite the name, ringworm is a fungal infection, typically localized to the scalp or the extremities; the infection causes hair loss and inflammation-like reactions (Figure 32.3b, c). These more severe superficial mycoses are usually treated topically with either miconazole nitrate or griseofulvin.

Subcutaneous Mycoses

Subcutaneous mycoses are fungal infections of deeper layers of skin than those of the superficial mycoses (Table 32.1). One disease in this class is *sporotrichosis* (Figure 32.4a), an occupational hazard of agricultural workers, miners, gardeners, and others who

come into close and continual contact with the soil. The causal organism, *Sporothrix schenckii* (Figure 32.1d), is a ubiquitous soil saprophyte whose spores can enter through a cut or abrasion and infect subcutaneous tissues (Figure 32.4a). *Chromoblastomycosis* is due to pathogenic fungal growth in both surface (cutaneous) and subcutaneous skin layers, forming crusty, wartlike lesions on the hand (Figure 32.4b) or leg. The disease is primarily one of tropical and subtropical countries and occurs when the fungus becomes implanted under the skin from a puncture wound. Both sporotrichosis and chromoblastomycosis can be treated with oral administration of azoles.

Systemic Mycoses

Systemic fungal pathogens normally live in soil, and humans become infected by inhaling airborne spores that later germinate and grow in the lungs. From there the organism migrates throughout the body, causing deep-seated infections in the lungs and other organs and in the skin. In the United States, the three major systemic mycoses are, in order of decreasing incidence: histoplasmosis, coccidioidomycosis, and blastomycosis. Mortality from these is high, about 10%.

Histoplasmosis (Figure 32.5a) is caused by *Histoplasma capsulatum* (Figure 32.1e), and *coccidioidomycosis* (San Joaquin Valley fever, Figure 32.5d) is caused by *Coccidioides immitis* (Figure 32.1f). Histoplasmosis is primarily a disease of rural areas in mid-western states of the United States, especially in the Ohio and Mississippi River valleys, whereas coccidioidomycosis is generally

restricted to the desert regions of the southwestern United States. In more tropical climates *blastomycosis*, caused by *Blastomyces dermatitidis*, is prevalent (Figure 32.5b). *Paracoccidioidomycosis*, caused by the fungus *Paracoccidioides brasiliensis*, is primarily a subtropical disease with lesions forming on the face (Figure 32.5e) or other extremities.

Cryptococcosis (Figure 32.5c), caused by the dimorphic yeast *Cryptococcus neoformans* (Figure 32.1a), can occur in virtually any organ of the body and is the major mycosis seen in HIV/AIDS patients. The dimorphic yeast *Candida albicans* (Figure 32.1c) is often present as a minor component of the human normal flora. However, this fungus can cause a variety of diseases including mild vaginal infections, more serious oral infections such as thrush (Figure 32.5f), and systemic infection of virtually any organ in those with HIV/AIDS. Like *Histoplasma* and *Coccidioides*, *Candida* and *Cryptococcus* are primarily opportunistic pathogens and rarely cause life-threatening infections outside of the immune compromised.

Our discussion transitions now from fungi to pathogenic parasites. Like fungi, parasites are eukaryotic microorganisms, but the pathogenic parasites typically attack quite different body tissues and organs than do the pathogenic fungi.

II • Visceral Parasitic Infections

Parasitism is a symbiotic relationship between two organisms, the parasite and the host (Chapter 22). The parasite derives essential nutrients from the host and may have little or no harmful effect on the host. However, in many cases, the parasite causes disease in the host. Many different phylogenetic groups of protists (Chapter 17) cause parasitic human diseases and we examine some of the key ones here.

Parasitic infections can be either visceral—inducing vomiting, diarrhea, and other intestinal symptoms—or infections of blood and internal tissues. Some of the major diseases of human history, malaria for example, are parasitic diseases. We begin here with the visceral parasites and then consider blood and tissue parasites. Table 32.2 summarizes some major parasitic human diseases.

32.3 Amoebae and Ciliates: *Entamoeba*, *Naegleria*, and *Balantidium*

The genera *Entamoeba* and *Naegleria* belong to a large group of protists that move by extending lobe-shaped pseudopodia, the *Amoebozoa* (Section 17.8). Both parasites can cause serious, even fatal infections, although *Naegleria* infections are very rare. *Balantidium* is a ciliated species of the alveolate group (Section 17.5) and is mainly a disease of tropical countries.

Entamoeba histolytica (Figure 32.6a) is transmitted by contaminated water or occasionally through contaminated food. *E. histolytica* is an anaerobe, and the organism's *trophozoites* (the active, motile, feeding stage of the parasite) lack mitochondria. Like another common waterborne pathogen, *Giardia* (Section 32.4), the trophozoites of *E. histolytica* produce cysts, which are the means of transmission. Ingested cysts germinate to form amoebae that grow both on and in intestinal mucosa. This leads to tissue invasion and ulceration that triggers diarrhea and severe intestinal cramps.

With further growth, the amoebae can invade the intestinal wall—a condition called *dysentery*, characterized by intestinal inflammation, fever, and the passage of intestinal blood and mucus. If the infection is not treated, *E. histolytica* can invade the

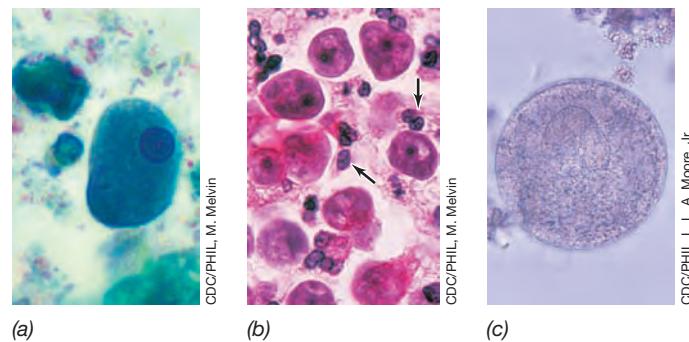

Figure 32.6 Parasitic amoebae and ciliates. (a) The growing stage (trophozoite) of *Entamoeba histolytica*; these can be up to 60 µm in length. (b) Trophozoites (arrows) of *Naegleria fowleri* in sectioned and stained brain tissue; the parasites are 10–25 µm in length. (c) *Balantidium coli* cyst present in a fecal sample.

liver, the lungs, and even the brain. Growth in these tissues causes abscesses that can be fatal. Nearly 100,000 people, primarily from developing countries where untreated sewage is allowed to enter surface waters, die each year from invasive amebic dysentery. *E. histolytica* amebiasis can be treated with a variety of drugs, but the host immune system plays a significant role in recovery as well. However, protective immunity is not conferred from a primary infection, and reinfection is common.

Naegleria fowleri can cause amebiasis, but in a very different form from that of *E. histolytica*. *N. fowleri* is a free-living amoeba present in soil and in runoff waters. *N. fowleri* infections result from swimming or bathing in warm, soil-contaminated waters such as warm springs or lakes and streams in summertime. *N. fowleri* enters the body through the nose and burrows directly into the brain. Here, the organism propagates, causing extensive hemorrhage and brain damage (Figure 32.6b), a condition called **meningoencephalitis**. Diagnosis of an *N. fowleri* infection requires observation of the amoebae in cerebrospinal fluid. If a definitive diagnosis is made quickly, the drug amphotericin B can save the patient; untreated infections are almost always fatal.

Balantidium coli is a ciliated intestinal human and swine parasite that alternates between the trophozoite and cyst (Figure 32.6c) stage; only the cysts are infective. *B. coli* is the only known ciliated parasite of humans. Cysts, typically transmitted in fecally contaminated water, germinate in the colon and infect mucosal tissues, leading to symptoms that resemble those of amebiasis, for which the disease is sometimes mistaken. An infected patient usually experiences a spontaneous recovery or may become an asymptomatic carrier, continuously shedding *B. coli* cysts in the feces. Compared with amebiasis, *B. coli* infections are uncommon, and cases are rarely fatal.

32.4 Other Visceral Parasites: *Giardia*, *Trichomonas*, *Cryptosporidium*, *Toxoplasma*, and *Cyclospora*

The protists *Giardia intestinalis* and *Trichomonas vaginalis* are flagellated anaerobic parasites that contain either mitosomes or hydrogenosomes in place of mitochondria (Sections 2.21 and 17.3); the parasites cause intestinal and sexually transmitted infections, respectively. The protist *Cryptosporidium* is related to *Toxoplasma*, but unlike *Toxoplasma*, which is primarily transmitted by infected food as is the pathogenic protist *Cyclospora*, *Cryptosporidium* is transmitted primarily by contaminated water. We consider all five of these major human parasites here.

Giardiasis

Giardia intestinalis (also called *Giardia lamblia*) is typically transmitted to humans in fecally contaminated water and causes an acute gastroenteritis, *giardiasis*. The trophozoites of *Giardia* (Figure 32.7a, c) produce highly resistant cysts (Figure 32.7b) that function in transmission. Ingested cysts germinate in the small intestine to form trophozoites, and these travel to the large intestine where they attach to the intestinal wall and cause the symptoms of giardiasis: an explosive, foul-smelling, watery diarrhea, intestinal cramps, flatulence, nausea, weight loss, and malaise. The foul-smelling diarrhea and the absence of fecal blood distinguish giardiasis from diarrheas due to bacterial or viral intestinal pathogens.

G. intestinalis causes a significant number of drinking water infectious disease outbreaks in the United States. The thick-walled cysts are resistant to chlorine, and most outbreaks have been associated with water systems that used only chlorination as a means of water purification. Water subjected to proper clarification and filtration followed by chlorination or other disinfection (Section 21.8)

should be free of *Giardia* cysts. Most surface water sources (lakes, ponds, and streams) contain *Giardia* cysts, as beavers and muskrats are carriers of this pathogen. This is why surface waters should never be drunk untreated but instead should be filtered and disinfected with iodine or chlorine or alternatively, filtered and boiled. The drugs quinacrine, furazolidone, and metronidazole are useful for treating acute giardiasis.

Trichomoniasis

Trichomonas vaginalis (Figure 32.8) causes a sexually transmitted infection, *trichomoniasis*. *T. vaginalis* does not produce resting cells or cysts and as a result, *Trichomonas* transmission is typically from person to person, generally by sexual intercourse. However, unlike most sexually transmitted bacterial pathogens, cells of *T. vaginalis* can survive for several hours on moist surfaces and up to a day in urine or semen. Hence, in addition to disease transmission by intimate contact, trichomoniasis can be transmitted by contaminated toilet seats, sauna benches, and towels.

T. vaginalis infects the vagina in women, the prostate and seminal vesicles of men, and the urethra of both males and females. Trichomoniasis is often asymptomatic in males. By contrast, trichomoniasis in females is characterized by a yellowish vaginal discharge (Figure 32.8b) that causes a persistent vaginal itching and burning. The infection is more common in females; surveys have shown that up to 25% of sexually active women are infected with *T. vaginalis* while only about 5% of males are infected. Trichomoniasis is diagnosed by observation of the motile protists in a wet mount of fluid discharged from the patient (Figure 32.8b). The antiprotozoal drug metronidazole is effective for treating trichomoniasis.

Cryptosporidiosis, Toxoplasmosis, and Cyclosporiasis

Cryptosporidium, *Toxoplasma*, and *Cyclospora* are genera of parasitic Coccidia (which group among the alveolates, Section 17.5). These parasites are transmitted to humans in fecally

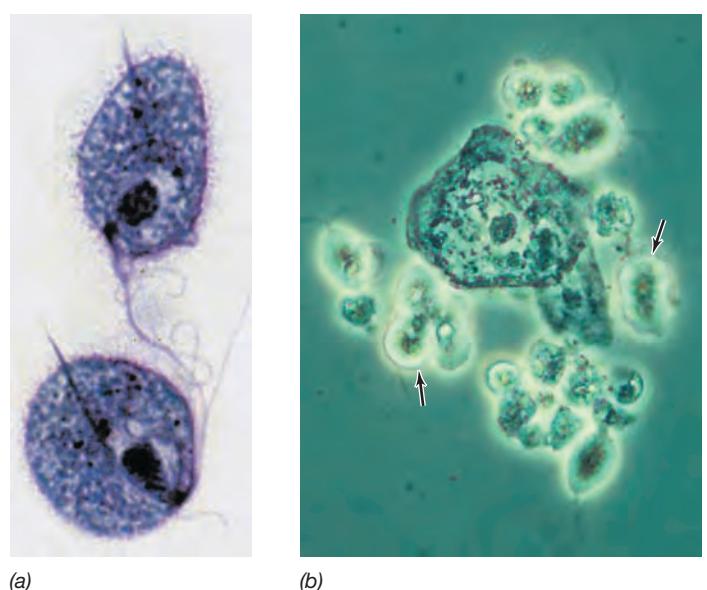

Figure 32.8 *Trichomonas vaginalis*. (a) Light micrograph of stained cells; cells vary from 10 to 20 µm in diameter. (b) Vaginal discharge from a female with trichomoniasis. *T. vaginalis* cells (arrows) are present along with vaginal secretions and epithelial cells.

This is why surface waters should never be drunk untreated but instead should be filtered and disinfected with iodine or chlorine or alternatively, filtered and boiled. The drugs quinacrine, furazolidone, and metronidazole are useful for treating acute giardiasis.

Trichomoniasis

Trichomonas vaginalis (Figure 32.8) causes a sexually transmitted infection, *trichomoniasis*. *T. vaginalis* does not produce resting cells or cysts and as a result, *Trichomonas* transmission is typically from person to person, generally by sexual intercourse. However, unlike most sexually transmitted bacterial pathogens, cells of *T. vaginalis* can survive for several hours on moist surfaces and up to a day in urine or semen. Hence, in addition to disease transmission by intimate contact, trichomoniasis can be transmitted by contaminated toilet seats, sauna benches, and towels.

T. vaginalis infects the vagina in women, the prostate and seminal vesicles of men, and the urethra of both males and females. Trichomoniasis is often asymptomatic in males. By contrast, trichomoniasis in females is characterized by a yellowish vaginal discharge (Figure 32.8b) that causes a persistent vaginal itching and burning. The infection is more common in females; surveys have shown that up to 25% of sexually active women are infected with *T. vaginalis* while only about 5% of males are infected. Trichomoniasis is diagnosed by observation of the motile protists in a wet mount of fluid discharged from the patient (Figure 32.8b). The antiprotozoal drug metronidazole is effective for treating trichomoniasis.

Cryptosporidiosis, Toxoplasmosis, and Cyclosporiasis

Cryptosporidium, *Toxoplasma*, and *Cyclospora* are genera of parasitic Coccidia (which group among the alveolates, Section 17.5). These parasites are transmitted to humans in fecally

contaminated food or water and can trigger serious bouts of diarrhea, or in the case of *Toxoplasma*, serious internal organ damage.

Cryptosporidium parvum infects many warm-blooded animals, in particular cattle. The organism forms small, coccoid cells that invade and grow intracellularly in mucosal epithelial cells of the stomach and intestine (Figure 32.9a), resulting in the gastrointestinal illness *cryptosporidiosis*. *C. parvum* produces thick-walled, highly resistant cysts called *oocysts* (Figure 32.9b), which enter water from the feces of infected animals. The infection is then transmitted to other animals and humans when they consume the fecally contaminated water.

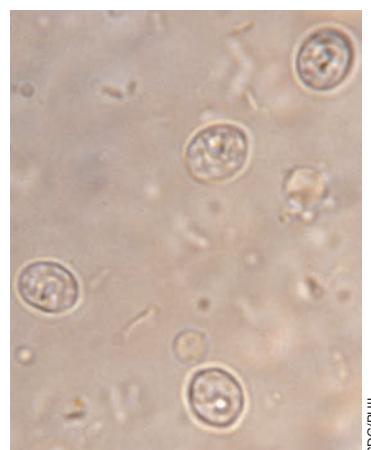

Cryptosporidium oocysts are highly resistant to chlorine, and because of this, sedimentation and filtration are the only reliable way to remove them from water supplies. In an average year, *Cryptosporidium* is responsible for the majority of recreational water-borne disease outbreaks in the United States (Chapter 31) but is only occasionally associated with drinking water outbreaks. Nevertheless, *C. parvum* was responsible for the largest single outbreak of disease associated with drinking water ever recorded in the United States. In the spring of 1993, one-quarter of the population of Milwaukee, Wisconsin (USA), developed cryptosporidiosis from consuming water from the municipal water supply. Spring rains and runoff from cattle manure on farmlands had drained into Lake Michigan (the water supply for the city) and overburdened the water purification system, leading to contamination by *C. parvum*.

Cryptosporidiosis typically causes only a mild self-limiting diarrhea, making treatment unnecessary. However, individuals with impaired immunity, such as that caused by HIV/AIDS, or the very young or old can develop serious complications from a *C. parvum* infection. The primary laboratory diagnostic method for cryptosporidiosis is the demonstration of oocysts in the stool (Figure 32.9b). Immunological and molecular tools are also available for more precise identification of strains of the pathogen when such tracking is necessary.

As for *C. parvum*, the parasite *Cyclospora cayetanensis* also forms oocysts and causes a mild to occasionally severe gastroenteritis, which is called *cyclosporiasis*. However, unlike *C. parvum*,

C. cayetanensis is primarily transmitted by fecally contaminated food products—typically fresh foods—rather than by contaminated water. Most cases of cyclosporiasis have been linked to contaminated fruits or vegetables, with a major outbreak occurring in the United States linked to packaged lettuce in the summer of 2013 (► Section 31.7).

Toxoplasmosis is caused by *Toxoplasma gondii* (Figure 32.10). This parasite infects many warm-blooded animals, and roughly half of all adults in the United States are infected but asymptomatic because their immune system keeps the organism in check. *T. gondii* is typically transmitted to humans in the form of cysts present in undercooked beef, pork, or lamb, by direct infection from cats, which are major carriers of *T. gondii*, and occasionally from contaminated water. A key step in the *T. gondii* life cycle is completed in felines and thus they are obligate hosts; humans and other animals are only incidental hosts. Most transmission to humans is thus probably from cats.

Toxoplasmosis can be associated with mild to severe symptoms. When cysts of *T. gondii* are ingested, they penetrate the wall of the small intestine. From this initial infection, symptoms can be inapparent or apparent but indistinguishable from those of a mild case of influenza (headache, muscle ache, general malaise). However, in some infected persons, *T. gondii* cysts migrate from the small intestine and circulate throughout the body. Subsequently, the parasite can penetrate nerve cells and infect tissues of the brain and eyes. Although disease symptoms in healthy adults are uncommon, in immune-compromised individuals, toxoplasmosis can damage the eyes, brain, and other internal organ systems. In addition, a first-time infection with *T. gondii* in expectant mothers can lead to birth defects in newborns; thus pregnant women who have not been in contact with cats should avoid cats until after giving birth.

III • Blood and Tissue Parasitic Infections

Several human parasites infect organs and tissues other than the gastrointestinal tract and are typically transmitted by insect vectors. We begin our consideration of these with malaria, the most devastating and widespread of parasitic diseases and one that remains a major global health problem today.

32.5 Plasmodium and Malaria

Malaria is caused by protists of the alveolate group (see Section 17.5). Several species of the protozoal genus *Plasmodium* cause malaria-like diseases in warm-blooded hosts; up to 500 million people worldwide contract malaria annually and about 1 million die from the disease. Malaria is thus one of the most common causes of death worldwide from infectious disease and certainly the most prevalent of parasitic diseases.

In malaria, the complex parasite life cycle requires a mosquito vector. Four species of *Plasmodium*—*P. vivax*, *P. falciparum*, *P. ovale*, and *P. malariae*—cause most human malaria. The most widespread disease is caused by *P. vivax*, whereas the most serious disease is caused by *P. falciparum*. Humans are the only reservoirs for these four species. The protists carry out part of their life cycle in the human and part in the female *Anopheles* mosquito, the only vector that transmits *Plasmodium* spp. The vector spreads the protist from person to person.

Malarial Life Cycle

The life cycle of *Plasmodium* is complex and involves a number of stages (Figure 32.11). First, the human host is infected by plasmodial sporozoites, small, elongated cells produced in

the mosquito that localize in the salivary gland of the insect. The mosquito (Figure 32.11 inset) injects saliva containing the sporozoites into the human when obtaining a blood meal. The sporozoites travel to the liver where they infect liver cells. Here they can remain quiescent for indefinite periods but eventually replicate and become enlarged in a stage called the *schizont* (see Figure 32.12b). The schizonts then segment into a number of small cells called *merozoites*, which exit the liver into the bloodstream. Some of the merozoites then infect red blood cells (erythrocytes).

The plasmodial life cycle in erythrocytes proceeds with repeated division, growth, and release of merozoites (Figure 32.12); this results in destruction of the host red blood cells. Plasmodial growth in red cells typically repeats at synchronized intervals of 48 h. During this 48-h period, the host experiences the defining clinical symptoms of malaria: chills followed by fever of up to 40°C (104°F). The chill–fever pattern coincides with the release of merozoites from the erythrocytes during the synchronized reproduction cycle. Vomiting and severe headache may accompany the chill–fever cycles, and over the longer term, characteristic symptomatic malaria can alternate with asymptomatic periods. Because of the destruction of red blood cells, malaria typically causes anemia and some enlargement of the spleen (splenomegaly).

Plasmodial merozoites eventually develop into *gametocytes*, cells that infect only mosquitoes. The gametocytes are ingested when an *Anopheles* mosquito takes a blood meal from an infected person, and they mature within the mosquito into *gametes*. Two gametes fuse to form a zygote, and the zygote

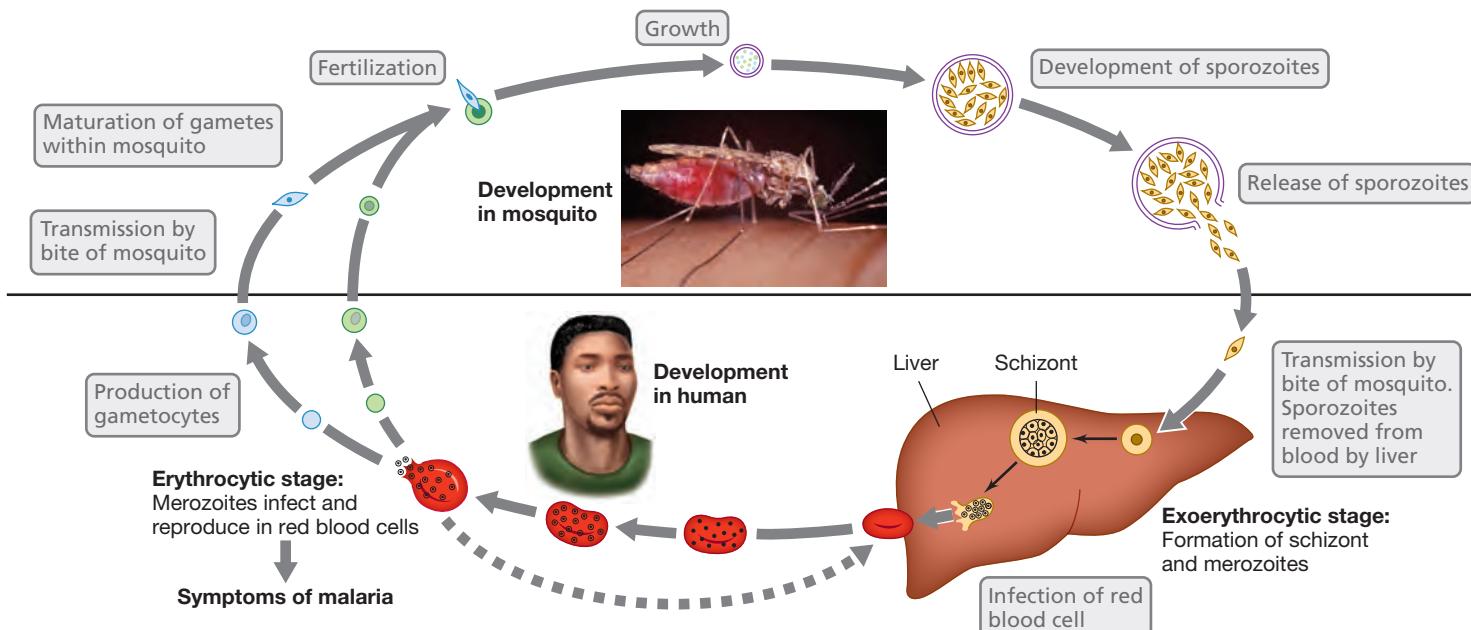

Figure 32.11 The life cycle of *Plasmodium*. The life cycle of *Plasmodium* requires both a warm-blooded host and the mosquito vector. migrates by amoeboid motility to the outer wall of the insect's intestine where it enlarges and forms several sporozoites. These are released and reach the salivary gland of the mosquito from where they can be inoculated into another human, and the cycle begins anew (Figure 32.11).

Epidemiology, Diagnosis, Treatment, and Control

Anopheles mosquitoes (Figure 32.11 inset) live predominantly in the tropics and subtropics and are the vector for malaria. Diagnosis of malaria requires the identification of *Plasmodium*-infected erythrocytes in blood smears (Figure 32.12). Fluorescent nucleic acid stains, nucleic acid probes, PCR assays, and various antigen-detection methods are also used to verify *Plasmodium* infections or to differentiate between infections with various *Plasmodium* species.

Treatment of malaria is typically accomplished with *chloroquine*. Chloroquine kills merozoites within red cells but does not kill sporozoites. The related drug *primaquine* eliminates sporozoites of *P. vivax* and *P. ovale* that may remain in liver cells. Thus treatment with both chloroquine and primaquine effectively cures most malaria. However, in some individuals, malaria reoccurs years after the primary infection when a few sporozoites not eliminated from the liver release a new generation of merozoites. Quinine-resistant strains of *Plasmodium* are now widespread and so *combination therapy*, where the malaria patient is treated with several antimalarial drugs at once, is now a common form of treatment.

Malaria can be controlled by either draining swamps and other breeding areas or by eliminating the mosquito with insecticides. Together, these measures have all but eliminated malaria in the United States, with most cases being imported. Several malaria vaccines are also in development, including synthetic peptide vaccines, recombinant particle vaccines, and DNA vaccines (➡ Section 24.7), but thus far no highly effective and reliable malaria vaccine has emerged for use in mass vaccination programs.

32.6 Leishmaniasis, Trypanosomiasis, and Chagas' Disease

Parasites of the genera *Leishmania* and *Trypanosoma* are transmitted by bloodsucking insect vectors. These parasites are *hemoflagellates*, organisms that reside in blood or related tissues such as the liver and spleen, and cause major human diseases, primarily in tropical and subtropical countries.

Leishmaniasis

Leishmaniasis is a parasitic disease of various forms caused by species of the genus *Leishmania*, a flagellated protozoan related to *Trypanosoma*. The disease is transmitted to humans by a bite from the sandfly. *Cutaneous leishmaniasis*, caused by either *L. tropica* or *L. mexicana*, is the most common form of leishmaniasis. Following transmission of the parasite in a blood meal (Figure 32.13a, b), the parasite infects and grows within human macrophage cells, leading eventually (weeks or months later) to the formation of a small nodule on the skin. The nodule then becomes ulcerated and can enlarge to form a major skin lesion (Figure 32.13c) that contains active parasites. In the absence of secondary bacterial infections, which are common if the ulcerated tissue is left open, the lesions heal spontaneously over a period of several months but can leave a permanent scar.

Leishmaniasis has historically been treated with injections of pentavalent antimony (Sb^{5+}) compounds. Although the mode of action of these compounds is unknown, it is thought that Sb^{5+} in some way stimulates or activates the immune response to better

attack the *Leishmania* parasites. At present, however, many *Leishmania* species are resistant to antimony compounds, but a variety of other drugs are available for treating resistant cutaneous forms of the disease. Estimates of cutaneous leishmaniasis prevalence worldwide are about 1 million.

Visceral leishmaniasis is caused by *Leishmania donovani* and is the most severe form of the disease. In visceral leishmaniasis, the parasite travels from the site of infection to internal organs, in particular the liver, spleen, and bone marrow; if left untreated, the visceral disease is almost always fatal. Common symptoms of visceral leishmaniasis include a cycling of fever and chills, a slow reduction in both red and white blood cell numbers, and significant enlargement of the spleen and liver that can lead to major distention of the abdomen. Treatment includes injections of antimony (as for the cutaneous disease), long periods of bed rest, and blood transfusions in acute cases if blood cell counts become dangerously low. Estimates of visceral leishmaniasis prevalence worldwide are about 300,000.

Trypanosomiasis and Chagas' Disease

Flagellated protozoans of the genus *Trypanosoma* (Section 17.4) cause two related forms of **trypanosomiasis**. Two subspecies of *Trypanosoma brucei* native to Africa, *T. brucei gambiense* (Figure 32.14a) and *T. brucei rhodesiense*, cause *African trypanosomiasis*, better known as *African sleeping sickness*. The species *T. cruzi* causes *Chagas' disease*, also known as *American trypanosomiasis*. These diseases are transmitted by insect bites from either a fly or a bug.

Sleeping sickness is transmitted by the tsetse fly (genus *Glossina*), an insect similar in dimensions to a housefly and native only to tropical regions of Africa; sleeping sickness is therefore endemic only in countries of sub-Saharan Africa. The disease begins with intermittent fever, headache, and malaise. The parasite multiplies in the blood and later infects the central nervous system and grows in spinal fluid. Neurological symptoms soon begin, including sleep patterns that are no longer diel. The parasite produces the aromatic alcohol *tryptophol*, a derivative of the amino acid tryptophan, which triggers a sleep response. Without treatment, the infection

gradually progresses to a coma, multiple organ failure, and eventually death after months or years depending on the case. A variety of anti-trypanosomal drugs are available for treating sleeping sickness; some are used primarily for treating the blood infection while others are used if the disease has progressed to the neurological stage. About 10,000 new cases of sleeping sickness are reported annually but most cases are thought to go unreported.

Chagas' disease, named for its discoverer, is caused by *T. cruzi*, a close relative of *T. brucei*, and is transmitted by the bite of the "kissing bug" (Figure 32.14b, c). Chagas' disease mainly occurs in Latin American countries. The parasite affects several organs including the heart, gastrointestinal tract, and central nervous system, causing inflammatory reactions and tissue destruction. The acute illness is usually self-limiting, but if chronic illness develops, heart disease is significant and is the eventual cause of premature death. About 20,000 deaths due to Chagas' disease occur annually in endemic Latin American countries.

Currently no vaccines are available for prevention of African or American trypanosomiases.

32.7 Parasitic Helminths: Schistosomiasis and Filariases

Some parasitic diseases are caused by helminths, tiny worms that burrow into the human host and cause debilitating diseases and death. We consider the most widespread of these here, schistosomiasis, along with brief coverage of two other less common helminth infections.

Schistosomiasis

Schistosomiasis, also called *snail fever*, is a chronic parasitic disease caused by species of trematodes (flatworms) of the genus *Schistosoma*; the major species is *S. mansoni* and adult worms can be up to a centimeter in length (Figure 32.15a). The life cycle of the parasite requires both snails and humans (or other mammals) as hosts. Schistosome eggs (Figure 32.15b) released into a freshwater aquatic environment hatch to generate *miracidia*, the form of the worm that infects snails. In the snail, miracidia are transformed into *cercaria* (Figure 32.15c), the motile stage of the parasite that is released and infects humans.

Cercaria burrow into the skin, leaving a small surface lesion (Figure 32.15d), and then migrate to the lungs and liver; in the process, the worm establishes a long-term infection in the blood vessels. From the liver, the parasite infects the bladder, kidneys, and urethra and the female worm produces large numbers of eggs. The eggs are shed in the urine and also pass through the intestinal wall and are shed in the feces. Large egg masses also become trapped along with fluids in the bladder, liver, and other organs, triggering

an inflammatory response and a major distention of the abdomen, a condition commonly seen in infected children (Figure 32.16a). Other symptoms include bloody urine, diarrhea, and abdominal pain. Eggs as well as adult worms can live in the body for years, causing chronic symptoms that can last from youth into adulthood.

Schistosomiasis is a disease of tropical countries, primarily those in Africa, but some cases also occur in subtropical countries such as Latin America and the Caribbean region. Schistosomiasis can be effectively treated with the drug praziquantel, and diagnosis is relatively easy by assessing symptoms and observing parasite eggs in the urine and feces. Mortality from schistosomiasis is low, about 0.1%, but schistosomiasis is second only to malaria in terms of total parasitic infections worldwide. In 2011, nearly 250 million cases of the disease were treated and many others probably went untreated.

Filarases

Several other parasitic helminth infections are known, and chief among these are the *filarases*, infections by parasitic nematodes (roundworms). Unlike the schistosomiasis parasite, these worms are clearly macroscopic in the adult stage (several centimeters in length, depending on the filariasis).

Bancroft's filariasis (also called “elephantiasis”) is a chronic infection of the lymphatic system by *Wuchereria bancrofti*. The worm is transmitted to humans in tiny *microfilariae* in a mosquito bite. Once in the host, microfilariae develop into adult worms and these interrupt lymph flow, leading to major accumulation of fluids (edema). Fluid accumulation in lower regions of the body can cause massive enlargement of the legs (Figure 32.16b). Over 120 million people in the tropics suffer from *W. bancrofti* infection, but the microfilarial stage of the disease is readily treatable.

Onchocerciasis (also called *river blindness*) is due to a chronic infection by the large parasitic roundworm *Onchocerca volvulus*. Humans are the only known host for this parasite, but flies are vectors when they become infected with microfilariae in a blood meal and transmit them to uninfected humans in a bite. The microfilariae invade the cornea and from there the iris and retina, triggering an inflammatory response that causes scarring and partial to total loss of vision. *O. volvulus* infection is second only to trachoma (➡ Section 29.13) as a cause of infectious blindness. It is estimated that about 20 million people are infected with this parasite, primarily in equatorial Africa.

The disease *trichinosis* (also called *trichinellosis*) is caused by species of the parasitic roundworm *Trichinella*. This worm commonly infects the muscle tissues of wild mammals and can occasionally infect domestic animals, especially swine; about 20 cases of human trichinosis are reported in the United States each year, usually from the consumption of undercooked wild game. Human infection with *Trichinella* begins when worm larvae enter intestinal mucosal cells, leading to either an asymptomatic condition or mild gastroenteritis. As the larvae mature and reproduce, new larvae circulate throughout the body and lead to systemic inflammatory reactions such as malaise, facial swelling, and fever. Untreated cases of trichinosis can progress to more severe organ-specific symptoms including heart damage, encephalitis, and even death. However, if properly diagnosed, usually by immunological assays, trichinosis is treatable with a variety of antihelminthic drugs.

BIG IDEAS

32.1 • Fungi include the molds and yeasts, and some fungi are dimorphic, meaning that both mycelial and yeast phases can occur. Superficial, subcutaneous, and systemic mycoses refer to fungal infections of the skin surface, skin subsurface, and internal organs, respectively. Fungal infections can be mild or serious, depending on the health and immune status of those infected.

32.2 • Superficial mycoses such as athlete's foot or jock itch are mild and easily treatable, whereas subcutaneous mycoses, such as sporotrichosis, or especially systemic mycoses, such as histoplasmosis, are more difficult to treat effectively. The ability of fungi that cause systemic mycoses to infect internal organs makes these pathogens particularly dangerous to the elderly or those otherwise immune compromised.

32.3 • The genera *Entamoeba* and *Naegleria* are amoebic human parasites that cause gastrointestinal and brain infections, respectively. *Entamoeba* is transmitted in fecally contaminated waters, whereas *Naegleria* inhabits warm, soil-contaminated waters. *Balantidium* is a ciliated intestinal parasite transmitted by fecally contaminated water.

32.4 • The protists *Giardia intestinalis* and *Cryptosporidium parvum* are major waterborne pathogenic parasites, whereas *Toxoplasma gondii* is primarily a foodborne or cat-transmitted parasite and *Trichomonas vaginalis* a sexually transmitted parasite. The pathogenic parasite *Cyclospora* is primarily transmitted by fresh vegetables such as lettuce and spinach.

contaminated with animal feces. None of these parasites cause life-threatening diseases in otherwise healthy individuals, although *T. gondii* can trigger severe and even fatal infections in immune-compromised hosts.

32.5 • Infections with *Plasmodium* spp. cause malaria, a widespread, mosquito-transmitted disease of the blood that causes significant morbidity and mortality in tropical and subtropical regions of the world. Malaria is treatable with quinines and other drugs but is not yet preventable by vaccination.

32.6 • Leishmaniasis is a parasitic disease caused by *Leishmania* species; the cutaneous form of the disease is most common. *Trypanosoma brucei* causes African trypanosomiasis (African sleeping sickness), while the related species *Trypanosoma cruzi* causes Chagas' disease. All of these diseases are transmitted by insect bites from an insect vector, either a fly or a bug.

32.7 • Schistosomiasis is a major parasitic disease caused by a microscopic worm, *Schistosoma mansoni*. The life cycle of the parasite requires both snails and mammals. The worm infects the liver and kidneys and produces large egg masses that accumulate in the body, leading to systemic inflammation and abdominal distention. Other parasitic worm diseases, such as elephantiasis and river blindness, also leave readily visible signs of infection.

REVIEW OF KEY TERMS

Leishmaniasis a disease of the skin or viscera caused by infection with species of a parasitic flagellated protozoan, *Leishmania*

Malaria a disease characterized by recurrent episodes of fever and anemia, caused by the protist *Plasmodium* spp., usually transmitted between mammals through the bite of the *Anopheles* mosquito

Meningoencephalitis the invasion, inflammation, and destruction of brain tissue by the amoeba *Naegleria fowleri* or a variety of other pathogens

Mycosis (plural, mycoses) any infection caused by a fungus

Opportunistic pathogens organisms that cause disease in the absence of normal host resistance

Schistosomiasis a chronic disease caused by a parasitic worm that leads to internal organ damage and accumulation of fluids and worm egg masses

Subcutaneous mycoses fungal infections of deeper layers of skin

Superficial mycoses fungal infections of the surface layers of skin, hair, or nails

Systemic mycoses fungal growth in internal organs of the body

Trypanosomiasis any parasitic disease of the blood and internal tissues caused by species of the flagellated protozoan *Trypanosoma*; African sleeping sickness and Chagas' disease are two major trypanosomiases

REVIEW QUESTIONS

1. Which are more common, superficial or systemic mycoses? Have you had a case of either one? (Section 32.1)
2. What are the most common systemic mycoses in the United States and which populations are most susceptible to such infections? (Section 32.2)
3. If you were to have one or the other, which would you rather have, an *Entamoeba* infection or a *Naegleria* infection? (Section 32.3)
4. In contrast to disease caused by *Trichomonas*, what do giardiasis and cryptosporidiosis have in common? (Section 32.4)
5. Malaria symptoms include fever followed by chills. These symptoms are related to activities of the pathogen. Describe the growth stages of *Plasmodium* spp. in the human host and relate them to the fever–chill pattern. (Section 32.5)
6. Contrast leishmaniasis with the two types of trypanosomiasis in terms of causative agents, symptoms, and transmission vectors. (Section 32.6)
7. Contrast schistosomiasis with all other parasitic infections covered in this chapter. In what major way does it differ? (Section 32.7)

APPLICATION QUESTIONS

1. Malaria eradication has been a goal of public health programs for at least 100 years. What factors preclude our ability to eradicate malaria? If an effective vaccine was developed, could malaria be eradicated?
2. In terms of public health, what is a common problem that unites many of the visceral parasitic infections covered in this chapter? How could this problem be attacked? Why are these diseases rare in developed countries?
3. Explain why the diseases malaria, leishmaniasis, and trypanosomiasis are primarily diseases of tropical regions. How could humans be affecting the future geographical ranges of these diseases?
4. Explain why systemic fungal infections are typically seen only in certain individuals even though many people have contact with the pathogen, whereas an outbreak of giardiasis affects virtually everyone that has come in contact with the pathogen.

Energy Calculations in Microbial Bioenergetics

The information here is intended to help the reader calculate changes in free energy accompanying chemical reactions carried out by microorganisms. It begins with definitions of the terms required to make such calculations and proceeds to show how knowledge of redox state, atomic and charge balance, and other factors are necessary to calculate free-energy problems successfully.

I. Definitions

- ΔG^0 = standard free-energy change of the reaction under “standard conditions” (1 atm pressure and 1 M concentrations); ΔG = free-energy change under the conditions specified; $\Delta G^{0'}$ = free-energy change under standard conditions at pH 7. The prime mark (') throughout this appendix indicates pH 7 (approximate cellular conditions).
- Calculation of ΔG^0 for a chemical reaction from the free energy of formation, G_f^0 , of products and reactants:

$$\Delta G^0 = \sum G_f^0(\text{products}) - \sum G_f^0(\text{reactants})$$

That is, sum the ΔG_f^0 of products, sum the ΔG_f^0 of reactants, and subtract the latter from the former.

- For energy-yielding reactions involving H^+ , converting from standard conditions (pH 0) to cellular conditions (pH 7):

$$\Delta G^{0'} = \Delta G^0 + m \Delta G_f^0(H^+)$$

where m is the net number of protons in the reaction (m is negative when more protons are consumed than formed) and $\Delta G_f^0(H^+)$ is the free energy of formation of a proton at pH 7 (-39.83 kJ) at 25°C.

- Effect of concentrations on ΔG : With soluble substrates, the concentration ratios of products formed to exogenous substrates used are generally equal to or less than 10^{-2} at the beginning of growth and equal to or greater than 10^{-2} at the end of growth. From the relation between ΔG and the equilibrium constant (see item 8), it can be calculated that ΔG for the free-energy yield in these situations differs from the free-energy yield under standard conditions by no more than 11.7 kJ, and so to a first approximation, free-energy yields under standard conditions can be used in most situations. However, if H_2 is a product, H_2 -consuming bacteria may consume the H_2 and keep its concentration so low that the free-energy yield of the reaction is significantly affected. Thus, in the fermentation of ethanol to acetate and H_2 by syntrophic bacteria ($C_2H_5OH + H_2O \rightarrow C_2H_3O^- + 2H_2 + H^+$), the $\Delta G^{0'}$ (at 1 atm H_2) is +9.68 kJ, but at 10^{-4} atm H_2 it is -36.03 kJ. With H_2 -consuming bacteria present, therefore, ethanol fermentation by syntrophic bacteria converts from an endergonic to an exergonic reaction. (See also item 9.)

5. Reduction potentials: By convention, electrode equations are written as *reductions*; that is, the direction is oxidant + ne^- reductant, where n is the number of electrons transferred. The standard reduction potential (E_0) of the hydrogen electrode, $2H^+ + 2e^- \rightarrow H_2$, is set by definition at 0.0 V at 1 atm pressure of H_2 gas and 1.0 M H^+ at 25°C. E_0' is the standard reduction potential at pH 7. See also Table A1.2.

6. Relation of free energy to reduction potential:

$$\Delta G^{0'} = -nF\Delta E_0' \quad \text{or} \quad \Delta G^{0'} = -RT\ln K'_{eq}$$

where n is the number of electrons transferred, F is the Faraday constant (96.48 kJ/V), and $\Delta E_0'$ is the E_0' of the electron-accepting couple minus the E_0' of the electron-donating couple. R and T are constants (see 8) and for K_{eq} , see 7.

- Equilibrium constant, K_{eq} . For the generalized reaction $aA + bB \leftrightarrow cC + dD$,

$$K_{eq} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

where A, B, C, and D represent reactants and products; a , b , c , and d represent number of molecules of each; and brackets indicate concentrations. This is true only when the chemical system is in equilibrium. K'_{eq} is K_{eq} at pH 7.

- Relation of equilibrium constant, K_{eq} , to free-energy change. At constant temperature, pressure, and pH,

$$\Delta G' = \Delta G^{0'} + RT\ln K'_{eq}$$

where R is the universal gas constant (8.315 J/mol/Kelvin) and T is the absolute temperature (in Kelvin).

- Two substances can react in a redox reaction even if the standard potentials are unfavorable, provided that the concentrations are appropriate.

Assume that normally the reduced form of A would donate electrons to the oxidized form of B. However, if the concentration of the reduced form of A was low and the concentration of the reduced form of B was high, it would be possible for the reduced form of B to donate electrons to the oxidized form of A. Thus, the reaction would proceed in the direction opposite that predicted from standard potentials. A practical example of this is the utilization of H^+ as an electron acceptor to produce H_2 . Normally, H_2 production in fermentative bacteria is not extensive because H^+ is a poor electron acceptor; the E_0' of the $2H^+/H_2$ pair is -0.41 V. However, if the concentration of H_2 is kept low by its continual removal (for example, by methanogenic Archaea, which use $H_2 + CO_2$ to produce methane, CH_4 , or by many other anaerobes capable of consuming H_2 anaerobically), the potential will be more positive and then H^+ will be a suitable electron acceptor.

II. Oxidation State or Number

1. The oxidation state of an element in an elementary substance (for example, H₂, O₂) is zero.
2. The oxidation state of the ion of an element is equal to its charge (for example, Na⁺ = +1, Fe³⁺ = +3, O²⁻ = -2).
3. The sum of oxidation numbers of all atoms in a neutral molecule is zero. Thus, H₂O is neutral because it has two H at +1 each and one O at -2.
4. In an ion, the sum of oxidation numbers of all atoms is equal to the charge on that ion. Thus, in the OH⁻ ion, O(-2) + H(+1) = -1.
5. In compounds, the oxidation state of O is almost always -2 and that of H is +1.
6. In simple carbon compounds, the oxidation state of C can be calculated by adding up the H and O atoms present and using the oxidation states of these elements as given in item 5, because in a neutral compound the sum of all oxidation numbers must be zero. Thus, the oxidation state of carbon in methane, CH₄, is -4 (4 H at +1 each = +4); in carbon dioxide, CO₂, the oxidation state of carbon is +4 (2 O at -2 each = -4).
7. In organic compounds with more than one C atom, it may not be possible to assign a specific oxidation number to each C atom, but it is still useful to calculate the oxidation state of the compound as a whole. The same conventions are used. Thus, the oxidation state of carbon in glucose, C₆H₁₂O₆, is zero (12 H at +1 = 12; 6 O at -2 = -12) and the oxidation state of carbon in ethanol, C₂H₆O, is -2 each (6 H at +1 = +6; one O at -2).
8. In all oxidation-reduction reactions there is a balance between the oxidized and reduced products. To calculate an oxidation-reduction balance, the number of molecules of each product is multiplied by its oxidation state. For instance, in calculating the oxidation-reduction balance for the alcoholic fermentation (glucose → 2 C₂H₆O + 2 CO₂), there are two molecules of ethanol at -4 (for a total of -8) and two molecules of CO₂ at +4 (for a total of +8), so the net balance is zero. When constructing model reactions, it is useful to first calculate redox balances to be certain that the reaction is possible.

III. Calculating Free-Energy Yields for Hypothetical Reactions

Energy yields can be calculated either from free energies of formation of the reactants and products or from differences in reduction potentials of electron-donating and electron-accepting partial reactions.

Calculations from Free-Energy Values

Free energies of formation are given in **Table A1.1**. The procedure to use for calculating energy yields of reactions follows.

1. **Balancing reactions.** In all cases, it is essential to ascertain that the coupled oxidation-reduction reaction is *balanced*.

Balancing involves three things: (a) the *total number of each kind of atom* must be identical on both sides of the equation; (b) there must be an *ionic balance* so that when positive and negative ions are added up on the right side of the equation, the total ionic charge (whether positive, negative, or neutral) exactly balances the ionic charge on the left side of the equation; and (c) there must be an *oxidation-reduction balance* so that all the electrons removed from one substance are transferred to another substance. In general, when constructing balanced reactions, one proceeds in the reverse of the three steps just listed. Usually, if steps (c) and (b) have been properly handled, step (a) becomes correct automatically.

2. **Examples:** (a) What is the balanced reaction for the oxidation of H₂S to SO₄²⁻ with O₂? First, decide how many electrons are involved in the oxidation of H₂S to SO₄²⁻. This can be most easily calculated from the oxidation states of the compounds, using the rules given previously. Because H has an oxidation state of +1, the oxidation state of S in H₂S is -2. Because O has an oxidation state of -2, the oxidation state of S in SO₄²⁻ is +6 (because it is an ion, and using the rules given in items 4 and 5 of the previous section). Thus, the oxidation of H₂S to SO₄²⁻ involves an *eight-electron transfer* (from -2 to +6). Because each O atom can accept two electrons (the oxidation state of O in O₂ is zero, but in H₂O is -2), this means that two molecules of molecular oxygen, O₂, are required to provide sufficient electron-accepting capacity. Thus, at this point, we know that the reaction requires 1 H₂S and 2 O₂ on the left side of the equation, and 1 SO₄²⁻ on the right side. To achieve an ionic balance, we must have two positive charges on the right side of the equation to balance the two negative charges of SO₄²⁻. Thus, 2 H⁺ must be added to the right side of the equation, making the overall reaction

By inspection, it can be seen that this equation is also balanced in terms of the total number of atoms of each kind on each side of the equation.

- (b) What is the balanced reaction for the oxidation of H₂S to SO₄²⁻ with Fe³⁺ as electron acceptor? We have just ascertained that the oxidation of H₂S to SO₄²⁻ is an eight-electron transfer. Because the reduction of Fe³⁺ to Fe²⁺ is only a one-electron transfer, 8 Fe³⁺ will be required. At this point, the reaction looks like this:

We note that the ionic balance is incorrect. We have 24 positive charges on the left and 14 positive charges on the right (16+ from Fe, 2- from sulfate). To equalize the charges, we add 10 H⁺ on the right. Now our equation looks like this:

To provide the necessary hydrogen for the H⁺ and oxygen for the sulfate, we add 4 H₂O to the left and find that the equation is now balanced:

^aValues for free energy of formation of various compounds can be found in Dean, J.A. 1973. *Lange's Handbook of Chemistry*, 11th edition. McGraw-Hill, New York; Garrels, R.M., and C.L. Christ. 1965. *Solutions, Minerals, and Equilibria*. Harper & Row, New York; Burton, K. 1957. In Krebs, H.A., and H.L. Komberg. Energy transformation in living matter, *Ergebnisse der Physiologie* (appendix). Springer-Verlag, Berlin; and Thauer, R.K., K. Jungermann, and H. Decker. 1977. Energy conservation in anaerobic chemotrophic bacteria. *Bacteriol. Rev.* 41: 100-180.

In general, ionic balance can be achieved by adding H^+ or OH^- to the left or right side of the equation, and because all reactions take place in an aqueous medium, H_2O molecules can be added where needed. Whether H^+ or OH^- is added generally depends on whether the reaction is taking place under acidic or alkaline conditions.

3. Calculation of energy yield for balanced equations from

free energies of formation. Once an equation has been balanced, the free-energy yield can be calculated by inserting the values for the free energy of formation of each reactant and product from Table A1.1 and using the formula in item 2 of the first section of this appendix. For instance, for the equation

$$G_f^0 \text{ values: } (-27.87) + (0) \longrightarrow \\ (-744.6) + 2(-39.83) \quad (\text{assuming pH 7})$$

$$\Delta G' = [(-744.6) + 2(-39.83)] - [(-27.87) + (0)] \\ = -796.39 \text{ kJ}$$

The G_f^0 values for the products (right side of reaction) are summed and subtracted from the G_f^0 values for the reactants (left side of reaction), taking care to ensure that the arithmetic signs are correct. From the data in Table A1.1, a wide variety of free-energy yields for reactions of microbiological interest can be calculated.

Calculation of Free-Energy Yield from Reduction Potential

Reduction potentials of some important redox pairs are given in **Table A1.2**. The amount of energy that can be released from two half reactions can be calculated from the *differences* in reduction potentials of the two reactions and from the number of electrons transferred. The farther apart the two half reactions are, and the greater the number of electrons transferred, the more energy released.

The conversion of potential difference to free energy is given by the formula $\Delta G^0' = -nF\Delta E_0'$, where n is the number of electrons, F is the Faraday constant (96.48 kJ/V), and $\Delta E_0'$ is the difference in reduction potentials. Thus, the $2 \text{ H}^+/\text{H}_2$ couple has a potential of -0.41 V and the $\frac{1}{2} \text{O}_2/\text{H}_2\text{O}$ pair has a potential of $+0.82$ V, and so the potential difference is 1.23 V, which (because two electrons are involved) is equivalent to a free-energy yield (ΔG^0) of -237.34 kJ. On the other hand, the potential difference between the $2 \text{ H}^+/\text{H}_2$

and the $\text{NO}_3^-/\text{NO}_2^-$ reactions is less, 0.84 V, which is equivalent to a free-energy yield of -162.08 kJ (☞ Figure 3.9).

Because many biochemical reactions are two-electron transfers, it is often useful to give energy yields for two-electron reactions, even if more electrons are involved. Thus, the $\text{SO}_4^{2-}/\text{H}_2$ redox pair involves eight electrons, and complete reduction of SO_4^{2-} with H_2 requires 4H_2 (equivalent to eight electrons). From the reduction potential difference between $2 \text{ H}^+/\text{H}_2$ and $\text{SO}_4^{2-}/\text{H}_2\text{S}$ (0.19 V), a free-energy yield of -146.64 kJ is calculated, or -36.66 kJ per two electrons. By convention, reduction potentials are given for conditions in which equal concentrations of oxidized and reduced forms are present. In actual practice, the concentrations of these two forms may be quite different. As discussed earlier in this appendix (Section I, item 9), it is possible to couple half reactions even if the potential difference is unfavorable, provided the concentrations of the reacting species are appropriate.

¹Bergey's Manual of Systematic Bacteriology, second edition, consists of 5 volumes; shown here are phyla and classes of prokaryotes found in this reference. Each class contains one or more orders, each order one or more families, each family one or more genera, and each genus one or more species. The genus name of many important prokaryotes forms part of the names of their higher-order taxa. Because bacterial taxonomy is a work in progress, updates to the list shown here occur regularly. For the most up-to-date prokaryotic taxonomy, refer to <http://www.bacterio.net>. An overview of prokaryotic diversity is presented in Chapters 14–16 of this text. Select orders of *Bacteria* are described in Chapters 14 and 15, including some not yet in *Bergey's Manual*.

²The phyla Thaumarchaeota, Nanoarchaeota, and Korarchaeota (see Chapter 16 and Figure 16.1 of this text) are recently established higher taxa of Archaea and should appear along with the Crenarchaeota and Euryarchaeota in a future edition of *Bergey's Manual*.

Phylum XVIII. Tenericutes

Class I. Mollicutes

Order I. *Mycoplasmatales*
Order II. *Entomoplasmatales*
Order III. *Acholeplasmatales*
Order IV. *Anaeroplasmatales*

Phylum XIX. Fibrobacteres

Class I. Fibrobacteres

Order I. *Fibrobacterales*

Phylum XX. Acidobacteria

Class I. Acidobacteria

Order I. *Acidobacterales*

Class II. Holophagae

Order I. *Holophagales*
Order II. *Acanthopleuribacterales*

Phylum XXI. Bacteroidetes

Class I. Bacteroidia

Glossary

Only the major terms and concepts are included. If a term is not here, consult the index.

ABC (ATP-binding cassette) transporter A membrane transport system consisting of three proteins, one of which hydrolyzes ATP, one of which binds the substrate, and one of which functions as the transport channel through the membrane.

Abscess A localized infection characterized by production of pus.

Acetic acid bacteria Obligately aerobic organisms that produce acetate from alcohols; used for making vinegar.

Acetogen A bacterium that carries out acetogenesis.

Acetogenesis Energy metabolism in which acetate is produced from either H₂ plus CO₂ or from organic compounds.

Acetotrophic Acetate consuming.

Acetyl-CoA pathway A pathway of autotrophic CO₂ fixation and acetate oxidation widespread in various obligate anaerobes including methanogens, acetogens, several clostridia, and sulfate-reducing bacteria.

Acetylene reduction assay A method of measuring activity of nitrogenase by substituting acetylene for the natural substrate of the enzyme, N₂. Acetylene is reduced to ethylene or ethane, depending on the nitrogenase system involved.

Acid-fastness A property of *Mycobacterium* species; cells stained with basic fuchsin dye resist decolorization with acidic alcohol.

Acid mine drainage Acidic water containing H₂SO₄ (sulfuric acid) derived from the microbial oxidation of iron sulfide minerals.

Acidophile An organism that grows best at acidic pH values.

Acridine orange A nonspecific fluorescent dye used to stain microbial cells in a natural sample.

Actinomycete A term used to refer to aerobic filamentous bacteria in the phylum *Actinobacteria*.

Activation energy The energy needed to make substrate molecules more reactive; enzymes function by lowering activation energy.

Activator protein A regulatory protein that binds to specific sites on DNA and stimulates transcription; involved in positive control.

Active immunity An immune state achieved by self-production of antibodies. Compare with *passive immunity*.

Active site The portion of an enzyme that is directly involved in binding substrate(s).

Active transport The energy-dependent process of transporting substances into or out of the cell without chemically changing the transported substances.

Acute infection A short-term infection, usually characterized by dramatic onset.

Adaptive immunity (antigen-specific immunity) The acquired ability to recognize and destroy a particular pathogen or its products; dependent on previous exposure to the pathogen or its products.

Adenosine triphosphate (ATP) A nucleotide that is the primary form in which chemical energy is conserved and utilized in cells.

Adherence The enhanced ability of a microorganism to attach to a cell or surface.

Aerobe An organism that grows in the presence of O₂; may be facultative, obligate, or microaerophilic.

Aerobic anoxygenic phototroph An organism that is an aerobic heterotroph and uses anoxygenic photosynthesis as a supplemental source of energy.

Aerobic secondary wastewater treatment Digestive reactions carried out by microorganisms under aerobic conditions to treat wastewater containing low levels of organic materials.

Aerosol Suspension of particles in airborne water droplets.

Aerotolerant anaerobe An anaerobic microorganism whose growth is not inhibited by O₂.

Agglutination A reaction between antibody and particle-bound antigen resulting in visible clumping of the particles.

Algae Phototrophic eukaryotic micro- and macroorganisms.

Alkaliphile An organism that grows best at high pH.

Allele A sequence variant of a given gene.

Allergy A harmful immune reaction, usually caused by a foreign antigen in food, pollen, or chemicals, which results in immediate-type or delayed-type hypersensitivity.

Allosteric protein An enzyme that contains two combining sites, an active site for binding substrate and an allosteric site for binding an effector molecule such as the end product of a biochemical pathway.

Amoeboid movement A type of motility in which cytoplasmic streaming moves the organism forward.

Amino acid One of the 22 monomers that make up proteins; chemically, a two-carbon carboxylic acid containing an amino group and a characteristic substituent on the alpha carbon.

Aminoacyl-tRNA synthetase An enzyme that catalyzes the attachment of the correct amino acid to the correct tRNA.

Aminoglycoside An antibiotic such as streptomycin, containing amino sugars linked by glycosidic bonds.

Anabolic reactions (anabolism) The biochemical processes involved in the synthesis of cell constituents from simpler molecules, usually requiring energy.

Anaerobe An organism that grows in the absence of O₂; some may even be killed by O₂ (obligate or strict anaerobes).

Anaerobic respiration Use of an electron acceptor other than O₂ in an electron transport-based oxidation leading to a proton motive force.

Anammox Anoxic ammonia oxidation.

Anaphylaxis (anaphylactic shock) A violent allergic reaction caused by an antigen–antibody reaction.

Anergy The inability to produce an immune response to specific antigens due to neutralization of effector cells.

Anoxic Oxygen-free. Usually used in reference to a microbial habitat.

Anoxic secondary wastewater treatment Digestive and fermentative reactions carried out by microorganisms under anoxic conditions to treat wastewater containing high levels of insoluble organic materials.

Anoxygenic photosynthesis The use of light energy to synthesize ATP by cyclic photophosphorylation without O₂ production.

Antenna pigments Light-harvesting chlorophylls or bacteriochlorophylls in photocomplexes that funnel energy to the reaction center.

Antibiogram A report indicating the sensitivity of clinically isolated microorganisms to the antibiotics in current use.

Antibiotic A chemical substance produced by a microorganism that kills or inhibits the growth of another microorganism.

Antibody A soluble protein produced by B lymphocytes and plasma cells that interacts specifically with antigen; also called *immunoglobulin*.

Anticodon A sequence of three bases in transfer RNA that base-pairs with a codon during protein synthesis.

Antigen A molecule capable of interacting with specific components of the immune system.

Antigen-presenting cell (APC) A macrophage, dendritic cell, or B cell that takes up and processes antigen and presents it to T-helper cells.

Antigenic drift In influenza virus, minor changes in viral proteins (antigens) due to gene mutation.

Antigenic shift In influenza virus, major changes in viral proteins (antigens) due to gene reassortment.

- Antimicrobial** Harmful to microorganisms by either killing or inhibiting growth.
- Antimicrobial agent** A chemical that kills or inhibits the growth of microorganisms.
- Antimicrobial drug resistance** The acquired ability of a microorganism to resist the effects of an antimicrobial drug to which it is normally susceptible.
- Antiparallel** In reference to double-stranded nucleic acids, the two strands run in opposite directions; one strand runs 5' → 3', the complementary strand 3' → 5'.
- Antiseptic (germicide)** A chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues.
- Antiserum** A serum containing antibodies.
- Antitoxin** An antibody that specifically interacts with and neutralizes a toxin.
- Apoptosis** Programmed cell death.
- Arbuscule** Branched or coiled hyphal structure within cells of the inner cortex of plants with a mycorrhizal infection.
- Archaea** Phylogenetically related prokaryotes distinct from *Bacteria*.
- Artificial chromosome** A single copy vector that can carry extremely long inserts of DNA and is widely used for cloning segments of large genomes.
- Aseptic technique** The manipulation of sterile instruments or culture media in such a way as to maintain sterility.
- Aspartame** A nonnutritive sweetener composed of the amino acids aspartate and phenylalanine, the latter as a methyl ester.
- ATP** Adenosine triphosphate, the principal energy carrier of the cell.
- ATPase (ATP synthase)** A multiprotein enzyme complex embedded in the cytoplasmic membrane that catalyzes the synthesis of ATP coupled to dissipation of the proton motive force.
- Attenuation** In a pathogen, a decrease or loss of virulence. Also, a mechanism for controlling gene expression; typically, transcription is terminated after initiation but before a full-length mRNA is produced.
- Autoantibody** An antibody that reacts to self antigens.
- Autoclave** A sealed sterilizing device that destroys microorganisms with temperature and steam under pressure.
- Autoimmunity** The immune reactions of a host against its own self antigens.
- Autoinducer** A small signal molecule that takes part in quorum sensing.
- Autoinduction** A gene regulatory mechanism involving small, diffusible signal molecules that are produced in larger amounts as population size increases.
- Autolysis** The lysis of a cell brought about by the activity of the cell itself.
- Autoradiography** Detection of radioactivity in a sample, for example, a cell or gel, by placing it in contact with a photographic film.
- Autotroph** An organism able to grow with CO₂ as its sole source of carbon.
- Auxotroph** An organism that has developed a nutritional requirement through mutation. Contrast with *prototroph*.
- B cell** A lymphocyte that has immunoglobulin surface receptors, may present antigens to T cells, and may form plasma cells, which produce immunoglobulin.
- B cell receptor (BCR)** A cell-surface antibody that acts as an antigen receptor on a B cell.
- Bacteremia** The presence of bacteria in the blood.
- Bacteria** Phylogenetically related prokaryotes distinct from *Archaea*.
- Bacterial artificial chromosome (BAC)** Circular artificial chromosome with bacterial origin of replication.
- Bacteriochlorophyll** A pigment of anoxygenic phototrophic organisms consisting of light-sensitive magnesium tetrapyrroles.
- Bacteriocidal agent** An agent that kills bacteria.
- Bacteriocins** Agents produced by certain bacteria that inhibit or kill closely related species.
- Bacteriocyte** A specialized insect cell in which bacterial symbionts reside.

- Bacteriome** A specialized region in several insect groups that contains insect bacteriocyte cells packed with bacterial symbionts.
- Bacteriophage** A virus that infects prokaryotic cells.
- Bacteriorhodopsin** A protein containing retinal that is found in the membranes of certain extremely halophilic *Archaea* and that is involved in light-mediated ATP synthesis.
- Bacteriostatic agent** An agent that inhibits bacterial growth.
- Bacteroid** A swollen, deformed *Rhizobium* cell found in the root nodule; capable of nitrogen fixation.
- Banded iron formation** Iron oxide-rich ancient sedimentary rocks containing zones of oxidized iron (Fe³⁺) formed by oxidation of Fe²⁺ by O₂ produced by cyanobacteria.
- Basal body** The “motor” portion of the bacterial flagellum, embedded in the cytoplasmic membrane and wall.
- Base composition** In reference to nucleic acids, the proportion of the total bases consisting of guanine plus cytosine or thymine plus adenine base pairs. Usually expressed as a guanine plus cytosine (GC) value, for example, 60% GC.
- Basic reproduction number (*R₀*)** The number of expected secondary transmissions from each single case of a disease in an entirely susceptible population.
- Batch culture** A closed-system microbial culture of fixed volume.
- β-Lactam antibiotic** An antibiotic such as penicillin that contains the four-membered heterocyclic β-lactam ring.
- Binary fission** Cell division whereby a cell grows by intercalary growth to twice its minimum size and then divides to form two cells.
- Binomial system** The system devised by Linnaeus for naming organisms by giving them a genus name and a species epithet.
- Biochemical oxygen demand (BOD)** The amount of dissolved oxygen consumed by microorganisms for complete oxidation of organic and inorganic material in a water sample.
- Biofilm** Microbial colonies encased in an adhesive, usually polysaccharide material and attached to a surface.
- Biofuel** A fuel made by microorganisms from the fermentation of carbon-rich feedstocks.
- Biogeochemistry** The study of microbially mediated chemical transformations of geochemical interest, for example, nitrogen or sulfur cycling.
- Bioinformatics** The use of computer programs to analyze, store, and access DNA and protein sequences.
- Biological warfare** The use of biological agents to kill or incapacitate a population.
- Bioluminescence** The enzymatic production of visible light by living organisms.
- Bioremediation** The use of microorganisms to remove or detoxify toxic or unwanted chemicals in an environment.
- Biosynthesis** The production of needed cellular constituents from other (usually simpler) molecules.
- Biotechnology** The use of organisms, typically genetically altered, in industrial, medical, or agricultural applications.
- Black smoker** A deep-sea hydrothermal vent emitting superheated 250–400°C water and minerals.
- Bone marrow** A primary lymphoid organ containing the pluripotent precursor cells for all blood and immune cells, including B cells.
- Botulism** Food poisoning due to ingestion of food containing botulinum toxin produced by *Clostridium botulinum*.
- Brewing** The manufacture of alcoholic beverages such as beer and ales from the fermentation of malted grains.
- Broad-spectrum antibiotic** An antibiotic that acts on both gram-positive and gram-negative *Bacteria*.
- Calvin cycle** The series of biosynthetic reactions by which many autotrophic organisms convert CO₂ to organic compounds.
- Canning** The process of sealing food in a closed container and heating to destroy living organisms and endospores.
- Capsid** The protein shell that surrounds the genome of a virus.
- Capsomere** The subunit of the virus capsid.

Capsule A dense, well-defined polysaccharide or protein layer closely surrounding a cell.

Carboxysome Polyhedral cellular inclusion of crystalline ribulose bisphosphate carboxylase (RubisCO), the key enzyme of the Calvin cycle.

Carcinogen A substance that causes the initiation of tumor formation. Frequently a mutagen.

Cardinal temperatures The minimum, maximum, and optimum growth temperatures for a given organism.

Carotenoid A hydrophobic accessory pigment present along with chlorophyll in photosynthetic membranes.

Carrier A subclinically infected individual who may spread a disease.

Cassette mutagenesis Creating mutations by the insertion of a DNA cassette.

Catabolic reactions (catabolism) The biochemical processes involved in the breakdown of organic or inorganic compounds, usually leading to the production of energy.

Catabolite repression The suppression of alternative catabolic pathways by a preferred source of carbon and energy.

Catalysis An increase in the rate of a chemical reaction.

Catalyst A substance that promotes a chemical reaction without itself being changed in the end.

CD4 cells T-helper cells. They are targets for HIV infection.

CD4 coreceptor A protein found exclusively on Th cells that interacts with MHC II on an antigen-presenting cell.

CD8 coreceptor A protein found exclusively on Tc cells that interacts with MHC I on a target cell.

Cell The fundamental unit of living matter.

Cell-mediated immunity An immune response generated by interactions with antigen-specific T cells. Compare with *antibody-mediated immunity*.

Cell wall A rigid layer present outside the cytoplasmic membrane that confers structural strength on the cell and protection from osmotic lysis.

Centers for Disease Control and Prevention (CDC) The agency of the United States Public Health Service that tracks disease trends, provides disease information to the public and to healthcare professionals, and forms public policy regarding disease prevention and intervention.

Chaperonin (molecular chaperone) A protein that helps other proteins fold or refold from a partly denatured state.

Chemiosmosis The use of ion gradients, especially proton gradients, across membranes to generate ATP.

Chemokine A small, soluble protein produced by a variety of cells that modulates inflammatory reactions and immunity.

Chemolithotroph An organism that obtains its energy from the oxidation of inorganic compounds.

Chemoorganotroph An organism that obtains its energy from the oxidation of organic compounds.

Chemostat A continuous culture device controlled by the concentration of limiting nutrient and dilution rate.

Chemotaxis Movement toward or away from a chemical.

Chemotherapeutic agent An antimicrobial agent that can be used internally.

Chemotherapy The treatment of infectious disease with chemicals or antibiotics.

Chitin A polymer of N-acetylglucosamine commonly found in the cell walls of fungi.

Chloramine A water purification chemical made by combining chlorine and ammonia at precise ratios.

Chlorination A highly effective disinfectant procedure for drinking water using chlorine gas or other chlorine-containing compounds as disinfectant.

Chlorine A chemical used in its gaseous state to disinfect water. A residual level is maintained throughout the distribution system.

Chlorophyll A pigment of phototrophic organisms consisting of light-sensitive magnesium tetrapyrroles.

Chloroplast The chlorophyll-containing organelle of phototrophic eukaryotes.

Chlorosome A cigar-shaped structure enclosed by a nonunit membrane and containing the light-harvesting bacteriochlorophyll (*c*, *d*, or *e*) in green sulfur bacteria and in *Chloroflexus*.

Chromogenic Producing color; for example, a chromogenic colony is a pigmented colony.

Chromosomal island A bacterial chromosome region of foreign origin that contains clustered genes for some extra property such as virulence or symbiosis.

Chromosome A genetic element carrying genes essential to cellular function. Prokaryotes typically have a single chromosome consisting of a circular DNA molecule. Eukaryotes typically have several chromosomes, each containing a linear DNA molecule.

Chronic infection A long-term infection.

-cidal Suffix indicating killing; for example, a bacteriocidal agent kills bacteria. Compare with *-static*.

Ciliate A protist characterized in part by rapid motility driven by numerous short appendages called cilia.

Cilium (plural, cilia) Short, filamentous structure that beats with many others to make a cell move.

Cirrhosis Breakdown of the normal liver architecture, resulting in fibrosis.

Citric acid cycle A cyclical series of reactions resulting in the conversion of acetate to CO₂ and NADH. Also called the tricarboxylic acid cycle or the Krebs cycle.

Clarifier (coagulation basin) A reservoir in which the suspended solids of raw water are coagulated and removed.

Clonal anergy The inability to produce an immune response to specific antigens due to the neutralization of effector cells.

Clonal deletion For T cell selection in the thymus, the killing of useless or self-reactive clone precursors.

Clonal selection A theory that each B or T lymphocyte, when stimulated by antigen, divides to form a clone of itself.

Clone In immunology, a copy of an antigen-reactive lymphocyte, usually in large numbers. Also, a number of copies of a DNA fragment obtained by allowing an inserted DNA fragment to be replicated by a phage or plasmid.

Cloning vectors Genetic elements into which genes can be recombined and replicated.

Coagulation The formation of large insoluble particles from much smaller, colloidal particles by the addition of aluminum sulfate and anionic polymers.

Coccoid Sphere-shaped.

Coccus A spherical bacterium.

Codon A sequence of three bases in messenger RNA that encodes a specific amino acid.

Codon bias The nonrandom usage of multiple codons encoding the same amino acid. Also called codon usage.

Coenocytic The presence of multiple nuclei in fungal hyphae without septa.

Coenzyme A low-molecular-weight molecule that participates in an enzymatic reaction by accepting and donating electrons or functional groups. Examples: NAD⁺, FAD.

Coevolution Evolution that proceeds jointly in a pair of intimately associated species owing to the effects each has on the other.

Coliform Gram-negative, nonsporulating, facultatively aerobic rod that ferments lactose with gas formation within 48 hours at 35°C.

Colonial The growth form of certain protists and green algae in which several cells live together and cooperate for feeding, motility, or reproduction; an early form of multicellularity.

Colonization The multiplication of a microorganism after it has attached to host tissues or other surfaces.

Colony A macroscopically visible population of cells growing on solid medium, arising from a single cell.

Cometabolism The metabolic transformation of a substance while a second substance serves as primary energy or carbon source.

Commensalism A type of symbiosis in which only one of two organisms in a relationship benefits.

- Commodity chemicals** Chemicals such as ethanol that have low monetary value and thus are sold primarily in bulk.
- Common-source epidemic** An epidemic resulting from infection of a large number of people from a single contaminated source.
- Communication** Interactions between cells using chemical signals.
- Community** Two or more cell populations coexisting in a certain area at a given time.
- Compatible solutes** Organic compounds (or potassium ions) that serve as cytoplasmic solutes to balance water relations for cells growing in environments of high salt or sugar.
- Competence** The ability to take up DNA and become genetically transformed.
- Complement** A series of proteins that react sequentially with antibody–antigen complexes, mannose-binding lectin, or alternate activation pathway proteins to amplify or potentiate target cell destruction.
- Complement fixation** The consumption of complement by an antibody–antigen reaction.
- Complementarity-determining region (CDR)** A varying amino acid sequence within the variable domains of immunoglobulins or T cell receptors where most molecular contacts with antigen are made. Also called a hypervariable region.
- Complementary** Nucleic acid sequences that can base-pair with each other.
- Complex medium** Any culture medium whose precise chemical composition is unknown. Also called undefined media.
- Concatemer** A DNA molecule consisting of two or more separate molecules linked end to end to form a long, linear structure.
- Congenital syphilis** Syphilis contracted by an infant from its mother during pregnancy.
- Conidia** Asexual spores of fungi.
- Conjugation** The transfer of genes from one prokaryotic cell to another by a mechanism involving cell-to-cell contact.
- Consensus sequence** A nucleic acid sequence in which the base present in a given position is that base most commonly found when many experimentally determined sequences are compared.
- Consortium** A two-membered (or more) bacterial culture (or natural assemblage) in which each organism benefits from the others.
- Contagious** Transmissible.
- Convergent evolution** A circumstance where a trait or set of traits that are similar in form and/or function between two organisms are not inherited from a shared ancestor (i.e., traits that are similar but not homologous).
- Core genome** The part of a genome shared by all strains of a species.
- Cortex** The region inside the spore coat of an endospore, around the core.
- Coryneform bacteria** Gram-positive, aerobic, nonmotile, rod-shaped organisms with the characteristic of forming irregular-shaped, club-shaped, or V-shaped cell arrangements, typical of several genera of unicellular *Actinobacteria*.
- Covalent bond** A nonionic chemical bond formed by a sharing of electrons between two atoms.
- Crenarchaeota** A phylum of *Archaea* that contains both hyperthermophilic and cold-dwelling organisms.
- Crista (plural, cristae)** An inner membrane in a mitochondrion; a site of respiration.
- Crown corrosion** The destruction of the upper half, or crown, of concrete wastewater pipes by sulfuric acid produced through the concerted activities of sulfate-reducing and sulfur-oxidizing bacteria.
- Culture** A particular strain or kind of organism growing in a laboratory medium.
- Culture medium** An aqueous solution of various nutrients suitable for the growth of microorganisms.
- Cutaneous** Relating to the skin.
- Cyanobacteria** Prokaryotic oxygenic phototrophs containing chlorophyll *a* and phycobilins.
- Cyclic AMP** A regulatory nucleotide that participates in catabolite repression.

- Cyst** A resting stage formed by some bacteria and protists in which the whole cell is surrounded by a thick-walled, chemically and physically resistant coating; not the same as a spore or endospore.
- Cytochrome** An iron-containing porphyrin complexed with proteins, which functions as an electron carrier in the electron transport system.
- Cytokine** A small, soluble protein produced by a leukocyte that modulates inflammatory reactions and immunity.
- Cytoplasm** The fluid portion of a cell, bounded by the cell membrane.
- Cytoplasmic membrane** A semipermeable barrier that separates the cell interior (cytoplasm) from the environment.
- Cytoskeleton** Cellular scaffolding typical of eukaryotic cells in which microtubules, microfilaments, and intermediate filaments define the cell's shape.
- DAPI** A nonspecific fluorescent dye used to stain microbial cells in a natural sample to obtain total cell numbers.
- Decontamination** Treatment that renders an object or inanimate surface safe to handle.
- Deep sea** Marine waters below a depth of 1000 m.
- Defective virus** A virus that relies on another virus, the helper virus, to provide some of its components.
- Defined medium** Any culture medium whose exact chemical composition is known. Compare with *complex medium*.
- Degeneracy** In relation to the genetic code, the fact that more than one codon can code for the same amino acid.
- Delayed-type hypersensitivity (DTH)** An inflammatory allergic response mediated by Th1 lymphocytes.
- Deletion** The removal of a portion of a gene.
- Denaturation** The irreversible destruction of a macromolecule, for example, the destruction of a protein by heat.
- Denaturing gradient gel electrophoresis (DGGE)** An electrophoretic technique capable of separating nucleic acid fragments of the same size that differ in sequence.
- Dendritic cell** A type of leukocyte having phagocytic and antigen-presenting properties, found in various body tissues; transports antigen to lymph nodes and spleen.
- Denitrification** Anaerobic respiration in which nitrate is reduced to nitrogen gases (primarily N_2) under anoxic conditions.
- Denitrifier** An organism that carries out denitrification.
- Dental caries** Tooth decay resulting from bacterial infection.
- Dental plaque** Bacterial cells encased in a matrix of extracellular polymers and salivary products, found on the teeth.
- Deoxyribonucleic acid (DNA)** A polymer of nucleotides connected via a phosphate–deoxyribose sugar backbone; the genetic material of cells and some viruses.
- Desiccation** Drying.
- Diazotroph** An organism that can assimilate N_2 into biomass by activity of the enzyme nitrogenase.
- Dideoxynucleotide** A nucleotide lacking the 3'-hydroxyl group on the deoxyribose sugar. Used in the Sanger method of DNA sequencing.
- Differential media** Growth media that allow identification of microorganisms based on phenotypic properties.
- Differentiation** The modification of a cell in terms of structure and/or function occurring during the course of development.
- Dipicolinic acid** A substance unique to endospores that confers heat resistance on these structures.
- Diploid** In eukaryotes, an organism or cell with two chromosome complements, one derived from each haploid gamete.
- Disease** An injury to a host organism, caused by a pathogen or other factor, that affects host function.
- Disinfectant** An antimicrobial agent used only on inanimate objects.
- Disinfection** The elimination of pathogens from inanimate objects or surfaces.
- Disproportionation** The splitting of a chemical compound into two new compounds, one more oxidized and one more reduced than the original compound.
- Dissimilative sulfate-reducer** An anaerobic microorganism that conserves energy through the reduction of SO_4^{2-} .

Dissimilative sulfur-oxidizer A microorganism that conserves energy for growth through oxidation of reduced sulfur compounds.

Dissimilative sulfur-reducer An anaerobic microorganism that conserves energy through the reduction of S⁰ but cannot reduce SO₄²⁻.

Distilled alcoholic beverage A beverage containing alcohol concentrated by distillation.

Distribution system Water pipes, storage reservoirs, tanks, and other means used to deliver drinking water to consumers or store it before delivery.

Divosome A complex of proteins that directs cell division processes in bacteria.

DNA Deoxyribonucleic acid, the genetic material of cells and some viruses.

DNA cassette An artificially designed segment of DNA that usually carries a gene for resistance to an antibiotic or some other convenient marker and is flanked by convenient restriction sites.

DNA–DNA hybridization The experimental determination of genomic similarity by measuring the extent of hybridization of DNA from the genome of one organism with that of another.

DNA gyrase An enzyme found in most prokaryotes that introduces negative supercoils in DNA.

DNA helicase An enzyme that uses ATP to unwind the double helix of DNA.

DNA ligase An enzyme that seals nicks in the backbone of DNA.

DNA polymerase An enzyme that synthesizes a new strand of DNA in the 5' → 3' direction using an antiparallel DNA strand as a template.

DNA vaccine A vaccine that uses the DNA of a pathogen to elicit an immune response.

Domain (1) The highest level of biological classification. The three domains of organisms are the *Bacteria*, the *Archaea*, and the *Eukarya*. (2) A region of a protein having a defined structure and function.

Downstream position Refers to nucleic acid sequences on the 3' side of a given site on the DNA or RNA molecule. Compare with *upstream position*.

Dysbiosis An alteration or imbalance of an individual's microbiome relative to the normal, healthy state, primarily observed in the microbiota of the digestive tract or skin.

Early protein A protein synthesized soon after virus infection and before replication of the virus genome.

Ecology Study of the interrelationships between organisms and their environments.

Ecosystem A dynamic complex of organisms and their physical environment interacting as a functional unit.

Ecotype A population of genetically identical cells sharing a particular resource within an ecological niche.

Effluent water Treated wastewater discharged from a wastewater treatment facility.

Ehrlichiosis One of a group of tick-transmitted diseases caused by rickettsias of the *Ehrlichia* genus.

Electron acceptor A substance that accepts electrons during an oxidation–reduction reaction.

Electron donor A compound that donates electrons in an oxidation–reduction reaction.

Electron transport phosphorylation Synthesis of ATP involving a membrane-associated electron transport chain and the creation of a proton motive force. Also called *oxidative phosphorylation*.

Electrophoresis Separation of charged molecules in an electric field.

Electroporation The use of an electric pulse to enable cells to take up DNA.

ELISA See *enzyme immunoassay*.

Emerging disease Infectious disease whose incidence recently increased or whose incidence threatens to increase in the near future.

Enantiomer One form of a molecule that is the mirror image of another form of the same molecule.

Endemic disease A disease that is constantly present in a population, usually in low numbers. Compare with *epidemic*.

Endergonic reaction A chemical reaction requiring an input of energy to proceed.

Endocytosis A process in which a particle such as a virus is taken intact into an animal cell. Phagocytosis and pinocytosis are two kinds of endocytosis.

Endoplasmic reticulum An extensive array of internal membranes in eukaryotes.

Endospore A differentiated cell formed within the cells of certain gram-positive bacteria that is extremely resistant to heat as well as to other harmful agents.

Endosymbiosis The engulfment of one cell type by another cell type and the subsequent and stable association of the two cells.

Endosymbiotic hypothesis The idea that a chemoorganotrophic bacterium and a cyanobacterium were stably incorporated into another cell type to give rise, respectively, to the mitochondria and chloroplasts of modern-day eukaryotes.

Endotoxin The lipopolysaccharide portion of the cell envelope of certain gram-negative *Bacteria*, which is a toxin when solubilized. Compare with *exotoxin*.

Enriched media Media that allow metabolically fastidious organisms to grow because of the addition of specific growth factors.

Enrichment bias A problem with enrichment cultures in which "weed" species tend to dominate in the enrichment, often to the exclusion of the most abundant or ecologically significant organisms in the inoculum.

Enrichment culture technique The use of selective culture media and incubation conditions to isolate specific microorganisms from natural samples.

Enteric bacteria A large group of gram-negative, rod-shaped *Bacteria* characterized by a facultatively aerobic metabolism and commonly found in the intestines of animals.

Enterotoxin A protein that is released extracellularly by a microorganism as it grows and that produces immediate damage to the small intestine of the host.

Entropy A measure of the degree of disorder in a system; entropy always increases in a closed system.

Enviroaped In reference to a virus, having a lipoprotein membrane surrounding the virion.

Enzootic An endemic disease present in an animal population.

Enzyme A catalyst, usually composed of protein, that promotes specific reactions or groups of reactions.

Enzyme immunoassay (EIA) A test that uses antibodies to detect antigens or antibodies in body fluids. Also called enzyme-linked immunosorbent assay (ELISA).

Epidemic A disease occurring in an unusually high number of individuals in a population at the same time. Compare with *endemic*.

Epidemiology The study of the occurrence, distribution, and determinants of health and disease in a population.

Epilimnion The warmer and less dense surface waters of a stratified lake.

Epitope The portion of an antigen that is recognized by an immunoglobulin or a T cell receptor.

Epizootic An epidemic disease present in an animal population.

Escherichia coli O157:H7 An enterotoxigenic strain of *E. coli* spread by fecal contamination of animal or human origin to food and water.

Eukarya The phylogenetic domain containing all eukaryotic organisms.

Eukaryote A cell or organism having a unit membrane–enclosed nucleus and usually other organelles; a member of the *Eukarya*.

Euryarchaeota A phylum of *Archaea* that contains primarily methanogens, extreme halophiles, *Thermoplasma*, and some marine hyperthermophiles.

Evolution Descent with modification; DNA sequence variation and the inheritance of that variation.

Evolutionary distance In phylogenetic trees, the sum of the physical distance on a tree separating organisms; this distance is inversely proportional to evolutionary relatedness.

- Exergonic reaction** A chemical reaction that proceeds with the liberation of energy.
- Exoenzyme** An enzyme produced by a microorganism and then excreted into the environment.
- Exons** The coding sequences in a split gene. Contrast with *introns*, the intervening noncoding regions.
- Exotoxin** A protein that is released extracellularly by a microorganism as it grows and that produces immediate host cell damage. Compare with *endotoxin*.
- Exponential growth** Growth of a microbial population in which the cell number doubles within a fixed time period.
- Exponential phase** A period during the growth cycle of a population in which growth increases at an exponential rate.
- Expression** The ability of a gene to function within a cell in such a way that the gene product is formed.
- Expression vector** A cloning vector that contains the necessary regulatory sequences allowing transcription and translation of a cloned gene or genes.
- Extein** The portion of a protein that remains and has biological activity after the splicing out of any inteins.
- Extracellular matrix (ECM)** Proteins and polysaccharides that surround an animal cell and in which the cell is embedded.
- Extreme halophile** An organism whose growth is dependent on large concentrations (generally >9%) of NaCl.
- Extreme piezophile** An organism requiring several hundred atmospheres of pressure for growth.
- Extremophile** An organism that grows optimally under one or more chemical or physical extremes, such as high or low temperature or pH.
- Facultative** Indicates that an organism is able to grow in either the presence or absence of an environmental factor (for example, "facultative aerobe").
- FAME** Fatty acid methyl ester; a technique for identifying microorganisms by their fatty acids.
- Fatty acid** An organic acid containing a carboxylic acid group and a hydrocarbon chain of various lengths; major components of lipids.
- Feedback inhibition** A decrease in the activity of the first enzyme of a biochemical pathway caused by buildup of the final product of the pathway.
- Fermentation** The anaerobic catabolism of an organic compound in which the compound serves as both an electron donor and an electron acceptor and in which ATP is usually produced by substrate-level phosphorylation.
- Fermentation (industrial)** A large-scale microbial process.
- Fermenter** An organism that carries out the process of fermentation.
- Fermentor** A growth vessel, usually quite large, used to culture microorganisms for the production of some commercially valuable product.
- Ferredoxin** An electron carrier of very negative reduction potential; small protein containing iron–sulfur clusters.
- Fever** An abnormal increase in body temperature.
- Filamentous** In the form of very long rods, many times longer than wide.
- Filtration** The removal of suspended particles from water by passing it through one or more permeable membranes or media (e.g., sand, anthracite, or diatomaceous earth).
- Fimbria (plural, fimbriae)** Short, filamentous structure on a bacterial cell; although flagella-like in structure, it is generally present in many copies and not involved in motility. Plays a role in adherence to surfaces and in the formation of pellicles. See also *pilus*.
- Finished water** Water delivered to the distribution system after treatment.
- FISH** See *Fluorescence in situ hybridization*.
- Fitness** The capacity of an organism to survive and reproduce as compared to competing organisms.
- Flagellum (plural, flagella)** A long, thin cellular appendage that rotates (in prokaryotic cells) and is responsible for swimming motility.

- Flavoprotein** A protein containing a derivative of riboflavin, which functions as an electron carrier in the electron transport system.
- Flocculation** The water treatment process after coagulation that uses gentle stirring to cause suspended particles to form larger, aggregated masses (flocs).
- Flow cytometry** A technique for counting and examining microscopic particles by suspending them in a stream of fluid and passing them by an electronic detection device.
- Fluorescence in situ hybridization (FISH)** A method employing a fluorescent dye covalently bonded to a specific nucleic acid probe for identifying or tracking organisms in the environment.
- Fluorescent** Having the ability to emit light of a certain wavelength when activated by light of another wavelength.
- Fluorescent antibody** An antibody molecule covalently modified with a fluorescent dye that makes the antibody visible under fluorescent light.
- Fluorescent protein** Any of a large group of proteins that fluoresce different colors, including the *green fluorescent protein (GFP)* for tracking genetically modified organisms and determining conditions that induce the expression of specific genes.
- Fomite** An inanimate object that when contaminated with a viable pathogen can transfer the pathogen to a host.
- Food infection** A microbial infection resulting from the ingestion of pathogen-contaminated food followed by growth of the pathogen in the host.
- Food poisoning (food intoxication)** A disease caused by the ingestion of food that contains preformed microbial toxins.
- Food spoilage** Any change in a food product that makes it unacceptable to the consumer.
- Frameshift mutation** A mutation in which insertion or deletion of nucleotides changes the groups of three bases in which the genetic code is read within an mRNA, usually resulting in a faulty product.
- Free energy (G)** Energy available to do work; G° is free energy under standard conditions.
- Fruiting body** A macroscopic reproductive structure produced by some fungi (for example, mushrooms) and some *Bacteria* (for example, myxobacteria), each distinct in size, shape, and coloration.
- FtsZ** A protein that forms a ring along the mid-cell division plane to initiate cell division.
- Functional diversity** The component of biological diversity that deals with the forms and functions of organisms as they relate to differences in physiology and ecology. Compare with *phylogenetic diversity*.
- Fundamental niche** The range of environments in which a species will be sustained when it is not resource-limited, such as may result from competition with other species.
- Fungi (singular, fungus)** Nonphototrophic eukaryotic microorganisms with rigid cell walls.
- Fungicidal agent** An agent that kills fungi.
- Fungistatic agent** An agent that inhibits fungal growth.
- Fusion inhibitor** A synthetic polypeptide that binds to viral glycoproteins, inhibiting fusion of viral and host cell membranes.
- Fusion protein** A protein that is the result of fusing two different proteins together by merging their coding sequences into a single gene.
- Gametes** In eukaryotes, the haploid germ cells that result from meiosis.
- Gas gangrene** Human tissue destruction due to the growth of proteolytic and gas-producing clostridia.
- Gas vesicle** A gas-filled structure made of protein; confers buoyancy on a cell when present in the cytoplasm in large numbers.
- GC ratio** In DNA (or RNA) from any organism, the percentage of the total nucleic acid that consists of guanine plus cytosine bases (expressed as mol% GC).
- Gel** An inert polymer, usually made of agarose or polyacrylamide, used for separating macromolecules such as nucleic acids and proteins by electrophoresis.
- Gel electrophoresis** A technique for separation of nucleic acid molecules by passing an electric current through a gel made of agarose or polyacrylamide.

- Gene** A unit of heredity; a segment of DNA (or RNA in some viruses) specifying a particular protein or polypeptide chain, or a tRNA or an rRNA.
- Gene chip** Small, solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern. Also called *microarrays*.
- Gene cloning** See *molecular cloning*.
- Gene disruption** Also called gene knockout. The inactivation of a gene by insertion of a DNA fragment that interrupts the coding sequence.
- Gene expression** Transcription of a gene followed by translation of the resulting mRNA into protein(s).
- Gene family** Genes that are related in sequence to each other as the result of a common evolutionary origin.
- Gene fusion** A structure created by joining together segments of two separate genes, in particular when the regulatory region of one gene is joined to the coding region of a reporter gene.
- General-purpose medium** A growth medium that supports the growth of most aerobic and facultatively aerobic organisms.
- Generation time** The time required for a cell population to double. Also called doubling time.
- Gene therapy** Treatment of a disease caused by a dysfunctional gene by introduction of a normally functioning copy of the gene.
- Genetically modified organism (GMO)** An organism whose genome has been altered using genetic engineering. The abbreviation is also used in terms such as GM crops and GM foods.
- Genetic code** The correspondence between nucleic acid sequence and amino acid sequence of proteins.
- Genetic drift** A process that results in a change in allele frequencies in a population as a result of random changes in the number of offspring from each individual over time.
- Genetic element** A structure that carries genetic information, such as a chromosome, a plasmid, or a virus genome.
- Genetic engineering** The use of *in vitro* techniques in the isolation, manipulation, alteration, and expression of DNA or RNA and in the development of genetically modified organisms.
- Genetic exchange** The transfer of genes or the acceptance of genes between prokaryotic cells.
- Genetic map** The arrangement of genes on a chromosome.
- Genetics** Heredity and variation of organisms.
- Genome** The total complement of genetic information of a cell or a virus.
- Genomic library (DNA library)** A collection of cloned DNA fragments that contains all the genetic information for a particular organism.
- Genomics** The discipline that maps, sequences, analyzes, and compares genomes.
- Genotype** The complete genetic makeup of an organism; the complete description of a cell's genetic information. Compare with *phenotype*.
- Genus** A taxonomic group of related species.
- Germicide (antiseptic)** A chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues.
- Global warming** The predicted and ongoing warming of the atmosphere and oceans attributed to anthropogenic release of greenhouse gases, primarily CO₂, that trap infrared radiation emitted by Earth.
- Glycocalyx** Polysaccharide components outside of the bacterial cell wall; usually a loose network of polymer fibers extending outward from the cell.
- Glycolysis** Reactions of the Embden–Meyerhof–Parnas pathway in which glucose is converted to pyruvate.
- Glycosidic bond** A type of covalent bond that links sugar units together in a polysaccharide.
- Glyoxylate cycle** A series of reactions including some citric acid cycle reactions that are used for aerobic growth on C₂ or C₃ organic acids.
- Gonococcus** *Neisseria gonorrhoeae*, the gram-negative diplococcus that causes the disease gonorrhea.
- Gram-negative cells** A major phylogenetic lineage of prokaryotic cells with a cell wall containing relatively little peptidoglycan, and an outer membrane composed of lipopolysaccharide, lipoprotein, and other complex macromolecules; stain pink in the Gram stain.
- Gram-positive cells** A major phylogenetic lineage of prokaryotic cells containing mainly peptidoglycan in their cell wall; stain purple in the Gram stain.
- Gram stain** A differential staining technique in which cells stain either pink (gram-negative) or purple (gram-positive), depending upon their structural makeup.
- Green fluorescent protein (GFP)** A protein that fluoresces green and is widely used in genetic analysis. See also *fluorescent protein*.
- Green nonsulfur bacteria** Anoxygenic phototrophs containing chlorosomes, a type II photosystem, bacteriochlorophylls *a* and *c* as light-harvesting chlorophyll, and typically growing best as photoheterotrophs.
- Green sulfur bacteria** Anoxygenic phototrophs containing chlorosomes, a type I photosystem, bacteriochlorophyll *c*, *d*, or *e* as light-harvesting chlorophyll, and typically growing with H₂S as an electron donor.
- Group translocation** An energy-dependent transport system in which the substance transported is chemically modified during the process of being transported by a series of proteins.
- Growth** In microbiology, an increase in cell number.
- Growth factor analog** A chemical agent that is related to and blocks the uptake or utilization of a growth factor.
- Growth rate** The rate at which growth occurs, usually expressed as the generation time.
- Guild** Metabolically similar microbial populations that exploit the same resources in a similar way.
- HAART (highly active antiretroviral therapy)** The treatment of HIV infection with two or more antiretroviral drugs at once to inhibit the development of drug resistance.
- Habitat** An environment within an ecosystem where a microbial community could reside.
- Halophile** An organism requiring salt (NaCl) for growth.
- Halorhodopsin** A light-driven chloride pump that accumulates Cl⁻ within the cytoplasm.
- Halotolerant** Capable of growing in the presence of NaCl, but not requiring it.
- Hantavirus pulmonary syndrome (HPS)** An emerging acute viral disease characterized by pneumonia, caused by rodent hantavirus.
- Haploid** An organism or cell containing only one set of chromosomes.
- Hapten** A low-molecular-weight substance not inducing antibody formation itself but still able to combine with a specific antibody.
- Healthcare-associated infection (nosocomial infection)** An infection contracted in a healthcare-associated setting.
- Heat shock proteins** Proteins induced by high temperature (or certain other stresses) that protect against high temperature, especially by refolding partially denatured proteins or by degrading them.
- Heat shock response** Response to high temperature that includes the synthesis of heat shock proteins together with other changes in gene expression.
- Heliobacteria** Anoxygenic phototrophs that contain bacteriochlorophyll *g*.
- Helix** A spiral structure in a macromolecule that contains a repeating pattern.
- Helper virus** A virus that provides some necessary components for a defective virus.
- Hemagglutination** Agglutination of red blood cells.
- Hemolysins** Bacterial toxins capable of lysing red blood cells.
- Hemolysis** Lysis of red blood cells.
- Hemorrhagic fever with renal syndrome (HFRS)** An emerging acute disease characterized by shock and kidney failure, caused by rodent hantavirus.
- Hepadnavirus** A virus whose DNA genome replicates by way of an RNA intermediate.
- HEPA filter** A high-efficiency particulate air filter used in laboratories and industry to remove particles, including microorganisms, from intake or exhaust air flow.
- Hepatitis** Liver inflammation, commonly caused by an infectious agent.

Herd immunity The resistance of a group to a pathogen as a result of the immunity of a large proportion of the group to that pathogen.

Herpes simplex The virus that causes both genital herpes and cold sores.

Heterocyst A differentiated cyanobacterial cell that carries out nitrogen fixation.

Heteroduplex A DNA double helix composed of single strands from two different DNA molecules.

Heterofermentative Describes lactic acid bacteria capable of making more than one fermentation product.

Heterotroph An organism that requires organic carbon as its carbon source; also a chemoorganotroph.

Hfr cell A cell with the F plasmid integrated into the chromosome.

High GC gram-positive bacteria Describes bacteria in the *Actinobacteria*.

Histones Basic proteins that protect and compact the DNA in eukaryotes and some *Archaea*.

Homoacetogens *Bacteria* that produce acetate as the sole product of sugar fermentation or from H₂ + CO₂. Also called *acetogens*.

Homofermentative In reference to lactic acid bacteria, producing only lactic acid as a fermentation product.

Homologs Genes related in sequence to an extent that implies common genetic ancestry; includes both orthologs and paralogs.

Homologous antigen An antigen that reacts with the antibody it has induced.

Homology Having shared ancestry.

Horizontal gene transfer The unidirectional transfer of genetic information between unrelated organisms as opposed to its vertical inheritance from parental organism(s). Also called *lateral gene transfer*.

Host (or host cell) An organism or cell type capable of supporting the growth of a virus or other parasite.

Host-to-host epidemic An epidemic resulting from host-to-host contact, characterized by a gradual rise and fall in disease incidence.

Human artificial chromosome (HAC) An artificial chromosome with a human centromere sequence array.

Human granulocytic anaplasmosis (HGA) Rickettsiosis caused by *Ehrlichia ewingii* or *Anaplasma phagocytophilum*.

Human leukocyte antigen (HLA) An antigen-presenting protein encoded by a major histocompatibility complex gene in humans.

Human monocytic ehrlichiosis (HME) A rickettsiosis caused by *Ehrlichia chaffeensis* or *Rickettsia sennetsu*.

Human papillomavirus (HPV) A sexually transmitted virus that causes genital warts, cervical neoplasia, and cancer.

Humoral immunity An immune response involving antibodies.

Humus Dead organic matter.

Hybridization Base pairing of single strands of DNA or RNA from two different (but related) sources to give a hybrid double helix.

Hydrogenase An enzyme, widely distributed in anaerobic microorganisms, capable of taking up or evolving H₂.

Hydrogen bond A weak chemical bond between a hydrogen atom and a second, more electronegative element, usually an oxygen or nitrogen atom.

Hydrogenosome An organelle of endosymbiotic origin present in certain microbial eukaryotes that oxidizes pyruvate to H₂, CO₂, and acetate, and couples this to ATP synthesis.

Hydrolysis Breakdown of a polymer into smaller units, usually monomers, by addition of water; digestion.

Hydrophobic interactions Attractive forces between molecules due to the close positioning of nonhydrophilic portions of the two molecules.

Hydrothermal vents Warm or hot water-emitting springs associated with crustal spreading centers on the seafloor.

Hydroxypropionate pathway An autotrophic pathway found in *Chloroflexus* and a few *Archaea*.

Hypersensitivity An immune reaction causing damage to the host, caused either by antigen–antibody reactions or cellular immune processes. See *allergy*.

Hyperthermophile A prokaryote having a growth temperature optimum of 80°C or higher.

Hypolimnion The colder, more dense, and often anoxic bottom waters of a stratified lake.

Icosahedron A geometrical shape occurring in many virus particles, with 20 triangular faces and 12 corners.

Immediate hypersensitivity An allergic response mediated by vasoactive products released from tissue mast cells.

Immobilized enzyme An enzyme attached to a solid support over which substrate is passed and converted to product.

Immune Able to resist infectious disease.

Immune memory The capacity to respond more quickly and vigorously to second and subsequent exposures to an eliciting antigen.

Immunity The ability of an organism to resist infection.

Immunization (vaccination) Inoculation of a host with inactive or weakened pathogens or pathogen products to stimulate protective immunity.

Immunoblot (Western blot) The detection of specific proteins by separating them via electrophoresis, transferring them to a membrane, and adding specific antibodies.

Immunodeficiency Having a dysfunctional or completely nonfunctional immune system.

Immunogen A molecule capable of eliciting an immune response.

Immunoglobulin (Ig) A soluble protein produced by B cells and plasma cells that interacts with antigen; also called *antibody*.

Immunoglobulin gene superfamily A family of genes that are evolutionarily, structurally, and functionally related to immunoglobulins.

Incidence The number of new disease cases reported in a population in a given time period.

Induced enzyme An enzyme subject to induction.

Induced mutation A mutation caused by external agents such as mutagenic chemicals or radiation.

Induction Production of an enzyme in response to a signal (often the presence of the substrate for the enzyme).

Industrial microbiology The large-scale use of microorganisms to make products of commercial value.

Infection Growth of an organism within a host.

Infection thread In the formation of root nodules, a cellulosic tube through which *Rhizobium* cells travel to reach and infect root cells.

Inflammation A nonspecific reaction to noxious stimuli such as toxins and pathogens, characterized by redness (erythema), swelling (edema), pain, and heat, usually localized at the site of infection.

Informational macromolecule Any large polymeric molecule that carries genetic information, including DNA, RNA, and protein.

Inhibition In reference to growth, the reduction of microbial growth because of a decrease in the number of organisms present or alterations in the microbial environment.

Innate immunity (nonspecific immunity) The noninducible ability to recognize and destroy an individual pathogen or its products that does not rely on previous exposure to a pathogen or its products.

Inoculum Cell material used to initiate a microbial culture.

Insertion A genetic phenomenon in which a piece of DNA is inserted into the middle of a gene.

Insertion sequence (IS) The simplest type of transposable element, which carries only genes involved in transposition.

Integrase The enzyme that inserts cassettes into an integron.

Integrase inhibitor A drug that interrupts the HIV replication cycle by interfering with integrase, the HIV protein that catalyzes the integration of viral dsDNA into host cell DNA.

Integrating vector A cloning vector that can be inserted into a host chromosome.

Integration The process by which a DNA molecule becomes incorporated into another genome.

Integron A genetic element that collects and expresses genes carried on mobile cassettes.

- Intein** An intervening sequence in a protein; a segment of a protein that can splice itself out.
- Interactome** The total set of interactions between proteins (or other macromolecules) in an organism.
- Intercalary growth** In cell division, enlargement of a cell at several growing points.
- Interferons** Cytokine proteins produced by virus-infected cells that induce signal transduction in nearby cells, resulting in transcription of antiviral genes and expression of antiviral proteins.
- Interleukin (IL)** Soluble cytokine or chemokine mediator secreted by leukocytes.
- Intermediate filament** A filamentous polymer of fibrous keratin proteins, supercoiled into thicker fibers, that functions in maintaining cell shape and the positioning of certain organelles in the eukaryotic cell.
- Interspecies hydrogen transfer** The process by which organic matter is degraded by the interaction of several groups of microorganisms in which H₂ production and H₂ consumption are closely coupled.
- Introns** The intervening noncoding sequences in a split gene. Contrast with *exons*, the coding sequences.
- Invasion** The ability of a pathogen to enter into host cells or tissues, spread, and cause disease.
- In vitro** In glass, away from the living organism.
- In vivo** In the body, in a living organism.
- Ionophore** A compound that can cause the leakage of ions across membranes.
- Irradiation** In food microbiology, the exposure of food to ionizing radiation to inhibit microorganisms and insect pests or to retard growth or ripening.
- Isolation** In the context of infectious disease, the separation of persons who have an infectious disease from those who are healthy. Compare with *quarantine*.
- Isomers** Two molecules that have the same molecular formula but that differ structurally.
- Isotopes** Different forms of the same element containing the same number of protons and electrons but differing in the number of neutrons.
- Isotopic fractionation** Discrimination by enzymes against the heavier isotope of the various isotopes of carbon or sulfur, leading to enrichment of the lighter isotopes.
- Jaundice** The production and release of excess bilirubin in the liver due to destruction of liver cells, resulting in yellowing of the skin and whites of the eye.
- Joule (J)** A unit of energy equal to 10⁷ ergs; 1000 joules equal 1 kilojoule (kJ).
- Kilobase (kb)** A 1000-base fragment of nucleic acid. A *kilobase pair* (kbp) is a fragment containing 1000 base pairs.
- Kinase** An enzyme that adds a phosphoryl group, usually from ATP, to a compound.
- Koch's postulates** A set of criteria for proving that a given microorganism causes a given disease.
- Korarchaeota** A phylum of *Archaea* that contains the hyperthermophile *Korarchaeum cryptophilum*.
- Lactic acid bacteria** Fermentative bacteria that produce lactic acid, are found in the *Firmicutes*, and are important in food production and preservation.
- Lagging strand** The new strand of DNA that is synthesized in short pieces during DNA replication and then joined together later.
- Lag phase** The period after inoculation of a culture before growth begins.
- Laser tweezers** A device used to obtain pure cultures by optically trapping a single cell with a laser beam and moving it away from surrounding cells into sterile growth medium.
- Latent virus** A virus present in a cell, yet not causing any detectable effect.
- Late protein** A protein synthesized later in virus infection after replication of the virus genome.
- Lateral gene transfer** The transfer of genes from a cell to another cell that is not its offspring. Also called *horizontal gene transfer*.
- Leaching** Removal of valuable metals from ores by microbial action.
- Leading strand** The new strand of DNA that is synthesized continuously during DNA replication.
- Leghemoglobin** An O₂-binding protein found in root nodules.
- Leishmaniasis** A disease of the skin or viscera caused by infection with species of a parasitic flagellated protozoan, *Leishmania*.
- Leukocidin** A substance able to destroy phagocytes.
- Leukocyte** A nucleated cell found in the blood; a white blood cell.
- Lichen** A fungus and an alga (or a cyanobacterium) living in symbiotic association.
- Lipids** Water-insoluble organic molecules important in structure of the cytoplasmic membrane and (in some organisms) the cell wall. See also *phospholipid*.
- Lipopolysaccharide (LPS)** Complex lipid structure containing unusual sugars and fatty acids found in most gram-negative *Bacteria* and constituting the chemical structure of the outer membrane.
- Listeriosis** A gastrointestinal food infection caused by *Listeria monocytogenes* that may lead to bacteremia and meningitis.
- Lophotrichous** Having a tuft of polar flagella.
- Lower respiratory tract** The trachea, bronchi, and lungs.
- Low GC gram-positive bacteria** Describes bacteria in the phylum *Firmicutes*.
- Luminescence** The production of light.
- Lyme disease** A tick-transmitted disease caused by the spirochete *Borrelia burgdorferi*.
- Lymph** A fluid similar to blood that lacks red blood cells and travels through a separate circulatory system (the lymphatic system) containing lymph nodes.
- Lymph nodes** Organs that contain lymphocytes and phagocytes arranged to encounter microorganisms and antigens as they travel through the lymphatic circulation.
- Lymphocytes** A subset of leukocytes in the blood that are involved in the adaptive immune response.
- Lyophilization (freeze-drying)** The process of removing all water from frozen food under vacuum.
- Lysin** An antibody that induces lysis.
- Lysis** Loss of cellular integrity with release of cytoplasmic contents.
- Lysogen** A prokaryote containing a prophage. See also *temperate virus*.
- Lysogenic pathway** After virus infection, a series of steps that leads to a state (lysogeny) in which the viral genome is replicated as a provirus along with that of the host.
- Lysogeny** A state following virus infection in which the viral genome is replicated as a provirus along with the genome of the host.
- Lysosome** An organelle containing digestive enzymes for hydrolyses of proteins, fats, and polysaccharides.
- Lytic pathway** A series of steps after virus infection that lead to virus replication and the destruction (lysis) of the host cell.
- Macromolecule** A large molecule (polymer) formed by the connection of a number of small molecules (monomers); proteins, nucleic acids, lipids, and polysaccharides in a cell.
- Macrophage** A large leukocyte found in tissues that has phagocytic and antigen-presenting capabilities.
- Magnetosome** A small particle of Fe₃O₄ present in cells that exhibit magnetotaxis (magnetic bacteria).
- Magnetotaxis** The directed movement of bacterial cells by a magnetic field.
- Major histocompatibility complex (MHC)** A genetic region that encodes several proteins important for antigen presentation and other host defense functions. MHC I proteins are expressed on all cells. MHC II proteins are expressed only on antigen-presenting cells.
- Malaria** An insect-transmitted disease characterized by recurrent episodes of fever and anemia; caused by the protist *Plasmodium* spp., usually transmitted between mammals through the bite of the *Anopheles* mosquito.

- Malignant** In reference to a tumor, an infiltrating metastasizing growth no longer under normal growth control.
- MAR-FISH** A technique that combines identification of microorganisms with measurement of metabolic activities (see *microautoradiography* and *FISH*).
- Mast cells** Tissue cells adjoining blood vessels throughout the body that contain granules with inflammatory mediators.
- Medium (plural, media)** In microbiology, the nutrient solution(s) used to grow microorganisms.
- Megabase (Mb)** One million nucleotide bases (or base pairs, abbreviated Mbp).
- Meiosis** A specialized form of nuclear division that halves the diploid number of chromosomes to the haploid number, for gametes of eukaryotic cells.
- Membrane** Any thin sheet or layer. See especially *cytoplasmic membrane*.
- Memory (immune memory)** The ability to rapidly produce large quantities of specific immune cells or antibodies after subsequent exposure to a previously encountered antigen.
- Memory B cell** A long-lived B cell responsive to an individual antigen.
- Meningitis** Inflammation of the meninges (brain tissue), sometimes caused by *Neisseria meningitidis* and characterized by sudden onset of headache, vomiting, and stiff neck, often progressing to coma within hours.
- Meningococcemia** A fulminant disease caused by *Neisseria meningitidis* and characterized by septicemia, intravascular coagulation, and shock.
- Meningoencephalitis** The invasion, inflammation, and destruction of brain tissue by the amoeba *Naegleria fowleri* or a variety of other pathogens.
- Mesophile** An organism living in the temperature range near that of warm-blooded animals and usually showing a growth temperature optimum between 20 and 40°C.
- Messenger RNA (mRNA)** An RNA molecule that contains the genetic information to encode one or more polypeptides.
- Metabolism** All biochemical reactions in a cell, both anabolic and catabolic.
- Metabolome** The total complement of small molecules and metabolic intermediates of a cell or organism.
- Metagenome** The total genetic complement of all the cells present in a particular environment.
- Metagenomics** Genomic analysis of pooled DNA or RNA from an environmental sample without first isolating or identifying the individual organisms. Also called environmental genomics.
- Metaproteomics** The measurement of whole-community protein expression using mass spectrometry to assign peptides to the amino acid sequences coded by unique genes.
- Metatranscriptomics** The measurement of whole-community gene expression using RNA sequencing.
- Metazoa** Multicellular animals.
- Methanogen** A methane-producing species of *Archaea*.
- Methanogenesis** The biological production of methane (CH_4).
- Methanotroph** An organism capable of oxidizing methane.
- Methylotroph** An organism capable of oxidizing organic compounds that do not contain carbon–carbon bonds; if able to oxidize CH_4 , also a methanotroph.
- MHC class I protein** An antigen-presenting molecule found on all nucleated vertebrate cells.
- MHC class II protein** An antigen-presenting molecule found on macrophages, B lymphocytes, and dendritic cells in vertebrates.
- Microaerophile** An organism requiring O_2 but at a level lower than that in air.
- Microarray** Small, solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern (also called a *gene chip*).
- Microautoradiography (MAR)** Measurement of the uptake of radioactive substrates by visually observing the cells in an exposed photograph emulsion.

- Microbial community** Two or more populations of cells that coexist and interact in a habitat.
- Microbial ecology** The study of microorganisms in their natural environments.
- Microbial leaching** The extraction of valuable metals such as copper from sulfide ores by microbial activities.
- Microbiologically influenced corrosion (MIC)** The contribution of microbial metabolic activities to accelerating the corrosion of metal and concrete structures.
- Microbial mat** A thick, layered, diverse community nourished either by light in a hypersaline or an extremely hot aquatic environment, and in which cyanobacteria are essential; or by chemolithotrophs growing on the surface of sulfide-rich marine sediments.
- Microbial plastics** Polymers consisting of microbially produced (and thus biodegradable) substances, such as polyhydroxyalkanoates.
- Microenvironment** The immediate, micrometer-scale physical and chemical surroundings of a microorganism.
- Microfilament** A filamentous polymer of the protein actin that helps maintain the shape of a eukaryotic cell.
- Micrometer** One-millionth of a meter, or 10^{-6} m (abbreviated μm), the unit used for measuring microorganisms.
- Microorganism** A microscopic organism consisting of a single cell or cell cluster, also including the viruses, which are not cellular.
- Microsensor** A small glass sensor or electrode for measuring pH or specific compounds such as O_2 , H_2S , or NO_3^- that can be immersed into a microbial habitat at microscale intervals.
- Microtubule** A filamentous polymer of the proteins α -tubulin and β -tubulin that functions in eukaryotic cell shape and motility.
- Middle protein** A protein with either a structural or a catalytic function synthesized after the early proteins in a virus infection.
- Minimum inhibitory concentration (MIC)** The minimum concentration of a substance necessary to prevent microbial growth.
- Minus (negative)-strand nucleic acid** An RNA or DNA strand that has the opposite sense of (would be complementary to) the mRNA of a virus.
- Missense mutation** A mutation in which a single codon is altered so that one amino acid in a protein is replaced with a different amino acid.
- Mitochondrion** A eukaryotic organelle responsible for the processes of respiration and electron transport phosphorylation.
- Mitosis** The normal form of nuclear division in eukaryotic cells in which chromosomes are replicated and partitioned into two daughter nuclei.
- Mixotroph** An organism that uses organic compounds as carbon sources but uses inorganic compounds as electron donors for energy metabolism.
- Modification enzyme** An enzyme that chemically alters bases within a restriction enzyme recognition site and thus prevents the site from being cut.
- Molds** Filamentous fungi.
- Molecular chaperone** A protein that helps other proteins fold or refold properly.
- Molecular clock** A DNA sequence, such as a gene for ribosomal RNA, that can be used as a comparative temporal measure of evolutionary divergence.
- Molecular cloning** The isolation and incorporation of a fragment of DNA into a vector where it can be replicated.
- Molecule** Two or more atoms chemically bonded to one another.
- Monoclonal antibody** A single type of antibody produced from a single clone of B cells. This antibody has uniform structure and specificity.
- Monocytes** Circulating white blood cells that contain many lysosomes and can differentiate into macrophages.
- Monomer** A building block of a polymer.
- Monophyletic** In phylogeny, a group descended from one ancestor.
- Monotrichous** Having a single polar flagellum.
- Morbidity** The incidence of illness in a population.
- Morphology** The shape of an organism.
- Mortality** The incidence of death in a population.

Most-probable-number (MPN) technique The serial dilution of a natural sample to determine the highest dilution yielding growth.

Motif In antigen presentation, a conserved amino acid sequence found in all peptide antigens that bind to a given MHC protein.

Motility The property of movement of a cell under its own power.

Mucosa-associated lymphoid tissue (MALT) A part of the lymphatic system that interacts with antigens and microorganisms that enter the body through mucous membranes, including those of the gut, the genitourinary tract, and bronchial tissues.

Mucous membrane Layers of epithelial cells that interact with the external environment.

Mucus Soluble glycoproteins secreted by epithelial cells that coat the mucous membrane.

Multilocus sequence typing (MLST) A taxonomic tool for classifying organisms on the basis of gene sequence variations in several housekeeping genes.

Multiple displacement amplification (MDA) A method to generate multiple copies of chromosomal DNA from a single organism.

Mushroom The aboveground fruiting body, or basidiocarp, of basidiomycete fungi.

Mutagen An agent that induces mutation, such as radiation or certain chemicals.

Mutant An organism whose genome carries a mutation.

Mutation An inheritable change in the base sequence of the genome of an organism.

Mutator strain A mutant strain in which the rate of mutation is increased.

Mutualism A type of symbiosis in which both organisms in the relationship benefit.

Myc factors Lipochitin oligosaccharides produced by mycorrhizal fungi to initiate symbiosis with a plant.

Mycorrhizae A symbiotic association between a fungus and the roots of a plant.

Mycosis Any infection caused by a fungus.

Myeloma A malignant tumor of a plasma cell (antibody-producing cell).

Nanoarchaeota A phylum of *Archaea* that contains the hyperthermophilic parasite *Nanoarchaeum equitans*.

Natural killer (NK) cell A specialized lymphocyte that recognizes and destroys foreign cells or infected host cells in a nonspecific manner.

Natural penicillin The parent penicillin structure, produced by cultures of *Penicillium* not supplemented with side-chain precursors.

Negative control A mechanism for regulating gene expression in which a repressor protein prevents transcription of genes.

Negative selection In T cell selection, the deletion of T cells that interact with self antigens in the thymus. See *clonal deletion*.

Negative strand A nucleic acid strand that has the opposite sense to (is complementary to) the mRNA.

Negative-strand virus A virus with a single-stranded genome that has the opposite sense to (is complementary to) the viral mRNA.

Neutralization An interaction of antibody with antigen that reduces or blocks the biological activity of the antigen.

Neutrophil A type of leukocyte exhibiting phagocytic properties, a granular cytoplasm (granulocyte), and a multilobed nucleus. Also called a *polymorphonuclear leukocyte (PMN)*.

Neutrophile An organism that grows best around pH 7.

Niche In ecological theory, an organism's residence in a community, including both biotic and abiotic factors.

Nitrification The microbial oxidation of ammonia to nitrate (NH_3 to NO_3^-).

Nitrifiers Chemolithotrophic *Bacteria* and *Archaea* that catalyze nitrification.

Nitrogenase The enzyme complex required to reduce N_2 to NH_3 in biological nitrogen fixation.

Nitrogen fixation Reduction of nitrogen gas to ammonia ($\text{N}_2 + 8 \text{ H}_2 \rightarrow 2 \text{ NH}_3 + \text{H}_2$) by the enzyme nitrogenase.

Nod factors Oligosaccharides produced by root nodule bacteria that help initiate the plant–bacterial symbiosis.

Noncoding RNA (ncRNA) An RNA molecule that is not translated into protein.

Nonnucleoside reverse transcriptase inhibitor (NNRTI) A nonnucleoside compound that inhibits the action of retroviral reverse transcriptase by binding directly to the catalytic site.

Nonperishable (stable) foods Foods of low water activity that have an extended shelf life and are resistant to spoilage by microorganisms.

Nonpolar Possessing hydrophobic (water-repelling) characteristics and not easily dissolved in water.

Nonsense codon Another name for a stop codon.

Nonsense mutation A mutation in which the codon for an amino acid is changed to a stop codon.

Normal microflora Microorganisms that are usually found associated with healthy body tissue.

Northern blot A hybridization procedure where RNA is the target in the gel and DNA or RNA is the probe. Compare with *Southern blot* and *immunoblot*.

Nosocomial infection (healthcare-associated infection) An infection contracted in a healthcare setting.

Nucleic acid A polymer of nucleotides. See *deoxyribonucleic acid* and *ribonucleic acid*.

Nucleic acid probe A strand of nucleic acid that can be labeled and used to hybridize to a complementary molecule from a mixture of other nucleic acids. In clinical microbiology or microbial ecology, a short oligonucleotide of unique sequence used as a hybridization probe for identifying specific genes.

Nucleocapsid The complete complex of nucleic acid and protein packaged in a virus particle.

Nucleoid The aggregated mass of DNA that makes up the chromosome of prokaryotic cells.

Nucleoside A nucleotide minus phosphate.

Nucleoside reverse transcriptase inhibitor (NRTI) A nucleoside analog compound that inhibits the action of viral reverse transcriptase by competing with nucleosides.

Nucleosome A spherical complex of eukaryotic DNA plus histones.

Nucleotide A monomeric unit of nucleic acid, consisting of a sugar, a phosphate, and a nitrogenous base.

Nucleus A membrane-enclosed structure in eukaryotes containing the genetic material (DNA) organized in chromosomes.

Nutrient A substance taken by a cell from its environment and used in catabolic or anabolic reactions.

Obligate Indicates an environmental condition always required for growth (for example, “obligate anaerobe”).

Oligonucleotide A short nucleic acid molecule, either obtained from an organism or synthesized chemically.

Oligotroph An organism that grows only or grows best at very low levels of nutrients.

Oligotrophic (1) Describes a habitat in which nutrients are in low supply. (2) Describes organisms that grow best under low-nutrient conditions.

Oncogene A gene whose expression causes formation of a tumor.

Open reading frame (ORF) A sequence of DNA or RNA that could be translated to give a polypeptide.

Operator A specific region of the DNA at the initial end of a gene, where the repressor protein binds and blocks mRNA synthesis.

Operon One or more genes transcribed into a single RNA and under the control of a single regulatory site.

Operon fusion A gene fusion in which a coding sequence that retains its own translational signals is fused to the transcriptional signals of another gene.

Opportunistic infection An infection usually observed only in an individual with a dysfunctional immune system.

Opportunistic pathogen An organism that causes disease in the absence of normal host resistance.

Opsonization The enhancement of phagocytosis due to the deposition of antibody or complement on the surface of a pathogen or other antigen.

Organelle A bilayer membrane–enclosed structure such as the mitochondrion found in eukaryotic cells.

Ortholog A gene found in one organism that is similar to that in another organism but differs because of speciation. See also *paralog*.

Osmophile An organism that grows best in the presence of high levels of solute, typically a sugar.

Osmosis The diffusion of water through a membrane from a region of low solute concentration to one of higher concentration.

Outbreak The occurrence of a large number of cases of a disease in a short period of time.

Outer membrane A phospholipid- and polysaccharide-containing unit membrane that lies external to the peptidoglycan layer in cells of gram-negative *Bacteria*.

Overlapping genes Two or more genes in which part or all of one gene is embedded in the other.

Oxic Containing oxygen; aerobic. Usually used in reference to a microbial habitat.

Oxidation A process by which a compound gives up electrons (or H atoms) and becomes oxidized.

Oxidation-reduction (redox) reaction A pair of reactions in which one compound becomes oxidized while another becomes reduced and takes up the electrons released in the oxidation reaction.

Oxidative (electron transport) phosphorylation The nonphototrophic production of ATP at the expense of a proton motive force formed by electron transport.

Oxygenase An enzyme that catalyzes the incorporation of oxygen from O₂ into organic or inorganic compounds.

Oxygenic photosynthesis The use of light energy to synthesize ATP and NADPH by noncyclic photophosphorylation with the production of O₂ from water.

Oxygen minimum zone (OMZ) An oxygen-depleted region of intermediate depth in the marine water column.

Palindrome A nucleotide sequence on a DNA molecule in which the same sequence is found on each strand but in the opposite direction.

Pandemic A worldwide epidemic.

Pan genome The totality of the genes present in the different strains of a species.

Paralog A gene within an organism whose similarity to one or more other genes in the same organism is the result of gene duplication (compare with *ortholog*).

Parasite An organism able to live in or on a host and cause disease.

Parasitism A symbiotic relationship between two organisms in which the host organism is harmed in the process.

Passive immunity Immunity resulting from transfer of antibodies or immune cells from an immune to a nonimmune individual.

Pasteurization The use of controlled heat to reduce the microbial load, including disease-producing microorganisms and spoilage microorganisms, in heat-sensitive liquids.

Pathogen A disease-causing microorganism.

Pathogen-associated molecular pattern (PAMP) A repeating structural component of a microbial cell or virus recognized by a pattern recognition receptor.

Pathogenicity The ability of a pathogen to cause disease.

Pathogenicity island A bacterial chromosome region of foreign origin that contains clustered genes for virulence.

Pathway engineering The assembly of a new or improved biochemical pathway, using genes from one or more organisms.

Pattern recognition receptor (PRR) A protein in a phagocyte membrane that recognizes a pathogen-associated molecular pattern (PAMP), such as a component of a microbial cell surface structure.

Penicillin A class of antibiotics that inhibit bacterial cell wall synthesis; characterized by a β-lactam ring.

Pentose phosphate pathway A major metabolic pathway for the production and catabolism of pentoses (C₅ sugars).

Peptide bond A type of covalent bond joining amino acids in a polypeptide.

Peptidoglycan The rigid layer of the cell walls of *Bacteria*, a thin sheet composed of N-acetylglucosamine, N-acetylmuramic acid, and a few amino acids.

Periplasm The area between the cytoplasmic membrane and the outer membrane in gram-negative *Bacteria*.

Perishable food Fresh food generally of high water activity that has a very short shelf life due to potential for spoilage by growth of microorganisms.

Peritrichous flagellation In flagellar arrangements, having flagella attached to many places on the cell surface.

Peroxisome An organelle that functions to rid the cell of toxic substances such as peroxides, alcohols, and fatty acids.

Pertussis (whooping cough) A disease caused by an upper respiratory tract infection with *Bordetella pertussis*, characterized by a deep, persistent cough.

pH The negative logarithm of the hydrogen ion (H⁺) concentration of a solution.

Phage See *bacteriophage*.

Phagocyte One of a group of cells that recognizes, ingests, and degrades pathogens and pathogen products.

Phagocytosis A mechanism for ingesting particulate food in which a portion of the cytoplasmic membrane surrounds the particle and brings it into the cell.

Phenotype The observable characteristics of an organism, such as color, motility, or morphology. Compare with *genotype*.

Phosphodiester bond A type of covalent bond linking nucleotides together in a polynucleotide.

Phospholipid A lipid containing a substituted phosphate group and two fatty acid chains on a glycerol backbone.

Photoautotroph An organism able to use light as its sole source of energy and CO₂ as its sole carbon source.

Photoheterotroph An organism using light as a source of energy and organic compounds as a carbon source.

Photophosphorylation The synthesis of energy-rich phosphate bonds in ATP using light energy.

Photosynthesis The series of reactions in which ATP is synthesized by light-driven reactions and CO₂ is fixed into cell material. See also *anoxygenic photosynthesis* and *oxygenic photosynthesis*.

Phototaxis Movement of a cell toward light.

Phototroph An organism that obtains energy from light.

Phycobilin The light-capturing open chain tetrapyrrole component of phycobiliproteins.

Phycobiliprotein The accessory pigment complex in cyanobacteria that contains phycocyanin or phycoerythrin coupled to proteins.

Phycobilisome An aggregate of phycobiliproteins.

Phylogenetic probe An oligonucleotide, sometimes made fluorescent by attachment of a dye, complementary in sequence to some ribosomal RNA signature sequence.

Phylogenetic tree A diagram that depicts the evolutionary history of an organism; consists of nodes and branches.

Phylogeny The evolutionary (natural) history of organisms.

Phylotype One or more organisms with the same or related sequences of a phylogenetic marker gene.

Phylum A major lineage of cells in one of the three domains of life.

Phytanyl A branched-chain hydrocarbon containing 20 carbon atoms, commonly found in the lipids of *Archaea*.

Phytopathogen A microorganism that causes plant disease.

Pickling The process of acidifying food, typically with acetic acid, to prevent microbial growth and spoilage.

Piezophile An organism that lives optimally at high hydrostatic pressure.

Piezotolerant An organism able to tolerate high hydrostatic pressure but growing best at 1 atm.

Pilus (plural, pili) A filamentous structure that extends from the surface of a cell and, depending on type, facilitates cell attachment, genetic exchange, or twitching motility.

Pinocytosis In eukaryotes, phagocytosis of soluble molecules.

Plague An endemic disease in rodents caused by *Yersinia pestis* that is occasionally transferred to humans through the bite of a flea.

- Plaque** A zone of lysis or growth inhibition caused by virus infection on a lawn of host cells.
- Plasma** The liquid portion of the blood containing proteins and other solutes.
- Plasma cell** A large, differentiated, short-lived B lymphocyte specializing in abundant (but short-term) antibody production.
- Plasmid** An extrachromosomal genetic element that is not essential for growth and has no extracellular form.
- Plate count** A viable counting method in which the number of colonies on a plate is used as a measure of cell number.
- Platelet** A noncellular disc-shaped structure containing protoplasm, found in large numbers in blood and functioning in the blood-clotting process.
- Plus-strand nucleic acid** An RNA or DNA strand that has the same sense as the mRNA of a virus.
- Point mutation** A mutation that involves a single base pair.
- Polar** Possessing hydrophilic characteristics and generally water-soluble.
- Polar flagellation** In flagellar arrangements, having flagella attached at one end or both ends of the cell.
- Poly- β -hydroxybutyric acid (PHB)** A common storage material of prokaryotic cells consisting of a polymer of β -hydroxybutyrate (PHB) or other β -alkanoic acids (PHA).
- Polyclonal antibodies** A mixture of antibodies made by many different B cell clones.
- Polyclonal antiserum** A mixture of antibodies to a variety of antigens or to a variety of determinants on a single antigen.
- Polygeny** The occurrence of multiple copies of evolutionarily, genetically, structurally, and functionally related genes.
- Polymer** A large molecule formed by polymerization of monomeric units. In water purification, a chemical in liquid form used as a coagulant to produce flocculation in the clarification process.
- Polymerase chain reaction (PCR)** Artificial amplification of a DNA sequence by repeated cycles of strand separation and replication.
- Polymorphism** In a population, the occurrence of multiple alleles for a gene locus at a higher frequency than can be explained by recent random mutations.
- Polymorphonuclear leukocyte (PMN)** Motile white blood cells containing many lysosomes and specializing in phagocytosis. Characterized by a distinct segmented nucleus. Also called a neutrophil.
- Polynucleotide** A polymer of nucleotides bonded to one another by phosphodiester bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polypeptide** Several amino acids linked together by peptide bonds.
- Polysaccharide** A long chain of monosaccharides (sugars) linked by glycosidic bonds.
- Polyvalent vaccine** A vaccine that immunizes against more than one disease.
- Population** A group of organisms of the same species in the same place at the same time.
- Porins** Protein channels in the outer membrane of gram-negative *Bacteria* through which small to medium-sized molecules can flow.
- Positive control** A mechanism for regulating gene expression in which an activator protein functions to promote transcription of genes.
- Positive selection** In T cell selection, the stimulation of growth and development of T cells that interact with MHC-self peptide in the thymus.
- Positive strand** A nucleic acid strand that has the same sense as the mRNA.
- Positive-strand virus** A virus with a single-stranded genome that has the same complementarity as the viral mRNA.
- Portable** In water purification, drinkable; safe for human consumption.
- Precipitation** A reaction between antibody and soluble antigen resulting in visible antibody-antigen complexes.
- Prevalence** The total number of new and existing disease cases reported in a population in a given time period.
- Pribnow box** The consensus sequence TATAAT located approximately 10 base pairs upstream from the transcriptional start site. A binding site for RNA polymerase.
- Primary adaptive immune response** The production of antibodies or immune T cells on first exposure to antigen; the antibodies are mostly of the IgM class.
- Primary antibody response** Antibodies made on first exposure to antigen; mostly of the class IgM.
- Primary disinfection** The introduction of sufficient chlorine or other disinfectant into clarified, filtered water to kill existing microorganisms and inhibit further microbial growth.
- Primary endosymbiosis** Acquisition of the alphaproteobacterial ancestor of the mitochondrion or of the cyanobacterial ancestor of the chloroplast by another kind of cell.
- Primary lymphoid organ** An organ in which precursor lymphoid cells develop into mature lymphocytes.
- Primary metabolite** A metabolite excreted during the exponential growth phase.
- Primary producer** An organism that synthesizes new organic material from CO_2 and obtains energy from light or from oxidation of inorganic compounds. Also an *autotroph*.
- Primary structure** In an informational macromolecule, such as a polypeptide or a nucleic acid, the precise sequence of monomeric units.
- Primary transcript** An unprocessed RNA molecule that is the direct product of transcription.
- Primary wastewater treatment** The physical separation of wastewater contaminants, usually by separation and settling.
- Primase** The enzyme that synthesizes the RNA primer used in DNA replication.
- Primer** A short length of DNA or RNA used to initiate synthesis of a new DNA strand.
- Prion** An infectious protein whose extracellular form contains no nucleic acid.
- Probe** See *nucleic acid probe*.
- Probiotic** A live microorganism that, when administered to a host, may confer a health benefit.
- Prochlorophyte** A bacterial oxygenic phototroph that contains chlorophylls *a* and *b* but lacks phycobilins.
- Prokaryote** A cell or organism lacking a nucleus and other membrane-enclosed organelles and usually having its DNA in a single circular molecule. Members of the *Bacteria* and the *Archaea*.
- Promoter** The site on DNA where the RNA polymerase binds and begins transcription.
- Prophage** The state of the genome of a temperate virus when it is replicating in synchrony with that of the prokaryotic host, typically integrated into the host genome. See *provirus*.
- Prophylactic** Treatment, usually immunological or chemotherapeutic, designed to protect an individual from a future attack by a pathogen.
- Propionic acid bacteria** Gram-positive fermentative bacteria that generate propionate as a fermentation end product and are important in the production of cheese.
- Prostheca (plural, prosthecae)** A cytoplasmic extrusion bounded by the cell wall, such as a bud, hypha, or stalk.
- Prosthetic group** The tightly bound, nonprotein portion of an enzyme; not the same as a *coenzyme*.
- Protease inhibitor** A compound that inhibits the action of viral protease by binding directly to the catalytic site, preventing viral protein processing.
- Protein** A polymeric molecule consisting of one or more polypeptides.
- Protein fusion** A gene fusion in which two coding sequences are fused so that they share the same transcriptional and translational start sites.
- Protein splicing** Removal of intervening sequences from a protein.
- Proteobacteria** A large phylum of *Bacteria* that includes many of the common gram-negative bacteria, including *Escherichia coli*.
- Proteome** The total set of proteins encoded by a genome or the total protein complement of an organism.

Proteomics The large-scale or genome-wide study of the structure, function, and regulation of the proteins of an organism.

Proteorhodopsin A light-sensitive retinal-containing protein found in some marine *Bacteria* that fuels a proton pump that yields ATP.

Protist A unicellular eukaryotic microorganism; may be flagellate or aflagellate, phototrophic or nonphototrophic, and most lack cell walls; includes algae and protozoa.

Proton motive force (pmf) A source of energy resulting from the separation of protons from hydroxyl ions across the cytoplasmic membrane, generating a membrane potential.

Protoplasm The complete cellular contents, cytoplasmic membrane, cytoplasm, and nucleus/nucleoid of a cell.

Protoplast A cell from which the wall has been removed.

Prototroph The parent from which an auxotrophic mutant has been derived. Contrast with *auxotroph*.

Protozoa Unicellular eukaryotic microorganisms that lack cell walls.

Provirus The genome of a temperate or latent animal virus when it is replicating in step with the host chromosome.

Pseudomonad A term used to refer to any gram-negative, polarly flagellated, aerobic rod able to use a diverse suite of carbon sources.

Psychrophile An organism able to grow at low temperatures and showing a growth temperature optimum of <15°C.

Psychrotolerant Able to grow at low temperature but having a growth temperature optimum of >20°C.

Public health The health of the population as a whole.

Pure culture A culture containing a single kind of microorganism.

Purine One of the nitrogen bases of nucleic acids that contain two fused rings; adenine and guanine.

Purple nonsulfur bacteria A group of anoxygenic phototrophic bacteria that contain bacteriochlorophyll *a* or *b*, grow best as photoheterotrophs, and have a relatively low tolerance for H₂S.

Purple sulfur bacteria A group of anoxygenic phototrophic bacteria containing bacteriochlorophylls *a* or *b* and characterized by the ability to oxidize H₂S and store elemental sulfur inside the cells (or, in the genera *Ectothiorhodospira* and *Halorhodospira*, outside the cell).

Pyogenic Pus-forming; causing abscesses.

Pyrimidine One of the nitrogenous bases of nucleic acids that contain a single ring; cytosine, thymine, and uracil.

Pyrite A common iron ore, FeS₂.

Pyrogenic Fever-inducing.

Quarantine The separation and restriction of well persons who may have been exposed to an infectious disease to see if they develop the disease. Compare with *isolation*.

Quaternary structure In proteins, the number and arrangement of individual polypeptides in the final protein molecule.

Quinolones Synthetic antibacterial compounds that interact with DNA gyrase and prevent supercoiling of bacterial DNA.

Quorum sensing A regulatory system that monitors the population size and controls gene expression based on cell density.

Rabies A usually fatal neurological disease caused by the rabies virus, which is usually transmitted by the bite or saliva of an infected carnivore.

Radioisotope An isotope of an element that undergoes spontaneous decay with the release of radioactive particles.

Raw water Surface water or groundwater that has not been treated in any way (also called *untreated water*).

Reaction center A photosynthetic complex containing chlorophyll (or bacteriochlorophyll) and other components, within which occur the initial electron transfer reactions of photophosphorylation.

Reading-frame shift See *frameshift mutation*.

Realized niche The range of natural environments supporting a species when that organism is confronted with factors such as resource limitation, predation, and competition from other species.

Recalcitrant Resistant to microbial attack.

Recombinant DNA A DNA molecule containing DNA originating from two or more sources.

Recombination Resorting or rearrangement of DNA fragments resulting in a new sequence combination.

Redox See *oxidation-reduction reaction*.

Reduction A process by which a compound accepts electrons to become reduced.

Reduction potential (E_0') The inherent tendency, measured in volts, of the oxidized compound of a redox pair to become reduced.

Reductive dechlorination An anaerobic respiration in which a chlorinated organic compound is used as an electron acceptor, usually with the release of Cl⁻.

Reemerging disease An infectious disease, previously under control, that produces a new epidemic.

Regulation Processes that control the rates of synthesis of proteins, such as induction and repression.

Regulatory nucleotide A nucleotide that functions as a signal rather than being incorporated into RNA or DNA.

Regulon A set of operons that are all controlled by the same regulatory protein (repressor or activator).

Replacement vector A cloning vector, such as a bacteriophage, in which some of the DNA of the vector can be replaced with foreign DNA.

Replication The synthesis of DNA using DNA as a template.

Replication fork The site on the chromosome where DNA replication occurs and where the enzymes replicating the DNA are bound to untwisted, single-stranded DNA.

Replicative form A double-stranded DNA molecule that is an intermediate in the replication of single-stranded DNA viruses.

Reporter gene A gene incorporated into a vector because the product it encodes is easy to detect.

Repression Prevention of the synthesis of an enzyme in response to a signal.

Repressor protein A regulatory protein that binds to specific sites on DNA and blocks transcription; involved in negative control.

Reservoir A source of viable infectious agents from which individuals may be infected.

Resolution In microbiology, the ability to distinguish two objects as distinct and separate under the microscope.

Respiration Catabolic reactions producing ATP in which either organic or inorganic compounds are primary electron donors and organic or inorganic compounds are ultimate electron acceptors.

Response regulator protein One of the members of a two-component system; a regulatory protein that is phosphorylated by a sensor protein (see *sensor kinase protein*).

Restriction enzymes (restriction endonucleases) Enzymes that recognize and cleave specific DNA sequences, generating either blunt or single-stranded (sticky) ends.

Restriction map A map showing the location of restriction enzyme cut sites on a segment of DNA.

Retrovirus A virus whose RNA genome has a DNA intermediate as part of its replication cycle.

Reverse citric acid cycle A mechanism for autotrophy in green sulfur bacteria and a few other autotrophic *Bacteria*, and also in some *Archaea*.

Reverse DNA gyrase A topoisomerase present in all hyperthermophilic prokaryotes that introduces positive supercoils in DNA.

Reverse electron transport The energy-dependent movement of electrons against the thermodynamic gradient to form a strong electron donor from a weaker electron donor.

Reverse transcriptase The retroviral enzyme that makes a DNA copy using RNA as template.

Reverse transcription The process of copying information found in RNA into DNA.

Reversion An alteration in DNA that reverses the effects of a prior mutation.

Rheumatic fever An inflammatory autoimmune disease triggered by an immune response to infection by *Streptococcus pyogenes*.

Rhizosphere The region immediately adjacent to plant roots.

Ribonucleic acid (RNA) A polymer of nucleotides connected via a phosphate–ribose backbone; involved in protein synthesis or as genetic material of some viruses.

Ribosomal RNA (rRNA) The types of RNA found in the ribosome; some rRNAs participate actively in the process of protein synthesis.

Ribosome A structure composed of RNAs and proteins upon which new proteins are made.

Riboswitch An RNA domain, usually in an mRNA molecule, that can bind a specific small molecule and alter its secondary structure; this in turn controls translation of the mRNA.

Ribotyping A means of identifying microorganisms from analysis of DNA fragments generated from restriction enzyme digestion of genes encoding their ribosomal RNA.

Ribozyme An RNA molecule that can catalyze a chemical reaction.

Ribulose monophosphate pathway A reaction series in certain methylotrophs in which formaldehyde is assimilated into cell material using ribulose monophosphate as the C₁ acceptor molecule.

Rickettsias Obligate intracellular bacteria that cause disease, including typhus, spotted fever rickettsiosis, and ehrlichiosis.

RNA Ribonucleic acid; functions in protein synthesis as messenger RNA, transfer RNA, and ribosomal RNA.

RNA editing Changing the coding sequence of an RNA molecule by altering, adding, or removing bases.

RNA interference (RNAi) A response that is triggered by the presence of double-stranded RNA and results in the degradation of ssRNA homologous to the inducing dsRNA.

RNA life A hypothetical ancient life form lacking DNA and protein, in which RNA had both a genetic coding and a catalytic function.

RNA polymerase An enzyme that synthesizes RNA in the 5' → 3' direction using an antiparallel 3' → 5' DNA strand as a template.

RNA processing The conversion of a precursor RNA to its mature form.

RNA replicase An enzyme that can produce RNA from an RNA template.

Rocky Mountain spotted fever See *spotted fever rickettsiosis*.

Rolling circle replication A mechanism, used by some plasmids and viruses, of replicating circular DNA, starting by nicking and unrolling one strand. For a double-stranded genome, the unrolled strand is used as a template for DNA synthesis; for a single-stranded genome, the other, still circular strand is used as the template for DNA synthesis.

Root nodule A tumorlike growth on certain plant roots that contains symbiotic nitrogen-fixing bacteria.

RubisCO The acronym for ribulose bisphosphate carboxylase, a key enzyme of the Calvin cycle.

Rumen The forestomach of ruminant animals in which cellulose digestion occurs.

Salmonellosis Enterocolitis or other gastrointestinal disease caused by any of several species of the bacterium *Salmonella*.

Sanitizers Agents that reduce, but may not eliminate, microbial numbers to a safe level.

Scale-up The conversion of an industrial process from a small laboratory setup to a large commercial fermentation.

Scarlet fever A disease characterized by high fever and a reddish skin rash resulting from an exotoxin produced by cells of *Streptococcus pyogenes*.

Schistosomiasis A chronic disease caused by a parasitic worm that leads to internal organ damage and accumulation of fluids and worm egg masses.

Screening A procedure that permits the identification of organisms by phenotype or genotype, but does not inhibit or enhance the growth of particular phenotypes or genotypes.

Secondary adaptive immune response The enhanced production of antibodies or immune T cells on second and subsequent exposures to antigen; the antibodies are mostly of the IgG class.

Secondary aerobic wastewater treatment Oxidative reactions carried out by microorganisms under aerobic conditions to treat wastewater containing low levels of organic materials.

Secondary anaerobic wastewater treatment Degradative and fermentative reactions carried out by microorganisms under anoxic conditions to treat wastewater containing high levels of insoluble organic materials.

Secondary antibody response Antibodies made on second (subsequent) exposure to antigen; mostly of the class IgG.

Secondary disinfection The maintenance of sufficient chlorine or other disinfectant residual in the water distribution system to inhibit microbial growth.

Secondary endosymbiosis The acquisition by a mitochondrion-containing eukaryotic cell of the chloroplasts of a red or green algal cell.

Secondary fermentation A fermentation in which the substrates are the fermentation products of some other organism.

Secondary lymphoid organ An organ at which antigens interact with antigen-presenting phagocytes and lymphocytes to generate an adaptive immune response; these include lymph nodes, spleen, and mucosa-associated lymphoid tissue.

Secondary metabolite A product excreted by a microorganism in the late exponential growth phase and the stationary phase.

Secondary structure The initial pattern of folding of a polypeptide or a polynucleotide, usually the result of hydrogen bonding.

Sediment (1) In water purification, the soil, sand, minerals, and other large particles found in raw water. (2) In large bodies of water (lakes, the oceans), the materials (mud, rock, and the like) that form the bottom surface of the water body.

Selection Placing organisms under conditions that favor or inhibit the growth of those with a particular phenotype or genotype.

Selective medium A growth medium that enhances the growth of certain organisms while inhibiting the growth of others due to an added media component.

Selective toxicity The ability of a compound to inhibit or kill pathogenic microorganisms without adversely affecting the host.

Self-splicing intron An intron that possesses ribozyme activity and splices itself out.

Semiconservative replication DNA synthesis yielding new double helices, each consisting of one parental and one progeny strand.

Semiperishable food Food of intermediate water activity that has a limited shelf life due to potential for spoilage by growth of microorganisms.

Semisynthetic penicillin A natural penicillin that has been chemically altered.

Sensitivity The lowest amount of antigen that can be detected by a diagnostic test.

Sensor kinase protein One of the members of a two-component system; a kinase found in the cell membrane that phosphorylates itself in response to an external signal and then passes the phosphoryl group to a response regulator protein (see *response regulator protein*).

Septicemia (sepsis) A bloodborne systemic infection.

Sequence alignment The insertion of gaps into a set of molecular sequences organized in rows so that homologous positions are organized in vertical columns. Alignment is necessary prior to phylogenetic analysis because deletion and insertion mutations cause variations in the length of molecular sequences.

Sequencing In reference to nucleic acids, deducing the order of nucleotides in a DNA or RNA molecule.

Serine pathway A reaction series in certain methylotrophs in which formaldehyde is assimilated into cell material by way of the amino acid serine.

Serology The study of antigen–antibody reactions in vitro.

Serum The fluid portion of blood remaining after the blood cells and materials responsible for clotting are removed.

Sewage Liquid effluents contaminated with human or animal fecal material.

Sexually transmitted infection (STI) An infection that is usually transmitted by sexual contact.

Shine-Dalgarno sequence A short stretch of nucleotides on a prokaryotic mRNA molecule upstream of the translational start site

that binds to ribosomal RNA and thereby brings the ribosome to the initiation codon on the mRNA. Also called ribosome-binding site.

Short interfering RNA (siRNA) Short double-stranded RNA molecules that trigger RNA interference.

Shotgun cloning Making a genomic library by random cloning of DNA fragments.

Shotgun sequencing Sequencing of DNA from previously cloned small fragments of a genome in a random fashion, followed by computational methods to reconstruct the entire genome sequence.

Shuttle vector A cloning vector that can replicate in two or more different organisms; used for moving DNA between unrelated organisms.

Sickle cell trait A genetic trait that confers resistance to malaria, but causes a reduction in the oxygen-carrying capacity of the blood by reducing the life expectancy of the affected red blood cells.

Siderophore An iron chelator that can bind iron present at very low concentrations.

Signal sequence A special N-terminal sequence of approximately 20 amino acids that signals that a protein should be exported across the cytoplasmic membrane.

Signal transduction Indirect transmission of an external signal to a target in the cell (see *two-component regulatory system*).

Silent mutation A change in DNA sequence that has no effect on the phenotype.

Simple transport system A transporter that consists of only a membrane-spanning protein and is typically driven by energy from the proton motive force.

Site-directed mutagenesis Construction *in vitro* of a gene with a specific mutation.

16S rRNA A large polynucleotide (~1500 bases) that functions as a part of the small subunit of the ribosome of *Bacteria* and *Archaea* and from whose sequence evolutionary relationships can be obtained; eukaryotic counterpart is 18S rRNA.

S-layer A paracrystalline outer wall layer composed of protein or glycoprotein and found in many prokaryotes.

Slime layer A diffuse layer of polymer fibers, typically polysaccharides, that forms an outer surface layer on the cell.

Slime molds Nonphototrophic eukaryotic microorganisms lacking cell walls, which aggregate to form fruiting structures (cellular slime molds) or simply masses of protoplasm (acellular slime molds).

Small subunit (SSU) RNA Ribosomal RNA from the 30S ribosomal subunit of *Bacteria* and *Archaea* or the 40S ribosomal subunit of eukaryotes, that is, 16S or 18S ribosomal RNA, respectively.

Solfatara A hot, sulfur-rich, generally acidic environment commonly inhabited by hyperthermophilic *Archaea*.

Somatic hypermutation The mutation of immunoglobulin genes at rates higher than those observed in other genes.

SOS repair A DNA repair system activated by DNA damage.

Southern blot A hybridization procedure where DNA is the target in the gel and RNA or DNA is the probe. Compare with *Northern blot* and *immunoblot*.

Species Defined in microbiology as a collection of strains that all share the same major properties and differ in one or more significant properties from other collections of strains; defined phylogenetically as a monophyletic, exclusive group based on DNA sequence.

Species abundance The proportion of each species in a community.

Species richness The total number of different species present in a community.

Specificity (1) The ability of the immune response to interact with individual antigens. (2) The ability of a diagnostic or research test to identify a specific pathogen.

Spheroplast A spherical, osmotically sensitive cell derived from a bacterium by loss of some but not all of the rigid wall layer. If all of the rigid wall layer has been completely lost, the structure is called a *protoplast*.

Spirilla (singular, spirillum) Spiral-shaped cells.

Spirochete A slender, tightly coiled gram-negative bacterium characterized by possession of endoflagella used for motility.

Spliceosome A complex of ribonucleoproteins that catalyze the removal of introns from RNA primary transcripts.

Splicing The RNA-processing step by which introns are removed and exons joined.

Spontaneous generation The hypothesis that living organisms can originate from nonliving matter.

Spontaneous mutation A mutation that occurs "naturally" without the help of mutagenic chemicals or radiation.

Spore A general term for resistant resting structures formed by many prokaryotes and fungi.

Sporozoa Nonmotile parasitic protozoa.

Spotted fever rickettsiosis A tick-transmitted disease caused by

Rickettsia rickettsii, characterized by fever, headache, rash, and gastrointestinal symptoms; formerly called Rocky Mountain spotted fever.

Stable isotope probing (SIP) A method for characterizing an organism that incorporates a particular substrate by supplying the substrate in ^{13}C or ^{15}N form and then isolating heavy isotope-enriched DNA and analyzing the genes.

Stalk An elongate structure, either cellular or excreted, that anchors a cell to a surface.

Start codon A special codon, usually AUG, that signals the start of a protein.

-static Suffix indicating inhibition of growth. For example, a bacteriostatic agent inhibits bacterial growth. Compare with *-cidal*.

Stationary phase The period during the growth cycle of a microbial population in which growth ceases.

Stem cell A cell that can develop into a number of final cell types.

Stereoisomers Mirror-image forms of two molecules having the same molecular and structural formulas.

Sterilant (sterilizer, sporicide) A chemical agent that destroys all forms of microbial life.

Sterile Free of all living organisms and viruses.

Sterilization The killing or removal of all living organisms and viruses from a growth medium.

Sterols Hydrophobic multiringed structures that strengthen the cytoplasmic membrane of eukaryotic cells and a few prokaryotes.

Stickland reaction The fermentation of an amino acid pair in which one amino acid serves as an electron donor and a second serves as an electron acceptor.

Stop codon A codon that signals the end of a protein.

Strain A population of cells of a single species all descended from a single cell; a clone.

Stratified water column A body of water separated into layers having distinct physical and chemical characteristics.

Stringent response A global regulatory control that is activated by amino acid starvation or energy deficiency.

Stroma The lumen of the chloroplast, surrounded by the inner membrane.

Stromatolite A laminated microbial mat, typically built from layers of filamentous and other microorganisms; may fossilize.

Subcutaneous mycoses Fungal infections of deeper layers of skin.

Substrate The molecule that undergoes a specific reaction with an enzyme.

Substrate-level phosphorylation The synthesis of energy-rich phosphate bonds through the enzymatic reaction of inorganic phosphate with an activated organic substrate.

Superantigen A pathogen product capable of eliciting an inappropriately strong immune response by stimulating greater than normal numbers of T cells.

Supercoil Highly twisted form of circular DNA.

Superficial mycoses Fungal infections of the surface layers of skin, hair, or nails.

Superoxide anion (O_2^-) A derivative of O_2 capable of oxidative destruction of cell components.

Suppressor A mutation that restores a wild-type phenotype without altering the original mutation, usually arising by mutation in another gene.

- Surveillance** Observation, recognition, and reporting of diseases as they occur.
- Suspended solid** A small particle of solid pollutant that resists separation by ordinary physical means.
- Symbiosis** An intimate relationship between two organisms, often developed through prolonged association and coevolution.
- Synthetic DNA** A DNA molecule that has been made by a chemical process in a laboratory.
- Syntrophy** The cooperation of two or more organisms to anaerobically degrade a substance neither can degrade alone.
- Systematics** The study of the diversity of organisms and their relationships; includes taxonomy and phylogeny.
- Systemic** Not localized in the body; an infection disseminated widely through the body.
- Systemic mycoses** Fungal growth in internal organs of the body.
- Systems biology** The integration of data from genomics and other “omics” areas to build an overall picture of a biological system.
- Taxis** A movement toward or away from a stimulus.
- Taxonomy** The science of identification, classification, and nomenclature.
- T cell** A lymphocyte that interacts with antigens through a T cell receptor for antigen; T cells are divided into functional subsets including Tc (T-cytotoxic) cells and Th (T-helper) cells. Th cells are further subdivided into Th1 (inflammatory) cells and Th2 cells, which aid B cells in antibody formation.
- T cell receptor** The antigen-specific receptor protein on the surface of T lymphocytes.
- T-cytotoxic cell (Tc)** A lymphocyte that interacts with MHC I-peptide complexes through its T cell receptor and produces cytotoxins that kill the interacting target cell.
- T-DNA** The segment of the *Agrobacterium* Ti plasmid that is transferred into plant cells.
- Teichoic acid** A phosphorylated polyalcohol found in the cell wall of some gram-positive *Bacteria*.
- Telomerase** An enzyme complex that replicates DNA at the end of eukaryotic chromosomes.
- Temperate virus** A virus whose genome is able to replicate along with that of its host without causing cell death in a state called lysogeny.
- Termination** Stopping the elongation of an RNA molecule at a specific site.
- Tertiary structure** The final folded structure of a polypeptide that has previously attained secondary structure.
- Tertiary wastewater treatment** The physicochemical or biological processing of wastewater to reduce levels of inorganic nutrients.
- Tetanus** A disease involving rigid paralysis of the voluntary muscles caused by an exotoxin produced by *Clostridium tetani*.
- Tetracycline** A member of a class of antibiotics characterized by a four-membered naphthacene ring.
- Th1, Th2, Th17** See *T-helper (Th) cells*.
- Thalassemia** A genetic trait that confers resistance to malaria, but causes a reduction in the efficiency of red blood cells by altering a red blood cell enzyme.
- Thaumarchaeota** A phylum of *Archaea* that contains widespread species capable of aerobic ammonia oxidation.
- T-helper (Th) cells** Lymphocytes that interact with MHC II-peptide complexes through a T cell receptor and produce cytokines that act on other cells. Th subsets include **Th1** cells that activate macrophages; **Th2** cells that activate B cells; **Th17** cells that activate neutrophils; and **Treg** cells that suppress adaptive immunity.
- Thermocline** The zone of water in a stratified lake in which temperature and oxygen concentration drop precipitously with depth.
- Thermophile** An organism with a growth temperature optimum between 45 and 80°C.
- Thermosome** A heat shock (chaperonin) protein complex that functions to refold partially heat-denatured proteins in hyperthermophiles.
- Thylakoid** A membrane layer containing the photosynthetic pigments in chloroplasts and in cyanobacteria.
- Thymus** The primary lymphoid organ responsible for development of T cells.
- Ti plasmid** A conjugative plasmid in the bacterium *Agrobacterium tumefaciens* that can transfer genes into plants.
- Titer** (1) In immunology, the quantity of antibody present in a solution. (2) In virology, the number of infectious virions in a viral suspension.
- Tolerance** The acquired inability to produce an immune response to a specific antigen.
- Toll-like receptor (TLR)** One of a family of pattern recognition receptors (PRRs) found on phagocytes, structurally and functionally related to Toll receptors in *Drosophila*, that recognize a pathogen-associated molecular pattern (PAMP).
- Toxicity** The ability of an organism to cause disease by means of a preformed toxin that inhibits host cell function or kills host cells.
- Toxic shock syndrome (TSS)** The acute systemic shock resulting from host response to an exotoxin produced by *Staphylococcus aureus*.
- Toxigenicity** The degree to which an organism is able to elicit toxic symptoms.
- Toxin** A microbial substance able to induce host damage.
- Toxoid** A toxin modified so that it is no longer toxic but is still able to induce antibody formation.
- Transcription** The synthesis of an RNA molecule complementary to one of the two strands of a double-stranded DNA molecule.
- Transcriptome** The complement of all RNAs produced in an organism under a specific set of conditions.
- Transduction** The transfer of host genes from one cell to another by a virus.
- Transfection** The transformation of a prokaryotic cell by DNA or RNA from a virus. Used also to describe the process of genetic transformation in eukaryotic cells.
- Transfer RNA (tRNA)** A small RNA molecule used in translation that possesses an anticodon at one end and has the corresponding amino acid attached to its other end.
- Transformation** (1) The transfer of genetic information via free DNA. (2) A process, sometimes initiated by infection with certain viruses, whereby a normal animal cell becomes a cancer cell.
- Transgenic organism** A plant or animal with foreign DNA inserted into its genome.
- Transition** A mutation in which a pyrimidine base is replaced by another pyrimidine or a purine is replaced by another purine.
- Translation** The synthesis of protein using the genetic information in a messenger RNA as a template.
- Transmissible spongiform encephalopathy (TSE)** A degenerative disease of the brain caused by prion infection.
- Transpeptidation** The formation of peptide bonds between the short peptides present in peptidoglycan, the cell wall polymer of *Bacteria*.
- Transporters** Membrane proteins that function to transport substances into and out of the cell.
- Transposable element** A genetic element with the ability to move (transpose) from one site to another on host DNA molecules.
- Transposase** An enzyme that catalyzes the insertion of DNA segments into other DNA molecules.
- Transposon** A type of transposable element that carries other genes in addition to those involved in transposition; often these genes confer selectable phenotypes such as antibiotic resistance.
- Transposon mutagenesis** The insertion of a transposon into a gene; this inactivates the host gene, leading to a mutant phenotype, and also confers the phenotype associated with the transposon gene.
- Transversion** A mutation in which a pyrimidine base is replaced by a purine or vice versa.
- Treg** See *T-helper (Th) cells*.
- Tuberculin test** A skin test for previous infection with *Mycobacterium tuberculosis*.
- Turbidity** A measurement of suspended solids in water.
- Two-component regulatory system** A regulatory system consisting of a sensor protein and a response regulator protein (see *sensor kinase protein* and *response regulator protein*).

Typhus A louse-transmitted disease caused by *Rickettsia prowazekii*, causing fever, headache, weakness, rash, and damage to the central nervous system and internal organs.

Universal tree of life A phylogenetic tree that shows the evolutionary positions of representatives of all domains of cellular life. Also called universal phylogenetic tree.

Untreated water Surface water or groundwater that has not been treated in any way (also called *raw water*).

Upper respiratory tract The nasopharynx, oral cavity, and throat.

Upstream position Refers to nucleic acid sequences on the 5' side of a given site on a DNA or RNA molecule. Compare with *downstream position*.

Vaccination (immunization) The inoculation of a host with inactive or weakened pathogens or pathogen products to stimulate protective active immunity.

Vaccine An inactivated or attenuated pathogen, or a harmless pathogen product used to induce artificial active immunity.

Vacuole A small space in a cell that contains fluid and is surrounded by a membrane. In contrast to a vesicle, a vacuole is not rigid.

Vector (1) A self-replicating DNA molecule that carries DNA segments between organisms and can be used as a cloning vector to carry cloned genes or other DNA segments for genetic engineering.
(2) A living agent, usually an insect or other animal, able to carry pathogens from one host to another.

Vector vaccine A vaccine made by inserting genes from a pathogenic virus into a relatively harmless carrier virus.

Vehicle A nonliving source of pathogens that transmits the pathogens to large numbers of individuals; common vehicles are food and water.

Viable Alive; able to reproduce.

Viable count A measurement of the concentration of live cells in a microbial population.

Viral load The number of viral genome copies in the tissue of an infected host, providing a quantitative assessment of the amount of virus in the host.

Viricidal agent An agent that stops viral replication and activity.

Virion A virus particle; the virus nucleic acid surrounded by a protein coat and in some cases other material.

Viroid Small, circular, single-stranded RNA that causes certain plant diseases.

Viristatic agent An agent that inhibits viral replication.

Virulence The relative ability of a pathogen to cause disease.

Virulent virus A virus that lyses or in some other way kills the host cell after infection; a nontemperate virus.

Virus A genetic element that contains either RNA or DNA and that replicates only in host cells; has an extracellular form.

Volatile fatty acids (VFAs) The major fatty acids (acetate, propionate, and butyrate) produced during fermentation in the rumen.

Wastewater The liquid derived from domestic sewage or industrial sources, which cannot be discarded in untreated form into lakes or streams.

Water activity (a_w) An expression of the relative availability of water in a substance. Pure water has an a_w of 1.000.

Western blot See *immunoblot*.

West Nile fever A neurological disease caused by West Nile virus, a virus transmitted by mosquitoes from birds to humans.

Wild type A strain of microorganism isolated from nature or one used as a parent in a genetics investigation. The usual or native form of a gene or organism.

Winogradsky column A glass column packed with mud and overlaid with water to mimic an aquatic environment in which various bacteria develop over a period of months.

Wobble In reference to protein synthesis, a less rigid form of base pairing allowed only in codon–anticodon pairing.

Xenobiotic A synthetic compound not produced by organisms in nature.

Xerophile An organism adapted to growth at very low water potentials.

Yeast The single-celled growth form of various fungi.

Yeast artificial chromosome (YAC) A genetically engineered chromosome with yeast origin of replication and centromere sequence.

Zoonosis Any disease primarily of animals that is occasionally transmitted to humans.

Zygote In eukaryotes, the diploid cell resulting from the union of two haploid gametes.

Phylogeny of *Bacteria*

Phylogeny of Archaea

Clear Step Text and Arrows

The virion is a key player in viral replication, an important aspect of microbiology courses. This figure clearly depicts the three relevant protein types that are integral to virion formation. Using didactic artwork along with clear step text and arrows, students can easily follow the steps of virion formation.

New Figures Depict Key Topics

The processes of transcription and translation are key to understanding protein synthesis. DNA, RNA, and protein are depicted in this new figure with visual prominence and are uniquely distinguished from each other. Step text and arrows guide student understanding.

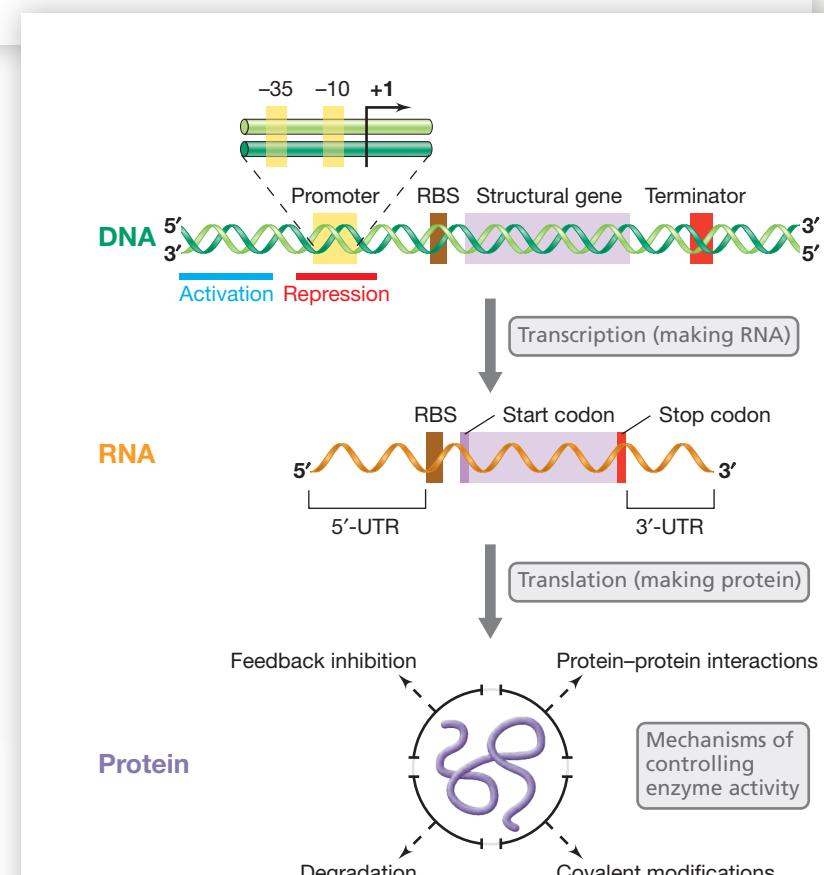

Figure 7.1 Gene expression and regulation of protein activity. The promoter and terminator as well as regions involved in transcriptional activation and repression are indicated. The 5' untranslated region (5'-UTR) is a short region between the start of transcription and the start of translation, while the 3' untranslated region (3'-UTR) is a short region between the stop codon and the transcription terminator. These are the regions where translational regulation often occurs. Mechanisms for regulating protein activity after translation are shown at the bottom.

EXPLORE THE MICROBIAL WORLD

General ecologists refer to two distinct categories of ecological niche, the **fundamental niche** and the **realized niche**. The fundamental niche refers to the range of environments in which a species will survive and when it is not overpopulated, such as may result from competition with other species. By contrast, the realized niche refers to the range of natural environments supporting a species when it is confronted with factors such as resource limitation, predation, and competition. The distinction between fundamental and realized niches yields a clue as to why some microorganisms are so difficult to isolate from the environment.

Establishing laboratory conditions that fall within a fundamental niche will be sufficient to maintain an organism in pure culture, but establishing laboratory conditions that support selectively enrich for that species when it must compete with other organisms present in the sample inoculum. Since the realized niche of most microorganisms is unknown, there has been an increasing emphasis on developing high-throughput methods for cultivation. High-throughput methods, using robotics to set up many cultivation attempts in parallel, high-throughput methods allow for simultaneous investigation of many alternative growth conditions in an attempt to replicate the realized niche or, alternatively, allow the organism to occupy its fundamental niche by relieving it from competition. The latter approach is more commonly used, since fewer media need to be prepared to support growth.

Methods for collecting and depositing a single cell in nutrient media are well developed, including the established dilution methods, as well as the more recent applications of flow cytometry, cell sorting, and laser tweezers.

When high-throughput methods are combined with molecular probes to screen for growth of novel organisms identified previously by culture-independent methods (Section 18.5),

there has been increasing success in isolating some interesting bacteria from the uncultured majority in nature. In fact, the general method for isolating bacteria from seawater has been one of the most abundant organisms on Earth, *Pelagibacter ubique* (Figure 1).¹ As discussed in Section 19.10, this bacterium is a species of highly successful marine bacterioplankton (unsuspected bacterial cells) that thrive on the very diluted food of organic matter present in the open ocean.

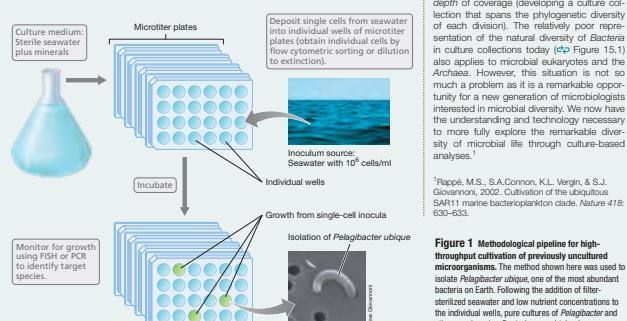

Dedicated patience is needed in any cultivation effort, as the discovery of slow-growing

Culturing the Uncultured

or dormant organisms may require months of incubation. Also, many or perhaps even most microorganisms in nature are adapted to extremely low nutrient concentrations, being incapable of normal growth at the concentrations used to grow organisms commonly used in the laboratory. In addition, others may depend on complex interspecies relationships that cannot be replaced by a defined growth medium.

Thus, high-throughput methods are ideally suited to surveying various combinations of media to find the set that best supports the laboratory culture of the most interesting and ecologically relevant organisms from nature.

Culture-independent methods have identified over 50 major divisions (phyla) within the domain Bacteria alone. Remarkably, only 12 of these divisions had been cultured prior to their bacterial divisions so far identified, only about half now have cultured representatives. Additionally, even when cultures are available for a division, they are generally few in number and therefore do not encompass much phylogenetic diversity within the group. Thus, the challenge of obtaining representative cultures is one of both breadth of coverage (obtaining at least one member of each division) and depth of coverage (developing a culture collection that spans the phylogenetic diversity of each division). This is a major problem for representation of the natural diversity of Bacteria in culture collections today (► Figure 15.1) also applies to microbial eukaryotes and the Archaea. However, this situation is not so much a problem as it is a remarkable opportunity for a new generation of microbiologists to develop innovative methods to increase the understanding and technology necessary to more fully explore the remarkable diversity of microbial life through culture-based analyses.¹

CHAPTER 32 • Eukaryotic Pathogens: Fungal and Parasitic Diseases

microbiologynow

Deadly Fungi

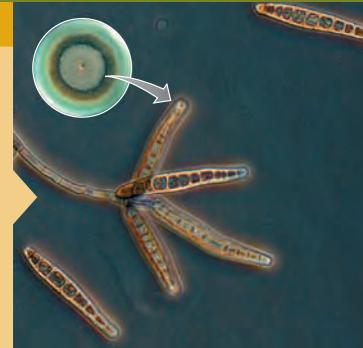

People usually associate fungi with decaying organic matter, or in a medical context, with superficial fungal infections such as athlete's foot. But fungi can cause serious, even deadly infections, as we were reminded when pathogenic fungi triggered a widespread outbreak of fungal meningitis in the United States in 2012.¹

Glucocorticoids such as methylprednisolone are often prescribed for pain relief, especially in adults suffering chronic lower back pain. The drug is typically injected directly into the outermost part of the spinal canal (epidural injection). Several lots of methylprednisolone formulated by a small pharmaceutical company in Massachusetts were found to be contaminated with fungi, including the mold *Exserohilum rostratum* (photo). *E. rostratum* is common in soil and can naturally infect several human tissues, in particular the cornea, lungs, and lining of the heart (pericardium). By early December of 2012 there were 590 fungal infections—mostly cases of meningitis—linked to injections of the contaminated drug, with 37 of these being fatal.

Using standard epidemiological techniques, the Centers for Disease Control and Prevention (Atlanta, Georgia, USA) and a specially formed multistate response team quickly linked the contaminated medication to the Massachusetts company and more specifically, to particular batches of the drug produced by this company. *E. rostratum* was found in sealed vials of methylprednisolone, and the nonpathogenic yeast *Rhodotorula* and mold *Rhizopus* were found in some others.

This outbreak of fungal disease underscores the critical importance of ensuring that drugs are both sterile and uncontaminated with foreign substances, especially drugs used for injections. In addition, the quick action by public health authorities to identify the disease source and prevent further infections is a testimony to the effectiveness of this branch of the healthcare system in the United States.

MicroLab Tutors

MicroLab Tutors prepare students for lab by introducing and assessing their understanding of lab concepts and techniques. Certain topics also include molecular animation, encouraging students to visualize what's happening at the cellular level.

Lab Technique Videos

Lab Technique Videos demonstrate specific lab techniques in 3–5 minutes. These videos cover important procedures and labs, such as aseptic technique, Gram staining, ELISA, and identification of an unknown, helping students prepare for wet lab and review techniques on their own.

A screenshot of the MasteringMicrobiology platform. The title "MasteringMicrobiology®" is at the top. Below it, a section titled "MicroLab Tutor: Gram Stain" is shown. It includes an introduction about the Gram stain, a video player showing a 3D molecular animation of bacteria being stained, and a "Part A" activity where students arrange steps of the Gram staining procedure. The video player shows a 3D model of bacterial cells with labels for "Gram-positive" and "Gram-negative". A legend indicates "Complexes of crystal violet and Gram's iodine". A sidebar on the right shows "Part 1" through "Part 5" of the video.

MicroFlix®

MicroFlix are 3D movie-quality animations with self-paced coaching activities and gradable quizzes that help students master the three toughest topics in microbiology: metabolism, DNA replication, and immunology. Additional 3D BioFlix® animations help students review relevant concepts from general biology.

MicroLab Practicals

MicroLab Practical assessments provide extra practice analyzing and interpreting lab results—putting knowledge into practice.

Additional resources include **Clinical Case Study Coaching Activities** and **MicroCareers Coaching Activities**.
